For a considerable period after the true system of the world was recognized, astronomers were disposed to consider the stars as so many insulated luminaries, scattered almost at random throughout the vast spaces of the universe. Having engaged in no very *extensive* surveys of the celestial vault, and resting contented with the idea that the stars were so many suns, dispersed in a kind of magnificent confusion through the immensity of space, they seemed to have formed no conception of any specific difference in the nature of these bodies, or of any systematic arrangement as existing among them. Hence it happened that no discoveries of importance were made in the region of the stars, from the time of Huygens and Cassini until near the latter part of the eighteenth century; so that a whole century elapsed without materially enlarging our views of the sidereal heavens and of the variety, order and arrangement of the numerous bodies which every portion of those expansive regions presents to view. During the last sixty or seventy years, the attention of astronomers has been more particularly directed to sidereal observations; and among those who have labored with success in this department of astronomical investigation, the late Sir William Herschel stands pre-eminent. Fired with a noble zeal for the improvement of his favorite science, and for the enlargement of his views of the distant regions of creation, he set to work with enthusiastic ardor, and constructed with his own hands telescopes of a size and magnifying power far superior to what had ever before been attempted. Mounted on the top of his forty feet reflecting telescope, he not only discovered new bodies within the limits of the planetary system, but brought to light innumerable phenomena in regions of the firmament where the eye of man had never before dared to penetrate. He explored the Milky-way throughout all its profundities, and found that whitish zone of the heavens to consist of a multitude of stars "which no man could number," fifty thousand of them having sometimes passed through the field of his telescope in the space of an hour. During the coldness and profound silence of many sleepless nights, he surveyed almost every portion of the celestial concave, and discovered more than two thousand *nebulæ*, or starry systems, of various forms and descriptions, along with multitudes of double, triple, and quadruple stars which had formerly been unknown, and ascertained, from the change of their relative positions, some of their real motions and periods of revolution. After more than half a century spent in unwearied observations of the heavens, this illustrious astronomer departed from this earthly scene, in 1822, without infirmities and without pain, in the eighty-fourth year of his age, leaving a son to prosecute his labors indued with virtues and talents, worthy of his father, and whose observations and researches have already enriched the science of astronomy, and extended our views of the sidereal system.

This department of astronomical science may be considered as still in its infancy. Years, and even centuries, must roll on, and the number of astronomical observers must be increased a hundred-fold, before the sidereal investigations now going forward can be nearly completed. A more extensive knowledge of the history of the heavens, of the bodies which lie hid in the yet unexplored regions of space, and of the changes and diversified motions to which they are subject, is doubtless reserved for generations to come; and from the attention which has lately been paid to this subject, and the ardor with which it is now prosecuted in different parts of the world, we have reason to expect that new scenes of divine wisdom and omnipotence will be gradually unfolding, and new and interesting results deduced from the nocturnal labors of those who have devoted themselves to celestial investigations. To what extent our knowledge of the objects of this science may yet reach, it is impossible for us to anticipate. The objects in the heavens present a scene which is absolutely boundless, — which all the generations of men that may arise until the termination of our terrestrial system will never be able fully to explore; a scene which will doubtless engage the study and contemplation of numerous orders of intellectual beings throughout all the revolutions of eternity.

In the following work, I propose to give only a very condensed view of the leading objects which have been lately discovered in the sidereal heavens. The facts in relation to this subject will be selected chiefly from the observations of Sir. W. Herschel, and several other astronomers, and some of them from personal observation. Most of the facts to which I allude were ascertained by Sir W. Herschel by means of telescopes of great size and power, and a considerable number of the double and triple stars, stellar and planetary nebulæ, and other phenomena, cannot be perceived with instruments of an ordinary size Certain interesting facts, too, particularly with regard to the motions of double stars, have lately been brought to light by the observations of Sir John Herschel, made in the southern hemisphere; but the bodies to which I allude cannot be seen in the northern latitudes in which we reside. A considerable portion therefore of our information on this subject must necessarily depend on the observations of the astronomers to whom I allude, and the statements they have published to the world; but these observations have, for the most part been abundantly verified by other observers.

It shall be our endeavor to state the prominent facts connected with the sidereal heavens in as plain and perspicuous a manner as possible; and while it forms no part of our plan to frame hypotheses, or launch out into theoretical disquisitions, we shall offer those remarks, and freely indulge in those moral reflections, which the contemplation of such august objects are calculated to suggest. The scenes we intend to exhibit are not only the workmanship of God, but display the glory of his attributes and the magnificence of his empire in a degree, and upon a scale, far surpassing what can be seen in any other department of creation; and therefore, in all our surveys of those grand and multifarious objects, we ought invariably to connect our views and investigations with the supreme agency of Him who brought them into existence, and to cherish those sentiments and emotions which may inspire us with reverence and adoration of that glorious and incomprehensible Being "by whom the worlds were framed," "who created all things, and for whose pleasure they are and were created "

CHAPTER I.

A GENERAL VIEW OF THE STARRY HEAVENS, WITH REPRESENTATIONS OF DETACHED PORTIONS OF THE FIRMAMENT.

If we could suppose a community of rational beings to have lived for ages in some subterraneous grottos far beneath the surface of the earth, and never to have visited the exterior portions of our globe, their ideas must have been extremely circumscribed, and their enjoyments extremely imperfect, even although they had been furnished with everything requisite for their animal subsistence. Could we imagine that such beings were all at once transported to the surface of the earth, with what astonishment and wonder would they be seized when they beheld the expansive landscape of the world, the lofty mountains towering to the clouds,--the hills crowned with magnificent forests, —the plains stretching to the boundaries of the horizon, and adorned with colors of every shade,—the expansive lake, like a magnificent mirror, embosomed among the hills,—the rivers rolling their watery treasures toward the ocean,—and the sun in the firmament revolving around the circuit of the sky, diffusing his light and heat on every surrounding object! Above all, with what emotions of admiration would they be filled when they beheld the solar globe descending below the western horizon, and soon after the moon displaying her silver crescent in the sky, and the stars, one after another, emerging from the blue ethereal, until the whole celestial concave appeared all over spangled with a thousand shining orbs, emitting their radiance from every part of the cope of heaven, and all moving, with an apparently slow and silent motion, along the spaces of the firmament! Such expansive and novel scenes would undoubtedly overwhelm the faculties of such beings with astonishment, and transport, and wonder inexpressible.

We are placed, perhaps, in a situation nearly similar in regard to the remote regions of the universe, as the beings we have supposed were situated with respect to the ample prospects we enjoy on the surface of our globe. Were such beings, from their subterranean abodes, to look through a narrow funnel which presented them with a feeble glimpse of our upper world, and of a portion of the sky, the view thus obtained would somewhat resemble the partial glimpse we have yet acquired of the splendor and sublimities of the distant universe; and were we transported to those far distant scenes, which appear through our telescopes only like dim specks of light, we should, doubtless, be as much overpowered with astonishment and wonder at the magnificent scenes which would open to our view, as our supposed subterraneous inhabitants could be at the amplitude and grandeur of our terrestrial abode.

In our present habitation we are confined to a mere point in the infinity of space. Ample as our prospects are, it is not improbable that the views we have already attained bear a less proportion to the whole immensity of creation than the limited range of a microscopic animalcule bears to the wide expanse of the ocean. What is seen by human eyes, even when assisted by the most powerful instruments, may be as nothing when compared to what is unseen and placed forever beyond the view of mortals. Since the heavens first began to be contemplated, our views have been carried thousands of times further into the regions of space than the unassisted eye could enable us to penetrate; and at every stage of improvement in optical instruments our prospects have been still further extended, new objects and new regions of creation have appeared rising to view, in boundless perspective, in every direction, without the least indication of a *boundary* to the operations of Omnipotence; leaving us no room to doubt that all we have hitherto discovered is but a small and inconsiderable part of the length and breadth, and the hight and depth of *immensity.* We may suppose, without the least degree of improbability or extravagance, that, were the whole of the *visible* system of creation annihilated, though it would leave a void immeasurable and incomprehensible by mortals, it would appear to the eye of Omniscience only as an inconsiderable blank scarcely discernible amidst the wonders of wisdom and omnipotence with which it is surrounded.

Such views and deductions have been derived from attentive surveys of the Starry Heavens. These heavens present, even to the untutored observer, a sublime and elevating spectacle. He beholds an immense concave hemisphere, surrounding the earth in every region, and resting, as it were, upon the circle of the horizon. Wherever he roams abroad, on the surface of the land or of the ocean, this celestial vault still appears encompassing the world; and after traveling thousands of miles, it seems to make no nearer an approach than when the journey commenced. From every quarter of this mighty arch numerous lights are displayed, moving onward in solemn silence, and calculated to inspire admiration and awe. Even the rudest savages have been struck with admiration at the view of the nocturnal heavens, and have regarded the celestial luminaries either as the residences of their gods, or the arbiters of their future destinies.

But to minds enlightened with the discoveries of science and revelation the firmament presents a scene incomparably more magnificent and august. Its concave rises toward immensity, and stretches, on every hand, to regions immeasurable by any finite intelligence; it opens to the view a glimpse of orbs of inconceivable magnitude and grandeur, and arranged in multitudes which no man can number, which have diffused their radiance on the earth during hundreds of generations; it opens a vista which carries our views into the regions of *infinity,* and exhibits a sensible display of the *immensity* of space, and of the boundless operations of Omnipotence; it demonstrates the existence of an eternal and incomprehensible Divinity, who presides in all the grandeur of his attributes over an unlimited empire; it overwhelms the contemplative mind with a display of the riches of his wisdom and the glories of his OMNIPOTENCE; it directs our prospects to the regions of other worlds, where ten thousand times ten thousands of intelligences, of various orders, experience the effects of divine love and beneficence. Amidst the silence and the solitude of the midnight scene, it inspires the soul with a solemn awe and with reverential emotions; it excites admiration, astonishment, and wonder in every reflecting mind, and has a tendency to enkindle the fire of devotion, and to raise the affections to that ineffable Being who presides in high authority over all its movements. While contemplating, with the eye of intelligence, this immeasurable expanse, it teaches us the littleness of man, and of all that earthly pomp and splendor of which he is so proud; it shows us that this world, with all its furniture and decorations, is but an almost invisible speck on the great map of the universe; and that our thoughts and affections ought to soar above all its sinful pursuits and its transitory enjoyments. In short, in this universal temple, hung with innumerable lights, we behold, with the eye of imagination, unnumbered legions of bright intelligences, unseen by mortal eyes, celebrating in ecstatic strains, the perfections of Him who is the creator and governor of all worlds,—we are carried forward to an eternity to come, amidst whose scenes and revolutions alone the magnificent objects it contains can be contemplated in all their extent and grandeur.

It is an evidence of the depraved and groveling dispositions of man that the firmament is so seldom contemplated with the eye of reason and devotion. No other studies can present an assemblage of objects so wonderful and sublime; and yet, of all the departments of knowledge which are generally prosecuted, no one is so little understood or appreciated by the bulk of mankind as the science of the heavens. Were it more generally studied, or its objects were frequently contemplated, it would have a tendency to purify and elevate the soul, to expand and ennoble the intellectual faculty, and to supply interesting topics for conversation and reflection. The objects in the heavens are so grand, so numerous, so diversified, and so magnificent, both in their size and in the rapidity of their motions, that there appears no end to speculation, to inquiry, to conjecture, to incessant admiration. There is ample room for all the faculties of the brightest genius to be employed, and to expatiate in all their energy on this boundless theme; and were they thus employed more frequently than they are, our views of the arrangement, and the nature of the magnificent globes of heaven, might be rendered still more definite and expansive.

While contemplating the expanse of the starry heavens, the mind is naturally led into a boundless train of speculations and inquiries. Where do these mighty heavens begin, and where do they end? Can imagination fathom their depth, or human calculations and figures express their extent? Have angels or archangels ever winged their flight across the boundaries of the firmament? Can the highest created beings measure the dimensions of those heavens, or explore them throughout all their departments? Is there a boundary to creation beyond which the energies of Omnipotence are unknown, or does it extend throughout the infinity of space? Is the immense fabric of the universe yet completed, or is almighty power still operating throughout the boundless dimensions of space, and new creations still starting into existence? At what period in duration did this mighty fabric commence, and when will it be completed? Will a period ever arrive when the operations of creating power shall cease, or will they be continued throughout all the revolutions of eternity? What various orders of intellectual beings people the vast regions of the universe? With what mental energies and corporeal powers are they endowed? Are they confined to one region of space, or are they invested with powers of locomotion, which enable them to wing their flight from world to word? Are they making rapid advances, from age to age, in intellectual improvement? Has moral evil ever made inroads into those remote regions of creation, or are all their inhabitants confirmed in a state of innocence and bliss? Is their history diversified by new and wonderful events, and do changes and revolutions happen among them? Are all the tribes of intellectual natures throughout creation connected together by certain relations and bonds of union, and will a period ever arrive in the future revolutions of eternity when they shall have had an intimate correspondence with one another? These, and hundreds of similar inquiries, are naturally suggested by serious contemplations of the objects connected with the starry heavens, and they have a tendency to lead the mind to sublime and interesting trains of thought and reflection, and to afford scope for the noblest energies of the human soul.

But leaving such reflections, in the meantime, let us now take a general view of the starry heavens as they appear to the eye of a common spectator.

When an untutored observer attempts to take a serious survey of the starry firmament for the first time, he is apt to be bewildered at the idea of the immense multitude of stars which seem to present themselves in every part of the sky, and the apparent confusion with which they seem to be arranged. He is apt to think that they are absolutely innumerable, and that all attempts to enumerate or to classify them would be in vain. There is something so magnificent and overpowering in a cursory view of a clear starry sky, that the mind shrinks from the idea of ever being able to form a distinct conception of the number and order of those luminous orbs, or of their distances and magnitudes; but the genius and industry of man have, in numerous instances, accomplished what at first view appeared beyond the reach of the human faculties. All the stars *visible to the naked eye* have been numbered, and their relative positions determined, with as much precision as the longitudes, latitudes, and bearings of places on the surface of the globe; and there is not a star visible to the unassisted eye, but its precise position can be pointed out, not only during the shades of night, but even during the day, when the sun is shining in all its splendor.

In order to prevent confusion in our first surveys of the starry heavens, let us fix upon a certain portion of the firmament, and the more conspicious stars which lie in its immediate vicinity. Let us suppose ourselves contemplating the heavens about the middle of January, at eight o'clock in the evening, in the latitude 52° north. At that time, if we turn our faces toward the south, we shall behold the splendid constellation of *Orion* a little to the east of the meridian, or nearly approaching the south. This constellation forms one of the most striking and beautiful clusters of stars in the heavens, and is generally recognized even by common observers. It is distinguished by four brilliant stars in the form of an oblong, or parallelogram; and particularly by three bright stars in a straight line near the middle of the square, or parallelogram, which are known by the names of "the Three Kings," or the "Ell," or "Yard." They are also termed Orion's *belt;* and in the book of Job, "the *bands* of Orion;" and the space they occupy is exactly three degrees in length. The line passing through these stars points to the *Pleiades*, or seven stars, on the one side, and to *Sirius*, or the Dog Star, on the other. The equinoctial circle passes through the uppermost of these stars, which is called *Mintika*. They are situated about eight degrees west from the *solstitial colure* or that great circle which passes through the poles of the heavens, and the first points of Cancer and Capricorn, in which the sun is in his greatest declination north and south, which happens on the 21st of June and 21st of December. There is a row of small stars which run down obliquely below the belt, and seem to hang from it, which is denominated the *sword* of Orion. About the middle of this row of stars there is perceived, by means of the telescope, one of the most remarkable *nebulæ* in the heavens. The whole number of stars visible by the naked eye in this constellation has been reckoned at about 78; of which two are of the first magnitude—namely, *Rigel*, in the left foot on the west, and *Betelguese*, on the east shoulder. They are connected by a line drawn through the uppermost star of the belt. There are four stars of the second magnitude, three of the third, and fifteen of the fourth; but several thousands of stars have been perceived by good telescopes within the limits of this constellation.

North by west of Orion is the constellation *Taurus*, or the Bull, one of the signs of the zodiac. The *Pleiades*, or the seven stars, so frequently alluded to both in ancient and modern times, form a portion of this constellation. At the time now supposed, they are a very little beyond the meridian to the west, and about thirty-seven degrees north by west of the belt of Orion, at an elevation above the horizon of about sixty-four degrees. This cluster was described by the ancients as consisting of seven stars, but at present only six can be distinguished by the naked eye. With powerful telescopes, however, more than 200 stars have been counted within the limits of this group. The *Hyades* is another cluster, situated about eleven degrees south-east from the Pleiades, consisting chiefly of small stars, so arranged as to form a figure somewhat like the letter V. On the left, at the top of the letter, is a star of the first magnitude, named *Aldebaran*, or the Bull's Eye, which is distinguished from most of the other stars by its *ruddy* appearance. This constellation is situated between *Perseus* and *Auriga* on the north, and has *Gemini* on the east, *Aries* on the west, and *Orion* and *Eridanus* on the south. It consists of about 140 stars visble to the naked eye.

The constellation *Gemini* is situated north-east from Orion, and almost due east from the Pleiades, and is one of the signs of the zodiac. It has *Cancer* on the east, *Taurus* on the west, and the *Lynx*, on the north. The orbit of the earth, or the apparent circle described by the sun in his annual course, passes through the middle of this constellation. From the 21st of June until the 23d of July, the sun passes through this sign, but the stars of which it is composed are then invisible, being overpowered by the superior brightness of the solar rays. This constellation is easily distinguished by two brilliant stars, denominated *Castor* and *Pollux*, which are within five degrees of each other. *Castor*, a star of the first magnitude, is the northernmost of the two; and *Pollux*, a star of the second magnitude, is situated a little to the south-east of it. Castor is found by the telescope to be a double star, the smaller one being invisible to the naked eye; and, from a long series of observations, it is found that the smaller star is revolving around the larger with a slow motion, and that a complete revolution will occupy more than 300 years. About twenty degrees south-west of Castor and Pollux are three small stars, nearly in a straight line, and about three or four degrees distant from each other. The southernmost of the three lies nearly in a line with Pollux and the star *Betelguese*, in the constellation of Orion, but somewhat nearer to Betelguese than to Pollux. These stars, in the hieroglyphic figure of Gemini, form the feet of the twins.

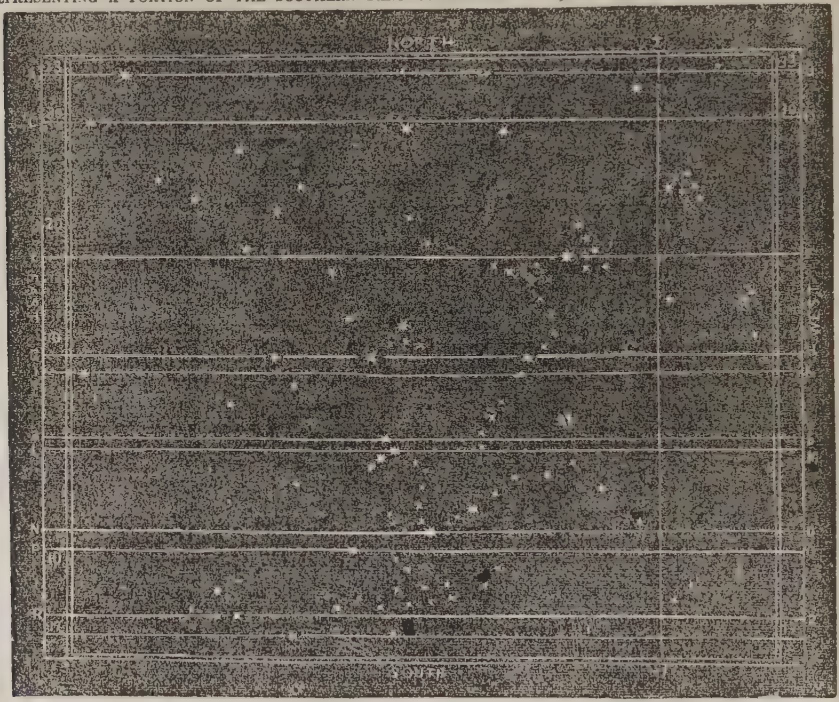
Directly south of Gemini is the constellation of *Canis Minor*, or the Lesser Dog. It is situated about midway between Gemini and *Canis Major*, or the Greater Dog, and has *Hydra* on the east, and Orion on the west. It consists of only about fourteen stars visible to the naked eye, the principal of which is *Procyon*, a bright star between the first and second magnitude. It is almost directly south from Pollux, and distant from it about twenty-four degrees. The next brightest star in this constellation, which is considerably smaller than Procyon, is called Gomelza, and is situated about four degrees north-west of Procyon.

South by west of Canis Minor, at the distance of nearly thirty degrees, is *Canis Major*, or the Greater Dog. It is south-east from the belt of Orion, and due east from the constellation of *Lepus*, or the Hare, at the distance of ten degrees. Canis Major is easily distinguished by the brilliancy of its principal star, *Sirius*, which is apparently the largest and brightest fixed star in the heavens, so that it is generally considered as one of the nearest of these distant orbs, though its distance from the earth is computed at not less than *twenty billions* of miles; and a cannon ball, moving over this immense space at the rate of nineteen miles a minute, would require more than two millions of years before it could reach this distant orb. Sirius is south by east of Betelguese in the left shoulder of Orion, at the distance of twenty-seven degrees, and south-east from the lower star in the belt, at the distance of twenty-three degrees. A line drawn through the three stars which form the belt, toward the south-east, leads the eye directly to Sirius, which, at the period and hour we have stated, is about twelve degrees above the south-easterly point of the horizon; a line drawn from Betelguese south-east toward Sirius, and thence to the north-east, meets Procyon in Canis Minor, and continued nearly due west, it again meets Betelguese, so that these three stars seem to form a large triangle, which is nearly equilateral Another triangle is formed by drawing a line eastward from Betelguese to Procyon, as a base, from Procyon straight north to Pollux, and from thence again south-west to Betelguese, which forms a right-angled triangle, having the right angle at the star Procyon, and the line extending from Pollux to Betelguese forms the hypotenuse.

In order to render these descriptions more definite, I have sketched in Plate I, a small map of this portion of the heavens, in which the principal stars in the constellations above described are represented. The *left*-hand side of this map represents the *east;* the *right*-hand side the *west;* the lower part, the south; and the upper part the north, or higher portion of the heavens. When used so as to compare it with the real firmament, the observer is supposed to have his face directed chiefly to the south and the south-eastern parts of the sky. He may then easily distinguish the principal stars laid down in it by the following directions:—A line drawn from *A* to *B*, at the top of the map, passes through the star *Castor* in Gemini, which is near the left-hand side. A line drawn from *C* to *D*, passes through *Pollux* in the same sign, which is four or five degrees to the south-east of Castor; it likewise passes near *Auriga*, a star of the second magnitude, in the constellation of the *Wagoner*, which is represented near the middle of the line. Almost directly north from Auriga, at the distance of seventeen degrees, is the star *Capella*, in the same constellation, which is one of the brighest stars in the heavens next to Sirius. It is about twenty-eight degrees north-east from the Pleiades, but is beyond the northern limits of the map. A line drawn from *E* to *F*, passes through *Aldebaran*, or the Bull's Eye, and the Hyades; north-west of which is the Pleiades, or seven stars, near the north-west part of the map. A line drawn from *G* to *H*, passes through the star *Betelguese*, in the east shoulder of Orion; the line from *I* to *K*, passes through *Bellatrix*, in the west shoulder, a star of the second magnitude, somewhat less brilliant than Betelguese, and likewise passes through *Procyon*, in Canis Minor, which appears near the left side of the map; and the line from *L* to *M* passes through the middle star of Orion's belt. The line from *N* to *O* passes through *Rigel*, in the left foot of Orion, a star of the first magnitude fifteen degrees south of Bellatrix. The line *P Q* passes through *Saiph*, a star of the third magnitude, in Orion's right knee, eight and a half degrees east of Rigel. The two form the lower end of the parallelogram of Orion. The line *R S* passes through the star *Sirius*, in Canis Major, which is east by south from Saiph, at the distance of fifteen degrees. The small stars to the west, or right hand of Sirius form a part of the constellation of *Lepus*, or the Hare. A line drawn from *T* to *U*, from the northern to the southern part of the map, will point out the position of the stars here represented with respect to the meridian, at the time these observations are supposed to be made. The stars on the right of this line are west of the meridian, and all those to the left are to the east of it.

PLATE I.

REPRESENTING A PORTION OF THE SOUTHERN PART OF THE HEAVENS, ABOUT THE MIDDLE OF JANUARY



By attending to the above directions, and comparing the delineations on the map with the heavens, all the stars and constellations noted above may be readily distinguished. The triangles formed by Betelguese, Procyon, and Sirius, and by Pollux, Procyon, and Betelguese, will likewise be seen on the map, as formerly described, and may be easily traced in the heavens. Although I have fixed on the middle of January, at eight o'clock in the evening, for these observations, yet the same stars may be traced, at different hours, during the months of November, December, January, February, and March. About the middle of November, at midnight, and the middle of December, at ten o'clock, P. M., this portion of the heavens will appear nearly in the same position as here represented. About the middle of February, Orion will be on the meridian about eight in the evening; and in the month of March, at the same hour, considerably to the west of it; but all the adjacent stars and constellations may be traced at this time in the manner already described. The stars and constellations delineated on this map comprehend a space in the heavens extending in breadth, from north to south, about fifty degrees — namely, from thirty-three degrees of north declination to seventeen degrees south; and in length, from west to east, about sixty degrees The *equator* runs through this portion of the heavens in the direction *a b*, or nearly corresponding to the line *L M*, so that it passes very near to the upper star in the belt of Orion. The degrees of north and south declination* from the equator are marked on the margin.

PLATE II.

EXHIBITING A PORTION OF THE CONSTELLATIONS, AS SEEN ABOUT THE FIRST OF SEPTEMBER.

Plate II represents another portion of the heavens as it appears about the beginning of September. It includes some of the larger stars belonging to the constellations *Cygnus*, *Lyra*, *Cerberus*, *Serpentarius*, *Aquila*, *Hercules*, and *Corona Borealis*. At ten o'clock in the evening of the 1st of September, the star Altair, in the constellation of Aquila, or the Eagle, will be nearly on the meridian, at an elevation above the horizon of about forty-six degrees. This star, which is between the first and second magnitude, is situated near the east or left-hand side of the map, near the bottom, and has a small star to the south, and another to the north-west of it. A line drawn from *T* to *U* passes through the star Altair, and a line from *V* to *W* passes through the meridian at the hour supposed.

The seven stars which are nearest Altair, toward the south, and west, and north-west, belong to the constellation of *Aquila*. All the stars on the map which are to the right-hand of Altair, are *west* of the meridian. A line drawn from *X* to *Y*, near the top of the map, passes through *Denib*, a bright star of the second magnitude in the constellation of *Cygnus*, or the Swan, which is the star next the left-hand side, nearly due north from Altair, at the distance of thirty-six degrees; the other four stars adjacent to it belong to the same constellation. A line drawn from *A* to *B* passes through the star *Vega*, or *a Lyræ*, a brilliant star of the first magnitude in the constellation of the *Harp*. The six small stars to the south-east of it likewise belong to this constellation.—The stars on the right, or to the westward of Vega, belong chiefly to the constellation of *Hercules*. A line drawn from *C* to *D* passes through the principal star *Corona Borealis*, or the Northern Crown, named *Alphacca*, which is of the third magnitude and near the right-hand side of the map. The star north and east from it belong to the same constellation. West from Alphacca is *Mirac*, at the distance of eleven degrees; and south-west of Mirac, at the distance of ten degrees, is *Arcturus*, a bright star of the first magnitude, which is then about eighteen degrees above the western horizon. Both these stars are in the constellation of *Bootes*, but they are not within the limits of the map. A line drawn from *F* to *G* passes through *Ras Algethi*, a star of the second magnitude, and the principal star in the constellation of *Hercules*, which is twenty-five degrees south-east of Corona Borealis. A line from *H* to *I* passes through *Ras Alhague*, a star of the second magnitude in the head of *Serpentarius*. This star is five degrees east by south of Ras Algethi. Most of the other stars to the south and east in the map belong to Serpentarius. Various other remarkable stars may be seen at this time beside those noted in the map, particularly the square of *Pegasus*, or the Flying Horse. About fifty-three degrees nearly east from Altair is *Markab*, a star of the second magnitude; sixteen and a half degrees east of Markab is *Algenib*, another star of the second magnitude; fourteen degrees north of Algenib is *Alpheratz*, and fourteen degrees west of Alpheratz is *Scheat*, both of them stars of the second magnitude. These four stars, of nearly equal magnitudes, form the *Square of Pegasus*, and appear nearly half-way between the eastern horizon and the meridian.

---

* The *declination* of a heavenly body is its distance north or south from the equinoctial, or equator, and corresponds to *latitude* on the terraqueous globe, which is the distance of a place from the equator The latitude of a *heavenly body* is its distance north or south of the *ecliptic*, or apparent path of the sun, which forms an angle of $23\frac{1}{2}$ degrees with the equinoctial.

All the stars alluded to above may likewise be seen during the months of July and August, when they will appear in a more *easterly* position than at the time stated above; and in the month of October, at eight o'clock, and in November, at six o'clock in the evening, they will be seen nearly in the positions which have been now represented.

Plate III represents a view of some of the principal stars around the pole, extending from the polar point, in every direction, about forty-five degrees. In using this map, the observer is supposed to be looking toward the north, in which case, the left hand side of the map is toward the *west*, and the right side toward the *east*. The large star near the center of the map is the Pole-star, which forms the tip of the tail of *Ursa Minor* the square of which, and the two other stars in the tail, will be seen ascending from it toward the right hand, when the map is so placed that the 1st of April is at the top. There is only one star of the first magnitude within the limits of this map —namely *Capella*, the principal star in the constellation of *Auriga*, opposite that part of the map where the month of December is marked. A line drawn from *C* to *D* passes through this star, which is adjacent to the extremity of the map. There are eleven stars of the second magnitude; five in the square and tail of *Ursa Major*, or the Great Bear—namely the two pointers, *Dubhe* and *Merak*, *Phad*, *Alioth*, and *Benetnasch*. The others are *Menkalina*, *Etanim*, *Rastaban*, *Algenib*, *Delta*, *Cygni*, and the *Pole-star*. A line drawn from *A* to *B* passes through Dubhe and Merak, and the Pole-star at the center of the map; and on the other side of the Pole-star it passes through a part of the constellation of *Cassiopeia*—the Pole-star being nearly equidistant between that constellation and the pointers. A line drawn from *E* to *F* passes through *Menkalina*, in the constellation of Auriga, about eight degrees from Capella. A line drawn from *G* to *H* passes through *Delta Cygni*, in the Swan, which is placed at the extremity of the map. A line from *I* to *K* passes through Algenib, the principal star in the constellation of *Perseus*. A line from *L* to *M* passes through *Etanim*, near the right-hand side of the map, a star of the second magnitude in the constellation of *Draco*, near to which, at the distance of four or five degrees is *Rastaban*, likewise a star of the second magnitude in the same constellation. With two other stars they form a kind of irregular square or trapezium, and, with another small star, they form a figure resembling an italic *V*. When the star Etanim comes to the meridian of London, it is exactly in the zenith of that place, which has rendered it of peculiar utility in certain nice astronomical observations. It is celebrated in modern times as being the star which Dr. Bradley selected to determine, if possible, the *Annual Parallax;* and from his observations of which he deduced the important discovery of the *Aberration of Light.*

Let us now suppose that we are to contemplate the northern part of the heavens about the beginning of *April*, at ten o'clock in the evening. Turning our faces toward the pole-star, or directly north, and holding that part of the map uppermost which is opposite to the beginning of April, those stars which are marked on the *upper* part of the map will appear not far from the zenith, or nearly overhead; those toward the lower part will appear at a low elevation, not far from the horizon; those on the right will appear in the east, and those on the left in the west, at different elevations, as here represented. The two pointers in the Great Bear, which are directly opposite to the 1st of April, will be seen nearly in the zenith, and to point *downward* to the pole-star; and at nearly an equal distance below the pole-star, they direct the eye to the constellation *Cassiopeia*, which is conceived to have a certain resemblance to a *chair*, and which appears only a small distance above the northern horizon. To the west or left-hand side of Cassiopeia is the constellation *Perseus*, of which Algenib is the principal star, and which is likewise at a low elevation. To the right, or east side of Cassiopeia is *Cepheus*—four stars of which, two of the third, and two of the fourth magnitude, form a kind of square, or rhombus. The stars farther to the east, and in a more elevated position, belong chiefly to the constellation of *Draco*, or the Dragon. The star *Etanim*, in this constellation, appears nearly due east of the pole-star, at the distance of forty degrees. The stars on the western side of the map, or on the left-hand nearly opposite to Etanim, belong to the constellation of Auriga; and those on the upper part are chiefly some of the prominent stars connected with the Great Bear. The bright star Capella appears nearly west by south from the pole-star, at a pretty high elevation, with *Menkalina* a little above it, and to the eastward.

Beside the stars marked on this map, there may be seen, at the same time, several brilliant stars of the first magnitude. Turning the eye east by south, the bright star *Arcturus*, in the constellation *Bootes*, is seen about half-way between the horizon and the zenith. Looking to the north-east, the brilliant star *Vega*, or Lyra, appears elevated twenty degrees above the horizon, in a direction nearly opposite to Capella, in the west. Farther to the north, but not quite so elevated as Lyra, is *Denib*, in the constellation of the Swan. Turning our eye to the west, Castor and Pollux will be seen about midway between the western horizon and zenith: and farther down, near the horizon, almost due west, are Betelguese and Bellatrix, the two stars in the shoulders of Orion, Betelguese appearing the more elevated of the two, the other portions Orion having descended below the horizon. To the south-west, midway between Pollux and the horizon, is *Procyon*, a star of the first magnitude in the Lesser Dog.

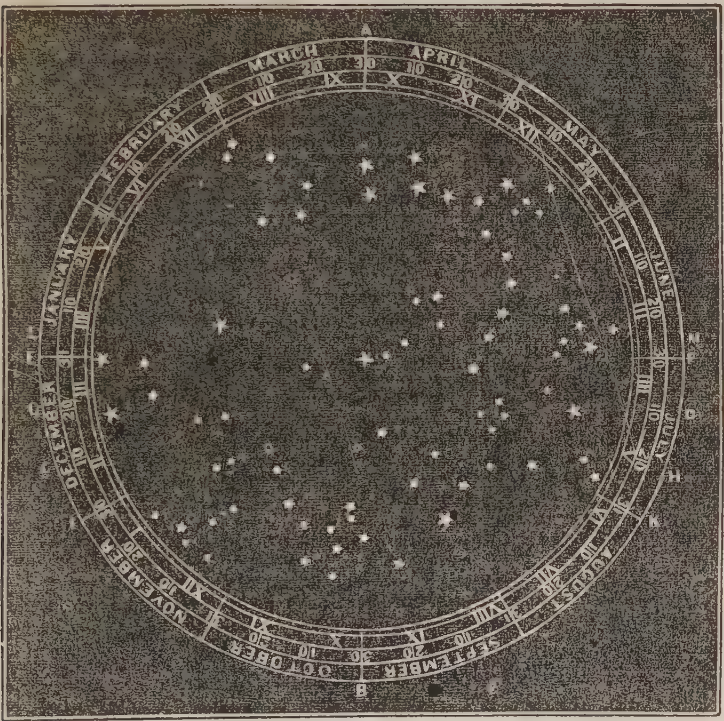
Suppose, now, we were to observe the same quarter of the heavens, at the same hour, about the beginning of October. In this case we have only to reverse the map so that the first of October may be uppermost. At this season, Cassiopeia will appear near the zenith and the two pointers of Ursa Major will be seen at the opposite side of the pole, at no great elevation above the horizon. Capella will appear toward the east, on the right, at a considerable altitude, and the five stars in the head of Draco considerably to the west, while Algenib, and the other stars in Perseus, will be seen in a high elevation, to the east of Cassiopeia. At this time, likewise, by turning our eyes toward the east and the south, Aldebaran, or the Bull's-eye, in the constellation

Taurus, will be seen elevated about twelve degrees above the eastern horizon, about sixteen degrees above which are the Pleiades, or seven stars. The star Altair will appear near the south-west, halfway between that point and the meridian, and *Fomalhaut*, in the Southern Fish, will be seen nearly on the meridian, only five or six degrees above the south point of the horizon.

In like manner, were we wishing to observe the position of the circumpolar stars *at any other hour*, at this period, than ten o'clock, P. M., suppose at eight in the evening, we have only to turn the line which marks the beginning of September uppermost instead of October, and the position at that hour will be seen; and if we choose to make our observations at six in the evening, we turn the first of August to the top, allowing two hours, at an average, for every month. If we would inspect their position at twelve midnight, the first of November must be turned round to the top, and so on for any other hour. If we would make our observations in the beginning of January at ten, P. M., that point must be turned to the top, and then the two pointers will be seen on the right, straight east of the pole-star, and the other five stars hanging down from them, Cassiopeia nearly straight west, and Capella not far from the zenith These circumpolar stars may therefore be seen at every season of the year, and their relative positions determined beforehand, by simply turning round the map to the month, or day of the month, required, so that that point may be at the top; and although the months are arranged so as to correspond with ten o'clock, P. M., yet the positions may be represented for any other hour, according to the directions given above.

PLATE III

THE NORTH CIRCUMPOLAR STARS.



The following remarks may be stated in reference to the stars depicted on this map:—1. All these stars never set in our latitude, but appear to move round *above* the horizon in circles of which the pole is the center. As the observer is supposed to be in fifty-two degrees N. latitude, all the stars within 52° of the pole never descend below the horizon. In one part of their diurnal course they appear above the pole, and some of them near the zenith, and in the opposite point they appear below the polar point, and sometimes near the northern horizon. 2. In the higher part of their course they appear to move from east to west, and in the lower part from west to east. Those nearest the pole describe small circles around the polar point, and those at greater distances describe larger circles; but their periods of apparent revolution are exactly the same—namely, twenty-three hours, fifty-six minutes, and four seconds. 3. The stars represented in this map are only those which are most prominent and obvious to the naked eye, in order to prevent confusion, and that the untutored observer may not be distracted with too many objects at one view. They chiefly consist of stars of the second, third, and fourth magnitudes. 4. In order that the observer may be able readily to estimate the apparent distances of the stars from each other and from the horizon, it may be proper to keep in mind that the distance between the two pointers is exactly five degrees, and between Dubhe (the nearest to the pole) and the pole-star, twenty-nine degrees. By applying these measures by the eye to other stars, their apparent distances may be very nearly estimated. 5. Although I have stated in general terms, that the pointers come to the southern meridian, or are nearly in the zenith, at ten, P. M., *about the beginning* of April, yet it is not before the seventh of this month that they are accurately in this position at ten in the evening; but the difference is not much perceptible by the eye during the course of a week or two, and therefore can lead to no great mistake. 6. If the circle containing the stars were cut out, and surrounded with the circle of months and days, and made to revolve within the circle of hours, it might be made to serve the purpose of an astronomical clock for pointing out the hours of the night, and likewise for showing the positions of the circumpolar stars for any hour of the day or night. 7. The delineations of the apparent distances of the stars on this map are on a scale of only one-half the size of that on which the two preceding maps were constructed.

The three preceding views of certain portions of the heavens, partly delineated from actual observation, are intended to convey to general observers a *natural* representation of those quarters of the firmament to which they refer, so that by a little further attention and observation, and an inspection of a celestial atlas, they may acquire a general view of the principal stars and constellations visible in our hemisphere; for on most celestial planispheres and globes there is such a group of eyes, noses, legs, tails, claws, and wings connected with the mythological figures of the constellations, no traces of which can be seen in the heavens, that the learner is sometimes confounded, and can scarcely trace any resemblance between what is depicted on such globes and planispheres and the real aspect of the firmament, the stars appearing, in many instances, as accidental spots, buried, as it were, amid the group of hieroglyphics with which they are connected.

CHAPTER II.

ON THE ARRANGEMENT OF THE STARS INTO CONSTELLATIONS, WITH SKETCHES OF THEIR MYTHOLOGICAL HISTORY.

In order to distinguish the stars from one another, the ancients divided the heavens into different portions or spaces, called *constellations*, or groups of stars. They supposed each group to occupy a space which a lion, a bear, a man, a harp, or other object would fill, if it were there delineated; and hence the different constellations were depicted as if they had borne a resemblance to dragons, dogs, rams, altars, ships, and similar objects, whether imaginary or real. The invention of the constellations, particularly those of the Zodiac, is generally attributed to the Chaldeans or the Egyptians; but most probably the merit, such as it is, is due to the former, although the Egyptians appear, at a very early period, to have derived the knowledge of astronomy from the inhabitants of Chaldea, and imparted it to the ancient Greeks and other nations. The first series of constellations which were formed appear to have been those of the Zodiac. Finding that the year consisted neither of twelve nor of thirteen lunations, in order to know the precise bounds of the annual course of the sun, they were under the necessity of carefully examining what stars were successively obscured in the evening by the motion of that globe, and what stars, after emerging from its rays, showed themselves again before the dawn of day.

Macrobius, an ancient Roman author, and Sextus Empiricus, a Greek writer, have handed down to us the ingenious method which the first astronomers used to determine exactly the course which the sun describes in the heavens, and to divide the year into equal portions, of which the following is a condensed description:

They every day saw the sun and the whole heavens turning round from east to west. In the meantime they observed that the sun, by a motion peculiar to it, receded, from day to day, from certain stars, and took its place under others, always advancing toward the east. As they found that twelve revolutions of the moon approximated to one revolution of the sun, but that a certain sensible difference existed, they wished that they might have twelve divisions of the year, which might be *exactly* equivalent to the year itself. For this purpose they took two brass open vessels, the one pierced at the bottom, and the other without any orifice below. Having stopped the hole of the first, they filled it with water, and placed it so that the water might run out into the other vessel the moment the cock should be opened. This done, they observed in that part of the heavens where the sun has its annual course, the rising of a star, remarkable either for its magnitude or its brightness, and at the critical instant it appeared on the horizon they began to let the water flow out of the upper vessel into the other, during the rest of the night and the whole following day, until the very moment when the same star began to appear anew on the horizon. The instant it was again seen they took away the under vessel, and threw the water that remained in the upper on the ground. The observers were thus sure of having one revolution of the whole heaven, between the first rising of the star and its return. The water which had flowed during that time now afforded them the means of measuring the duration of one whole revolution of the starry firmament, and of dividing that duration into seveal equal portions. They then divided the water of the under vessel into twelve parts, *perfectly equal*, and prepared two other small vessels capable of containing exactly one of these portions, and no more. They again poured into the great copper vessel the twelve parts of water all at once, keeping the vessels shut. They then placed under the cock, still shut, one of the two small vessels, and another near it to succeed the first as soon as it should be full. All these preparations being ready, the next night they observed that part of the heavens toward which they had remarked the sun took his course, and waited for the rising of the constellation which has since been called *Aries*. The instant Aries appeared, and they saw the first star of it ascending, they let the water run into the little measure. As soon as it was full they removed it, and threw the water out. In the meantime they put the other empty measure under the fall. They observed accurately all the stars that rose during all the periods which the measure took in filling, and that part of the heavens was terminated in their observations by the star which appeared last on the horizon the moment the measure was just full. In like manner they proceeded with the other vessel alternately, until the two small vessels were three times filled, which marked out six divisions, or one-half of the course of the sun in the heavens. They were then forced to defer the observation and measurement of the other half of the firmament until the opposite season of the year, when they proceeded as before.

Having in this maner determined the twelve divisions of the heavens, and marked the clusters of stars peculiar to each, they proceeded to give them names, and in general termed them the stations or *houses* of the sun, three of which were assigned to each season. The particular names given to each of the twelve constellations of the Zodiac are generally supposed to refer to certain circumstances peculiar to the different months. As the Chaldean observers seem to have been of opinion that there were, during the spring, no productions more useful than lambs, calves, and rams, they gave the constellations through which the sun passes during that season the names of the three animals by which they were most enriched. The first was named *Aries*, or the Ram; the second *Taurus*, or the Bull; and the third *Gemini*, or the Twins,—that is, the two goats, which commonly bring forth two young at a time. The Greeks afterward represented them by Castor and Pollux, two twin brothers, sons of Jupiter, by Leda, the wife of Tyndarus, and as such they are represented on our globes. Having remarked that there was a point to which the sun approached when passing these signs, but which it never went beyond, and that it afterward receded from that point for six months together, this retreat of the sun backward led them to distinguish it by the name of an animal which walks backward, and hence it was denominated *Cancer*, or the Crab. As the heats in the next month (July) are most intense, they compared them to the raging and fierceness of a lion, and hence they called the sign *Leo*, that is, the Lion. As in the next month harvest commences, and as young girls were generally set to *glean* in the fields, they denominated the sign corresponding to this month *Virgo*, or the Virgin, which is represented by the figure of a young woman holding an ear of corn.

The perfect equality of days and nights which happens when the sun quits the sign of Virgo, caused astronomers to give the next sign the name of *Libra*, that is, the Balance, poised so as to represent equal day and night. The frequent diseases which are produced in consequence of the sun retiring to the south procured the next sign the name of *Scorpio*, or the Scorpion, because it is mischievous, and drags after it a sting and venom. When harvest is over, and the fields cleared of the crops, then is the season for hunting, and therefore the sign in which the sun enters at that time has obtained the name of *Sagittarius*, that is, the Archer, or Huntsman. The next constellation, *Capricorn*, had its origin from the wild goat, whose nature being to seek its food from the bottom to the top of mountains, was considered emblematical of the ascent of the sun from the lowest point of its course, in the beginning of this sign, to its highest pitch or summit in the summer solstice, when it enters the sign Cancer. The next sign is called *Aquarius*, or the Water-bearer, emblematical of the rains which generally fall at this season of the year; and the last sign is named *Pisces*, or the Fishes, which name seems to have been given because at the time when the sun enters it, fishes are then considered as fattest and most in season for use.

Such were the names and symbols which the ancients appropriated to that great circle or zone of the heavens through which the sun, moon, and planets appeared to move. As the names of ten of these signs or constellations are borrowed from several animals, astronomers gave the annual zone which they compose, the name of *the Zodiac*, that is, the circle of animals, from the Greek word *zoon*, an animal. By this division of the heavens, mankind acquired a new method of measuring time and of regulating all their labors. From the knowledge of the Zodiac they obtained an exact knowledge of the year and of its several subdivisions, and the periods when sowing ought to commence, and when the fruits of harvest might be expected to arrive at maturity. When, after the setting of the sun, they saw the stars of the sign *Aries* ascend the opposite horizon, and distant from the sun by one-half of the sphere of the heavens, they then knew that the sun was under the sign *Libra*, which, being the seventh of the celestial signs, was distant from the first by one-half of the whole Zodiac. When, at the approach of day, they saw, in the middle of the firmament, or on their meridian, at an equal distance from east and west, the principal star of the sign *Leo*, they understood that the sun, then about to rise, was at the distance of *three* signs from Leo, and removed toward the east one-fourth part of its circle. Thus, without seeing the stars, which were obscured and overpowered by the sun's rays as he passed through them, they could say, with a perfect assurance, "the sun is now in *Scorpio*, and in two months hence the shortest day will arrive." On the sight of a single constellation, placed either in the eastern, western, or middle part of the heavens, they could immediately tell in what sign the sun was, how far the year was advanced, and what kinds of labor were requisite to be performed. It is therefore to astronomy we are originally indebted for our knowledge of the length of the year, and the commencement of its different seasons.

The ancients next proceeded to arrange into constellations the other groups of stars which were situated to the north and south of the Zodiac. In forming this arrangement they proceeded on principles similar to those by which they had delineated the signs of the Zodiac. They conceived the different groups as if they bore a certain resemblance to birds, beasts, serpents, or to certain imaginary beings, and gave them names corresponding to such conceptions. This they seem to have done for the sake of assisting the memory and imagination in forming a general idea of the forms and the relative positions of the several clusters of stars, and to enable the observer more readily to distinguish and to point out any particular star; but it would be too tedious, and would convey little profitable instruction, to inquire into the reasons of the emblematical figures they adopted, or to attempt a detailed view of their mythological history.

The following table contains a list of all the constellations, ancient and modern, with the number of stars in each, as stated in the *Historia Cœlestis* of *Flamstead*, formerly Royal Professor of Astronomy at Greenwich. The first column contains the *name* of the constellation, the second column, the number of stars it contains, and the third column, the principal stars and their magnitudes. The number 1, expresses stars of the first magnitude; 2, those of the second magnitude, &c.

NORTHERN CONSTELLATIONS.

Name.	No. of Stars.	Principal Stars.
Ursa Minor—the Little Bear	24	Pole star, 2.
Ursa Major—the Great Bear	87	Dubhe, 1; Alioth, 2
Draco—the Dragon	80	Rastaben, 2
Cepheus [East of Draco]	35	Alderamin, 3.
Bootes—the Herdsman	54	Arcturus, 1; Mirac, 3
Corona Borealis–the Northern Crown [East of Bootes]	21	Alphecca, 2.
Hercules, with Cerberus	113	Ras Algethei, 2.
Lyra—the Harp	21	*Vega*, or Lyra, 1.
Cygnus—the Swan	81	Deneb, 2.
Cassiopeia—Lady in her chair	55	Schedir, 3.
Perseus, and Head of Medusa	59	Algenib, 2; Algol, 2
Auriga—the Wagoner	66	Capella, Alajoth, 1.
Serpentarius—Serpent Bearer	74	Ras Alhague, 2.
Serpens—the Serpent	64	
Sagitta—the Arrow [N. of Aquila]	18	
Aquila and Antinous—the Eagle, &c.	71	Altair, 1 or 2.
Delphinus—the Dolphin	18	
Equuleus—the Horse's Head	10	
Pegasus—the Flying Horse	89	Markab, 2; Scheat, 2.
Andromeda	66	Alamak, 2; Mirack, 2
Triangulum—the Triangle	16	
Camelopardalis—Camelopard	58	
Leo Minor—the Little Lion	53	
Coma Berenices—Berenices' Hair [North of Virgo]	43	
Vulpecula et Anser—the Fox and Goose [South of Cygnus]	35	
Lacerto—the Lizard [East of Cygnus]	16	
Scutum Sobieski [North of Sagittarius]	8	
Canis Venatici—the Greyhounds	25	
Lynx	44	
Cerberus	4	
Mons Menelaus [S. E. of Bootes]	11	
Taurus Poniatowski—the Bull of Poniatowski [W. of Aquila]	7	
Musca—the Fly [N. of Aries]	6	
Tarandus—Reindeer [at N. Pole]	12	
Total number of stars in the Northern Constellations	1444	

SOUTHERN CONSTELLATIONS.

Those Constellations marked thus † never rise in N. latitude 52 degrees.

Name.	No. of Stars.	Principal Stars.
Cetus—the Whale	97	Menkar, 2; Mira, 2.
Orion	78	Betelguese, 1; Rigel, 1
Eridanus—the River Po	84	Achernar, 1.
Lepus—the Hare [S. of Orion]	19	
Canis Major—the Great Dog	31	Sirius, 1.
Canis Minor [N. of Monoceros]	14	Procyon, 1.
Argo Navis—the Argo	64	Canopus, 1; Naos, 2
Hydra—the Serpent	60	Cor Hydræ, 1
Crater—the Cup [S. of Virgo]	31	Algorab, 3.
Corvus—the Crow [S. of Virgo]	9	Alkes, 3.
Centaurus—the Centaur	35	
Lupus—the Wolf	24	
Ara†—the altar	9	
Corona Australis—Southern Crown	12	
Piscis Australis—[S. of Aquarius]	24	Fomalhaut, 1.
Columbo Noachi—Noah's Dove	10	
Rober Caroli† [E. of Argo Navis]	12	
Grus†—the Crane	13	
Phœnix‡	13	
Indus†—the Indian	12	
Pavo†—the Peacock	14	
Apus†—the Bird of Paradise	11	

Name.	No. of Stars.	Principal Stars
Apis Musca† Australis	4	
Triangulum Australis† [South Triangle]	5	
Piscis Volans†—the Flying Fish	8	
Chameleon† [near the S. Pole]	10	
Dorado†—the Sword Fish	6	
Toucan†—the American Goose	9	
Hydrus†—the Water Snake	10	
Sextans—the Sextant [S. of Leo]	41	
Monoceros—the Unicorn	31	
Crux—the Cross†	6	
The Sculptor's Apparatus	12	
Circinus †—The Compasses	7	
Brandenburgium Sceptrum [S. W. of Orion]	6	
Equuleus Pictorius	8	
Fornax Chemica	14	
Horologium†—the Clock	12	
Mons Mensa†—the Table Mountain	30	
Machina Pneumatica—the Air Pump	24	
Norma, or Euclid's Square	12	
Octans Hadleianus†—Hadley's Octant	43	
Pyxis Nautica—Mariner's Compass	8	
Reticula Rhomboidalis†	10	
Telescopium†—the Telescope	9	
Sculptorio†—the Engraver's Tools	16	
Microscopium—the Microscope	10	
Total number of stars in the Southern Constellations	1027	

ZODIACAL CONSTELLATIONS.

Name.	No. of Stars.	Principal Stars.
Aries—the Ram	66	*a* Arietis, 2.
Taurus—the Bull	141	Aldebaran, 1; Pleiades.
Gemini—the Twins	85	Castor, 1; Pollux, 1.
Cancer—the Crab	83	Acubens, 3.
Leo—the Lion	95	Regulus, 1; Denebola, 2.
Virgo—the Virgin	110	Spica Virginis, 1.
Libra—the Balance	51	Zubeneschamale, 2.
Scorpio—the Scorpion	44	Antares, 1
Sagittarius—the Archer	69	
Capricornus—the Goat	51	
Aquarius—the Water Bearer	108	Scheat, 3.
Pisces—the Fishes	113	
Total number of stars in the Zodiac	1016	
Total number of stars in all the Constellations		3487

Thus all the visible stars in the firmament have been arranged into ninety-four constellations, of which forty-eight were formed by the ancients, and the rest within the last two or three hundred years. Of the stars above enumerated, there are about 17 of the first magnitude, 76 of the second, 223 of the third, and the remainder of the fourth, fifth, and sixth magnitudes. The different classes of magnitudes are intended to express their apparent brightness. The brightest stars are said to be of the first magnitude; those which appear next in brightness, or inferior to the first, are classed in the second magnitude; and so on down to the sixth magnitude, which comprises the smallest stars visible to the naked eye in the clearest night; though there are but few eyes that can distinguish those which belong to the sixth magnitude. All the stars beyond these limits come under the general denomination of *Telescopic stars;* and with the most powerful telescopes, stars may be perceived of all classes, from the sixth to the sixteenth order of magnitudes. Every increase in the power of these instruments brings into view innumerable multitudes of those orbs which were before invisible, so that no definite limits can be assigned to the apparent brightness or magnitude of the stars. This classification into magnitudes, however, as it is entirely arbitrary, so it is extremely indefinite, and can convey no very accurate ideas even of their *apparent* brightness or intensity of light. This consideration has led some eminent astronomers to endeavor to estimate the apparent brightness of each star by experiments made with the photometer. From various experimental comparisons of this kind, the late Sir Wm. Herschel deduced the following conclusions:

	Magnitude.			
Light of a star of the average	1st	-	=	100
	2d	-	=	25
	3d	-	=	12
	4th	-	=	6
	5th	-	=	2
	6th	-	=	1

So that the light of a star of the second magnitude is one-fourth of that of a star of the first magnitude; the light of one of the third, one-eighth; of the fourth, one-sixteenth; of the fifth, one-fiftieth; and of the sixth, only one-hundredth part. Sir John Herschel informs us that, from his own experiments, he has found that the light of

Sirius, the brightest of all the fixed stars, is about 324 times that of an average star of the sixth magnitude.

It may be proper to observe that the stars specified in the statements inserted above are not all visible to the naked eye, nearly two-thirds of them being perceptible only by the telescope; but they are those stars whose latitudes and longitudes, and whose right ascensions and declinations, have been accurately determined. They form only *a very small proportion* of those which are found to exist in the most distant regions of the firmament; for by powerful telescopes there have been explored, in a sinlge speck of the heavens, a number which far exceeds that of all the visible stars in the sky; and catalogues have been formed in modern times which comprise from fifty to a hundred thousand of these luminaries.

The first astronomer, so far as we know, who attempted to take a catalogue of the stars, was *Hipparchus* of Rhodes, who flourished about 120 years before Christ. Having observed a new star, which he had never seen before, he began to doubt whether there might not be changes occasionally taking place among these luminaries, and therefore commenced making a catalogue of them, noting down the position and magnitude of each star, with the view that, if any new stars should again appear, or any of those observed by him should increase or diminish in magnitude, or totally disappear, such changes might be known to those who should live in future ages. This catalogue, which was handed down to us by Ptolemy, an ancient Egyptian astronomer, has been of special use to modern astronomers, both in determining the rate of the precession of the equinoxes, and in proving that certain stars which then existed are no longer to be seen in the heavens; thus indicating that changes and revolutions are taking place among the distant bodies of the universe. The catalogue of Hipparchus contained a description of the places of 1026 stars. The Arabians are the next whom history represents as having attempted to form a descriptive catalogue of the stars. This was effected by *Ulug Beigh*, the grandson of Tamerlane, from his own observations made at Samarcand, whose catalogue contains 1022 stars. Tycho Brahe, the celebrated Danish astronomer, who lived in the sixteenth century, by means of the large and accurate instruments he invented, formed a catalogue of 777 stars, which are considered as superior in correctness to those of Hipparchus and Ulug Beigh. He was prompted to this laborious undertaking by the sudden appearance of a new star in Cassiopeia in the year 1572, which shone with the brilliancy of Venus, and was visible even at noonday. *Bayer* soon after published a catalogue of 1160 stars, in which he introduced the practice of distinguishing the stars by the letters of the Greek alphabet. All the catalogues now mentioned were formed before the telescope was invented, and contained nearly all the stars which could be perceived by the unassisted eye. Soon after the invention of the telescope, in the beginning of the seventeenth century, the celebrated Hevelius composed a catalogue of 1888 stars, of which 1553 were observed by himself, and their places computed for the year 1660. But some of our modern observers of the heavens have published catalogues which contain the positions of many thousands of stars beside multitudes of nebulæ, of various descriptions, double, triple, and quadruple stars, and various other celestial phenomena.

The division of the heavens into constellations, and the names and figures by which they are distinguished, seem to have been of a very ancient date. Job, who is supposed to have lived in a period prior to that of Moses, refers to some of them by the same names which they still bear. "Canst thou bind the sweet influences of *Pleiades*" —or the seven stars,—"or loose the bands of Orion?" that is, the *belt* of Orion, which consists of three equidistant stars in a straight line.— "Canst thou bring forth Mazzaroth in his season? or canst thou guide Arcturus with his sons?" Arcturus is a bright star of the first magnitude in the constellation of Bootes, and is here put for the constellation itself. The expression "his sons" is supposed to refer to *Asterion* and *Chara*, the two Greyhounds, with which he seems to be pursuing the Great Bear around the North pole, in the diurnal revolution of the heavens. *Mazzaroth* is generally supposed to refer to the twelve signs of the zodiac, which, by their appointed revolutions, produce the succession of day and night, and the seasons of the year. In another part of this book, Job, when filled with profound reverence of the majesty of God, declares that He alone "spreadeth out the heavens, and maketh Arcturus, Orion, and the Chambers of the South." The prophet Amos, who lived 800 years before the Christian era, alludes to the same objects in the fifth chapter of his prophesy—"Ye who turn judgment to wormwood, and leave off righteousness in the earth, seek him who maketh the seven stars and Orion, who turneth the shadow of death into morning, and maketh the day dark with night; that calleth for the waters of the sea, and poureth them out upon the face of the earth; the Lord of Hosts is his name."

The names of the constellations, and the hieroglyphic figures by which they are represented, appear, however, to have had their origin in superstitions and idolatrous notions. The Egyptians, it is well known, worshiped the host of heaven under the figures of most of the animals which represent the celestial constellations, particularly the signs of the Zodiac. They imagined the sun, which they called *Osiris*, to be a proper representative of the Spirit of Nature, or the Supreme Being, who, like the sun, appears everywhere present, exercising his influence over the universe. The moon, as she receives her light from the sun, was looked upon as a female divinity, and called *Isis*,—which goddess was made to signify universal nature considered as passive, and susceptible of various impressions, forms, and qualities.—They found, or imagined they found, in various animals, some properties or qualities corresponding to the motions, appearances, or influences of the sun, moon, and stars. This induced them not only to use those animals in their hieroglyphic representations of their deities, but also to pay them honors. Thus, by the *Ram*, a prolific animal, they represented the genial, fertilizing influence of the sun in spring; and by the hot and furious *Lion*, his violent scorching heat in the summer; and the Bull was an emblem of the various powers of the sun in forwarding the business of agriculture, in which this animal was of particular service. As the overflowing of the Nile is particularly beneficial to the land of Egypt, and as that river was observed to begin to swell at the rising of Sirius, or the Dog Star, so they had a special veneration for that orb, as if its divine influence had contributed to that fertility which was produced by the inundation of the Nile. That the Egyptians worshiped all the animals depicted on the Zodiac, and those which represent several of the other constellations, is proved by the testimony of several ancient authors, particularly Herodotus, who says that "in Egypt all sorts of beasts, whether wild or tame, were accounted as sacred, and received divine honors." And it is not improbable that this worship of the host of heaven, through the hieroglyphics of various animals, was a general practice during the abode of the Children of Israel in that country, and that the following admonition of Moses has a reference to this circumstance:—"Take heed lest ye corrupt yourselves and make you a graven image, the similitude of any figure, the likeness of any male or female, the likeness of any beast that is on the earth, the likeness of any fowl that flieth in the air, the likeness of anything that creepeth upon the ground, the likeness of any fish that is in the waters beneath the earth; and lest thou lift up thine eyes to heaven, and when thou seest the sun, and the moon, and the stars, even all the host of heaven, shouldst be driven to worship them and serve them, which the Lord thy God hath divided unto all nations under the whole heaven. But the Lord thy God hath taken you, and brought you forth out of the iron furnace, even out of Egypt." The reference here made to their being brought out of Egypt seems evidently intended to put the Israelites in mind of their deliverance *from the idolatrous practices* of the inhabitants of that country, as well as from the slavery to which they had been subjected, and consequently implies that the Egyptians indulged in the superstitious worship to which we have alluded.

As it is the practice of astronomers to denote the relative apparent magnitudes of stars in each constellation by the letters of the Greek alphabet, the whole of this alphabet is here inserted, that the unlearned reader may be enabled to distinguish the different characters, and the order in which they follow each other.

The first letter of the Greek Alphabet α, denotes the largest or brighest star in each constellation. Thus, α Lyræ is the brightest star in the constellation of Lyra, or the Lyre; β Lyræ, the star next in brightness to alpha; and so on throughout all the letters of the Greek alphabet. When the number of stars to be distinguished in any constellation is greater than the number of letters in the Greek alphabet, astronomers have recourse to the letters of the English alphabet, and distinguish the remaining stars, according to their apparent brilliancy, by the letters a, b, c, d, &c.; and if more stars still remain to be distinguished, they resort to numerals,—thus, a^2, d^4, &c. From this mode of distinguishing the apparent magnitude of the stars, the reader will easily perceive that those stars which are distinguished by the first letters of the Greek alphabet are the largest in any particular constellation, while those which are marked with letters toward the close of the alphabet are among the smaller stars.

CHAPTER III.

ON THE PROPRIETY OF ADOPTING A MORE NATURAL ARRANGEMENT AND DELINEATION OF THE STARRY GROUPS.

THE figures of the celestial constellations to which we have now adverted are still depicted in our celestial globes and planispheres, and present, in my opinion, a very awkward and *unnatural* representation of the starry heavens. It is rather a strange circumstance, that for a period of more than two thousand years the firmament has been contemplated, and the arrangements of the bodies it contains studied, through the medium of bears, serpents, lizards, rams, whales, centaurs, dolphins, flying-horses, three-headed dogs, hydras, dragons, and many other grotesque and incongruous figures. The sublime wonders of the evening sky have thus been associated with a group of mean, ridiculous, and imaginary objects, of which we have scarcely any prototype in nature, and in which there is not the least shadow of a resemblance to the objects they are intended to represent. When the young student of astronomy wishes to distinguish particular assemblages of suns and systems of worlds, he is required to connect them in his imagination with wolves, lions, snakes, and numerous fantastical figures, which are bent and twisted into unnatural shapes, which have as little resemblance to the objects in the heavens as the gloom of midnight to the splendors of the meridian sun. Such representations have a tendency to convey to juvenile minds a mean idea of the most august bodies in nature, and of the ample spaces which surround them, and in which they perform their revolutions.

The terms used in any science, the mode of communicating its instructions, and the delineations which such instructions require, ought undoubtedly to be accommodated to the discoveries which have been made in the course of ages, and to the present state and objects of that science; and unless we can show that the terms and figures to which I allude are the best calculated to the present state and objects of astronomical science, and fitted to assist the student in forming natural and correct ideas of the arrangement of the celestial orbs, it is expedient that some change and improvement in this respect should be adopted, in accordance with the new modifications and arrangements which have been introduced into other departments of science. The propriety of introducing some changes in delineating the constellations, and in their nomenclature may perhaps appear from the following considerations:

1. The natural and hieroglyphic figures now in use have no resemblance to the groups of stars they are intended to represent. What resemblance, for example, exists between an eagle, a wolf, a centaur, a flying-fish, or Hercules with his club—and the constellations which bear their names and are attempted to be delineated by their figures? Even when imagination has stretched itself to the utmost in order to fancy a resemblance, it is obliged to represent such creatures in the most unnatural positions; and after all, it is found impossible to bend and twist their wings, and legs, and tails, and claws, in such a manner as to take in all the stars in the group, some pretty conspicuous ones being still left unformed in the intermediate spaces. Beside, the discovery of new stars by the telescope has now completely deranged the figures of the ancient constellations; so that however much the legs, arms, and feet of the figures may be twisted, they cannot be made to coincide with hundreds of stars which are known to exist. The only constellations which may be said to bear a very rude resemblance to the natural figures are Orion and Ursa Major; but even in these the resemblance is very distant. Hence what is commonly called a *bear* is also conceived to resemble a *plow* and a *wagon*, and is, by the vulgar, distinguished by these names. Hence, also, different nations represent the same constellation by different figures:—thus, instead of our hieroglyphic delineations, the Hindoos have bespattered the firmament with bedsteads, dogs' tails, ear-rings, couches, elephants' teeth, cats' claws, red saffron, children's pencils, lions' tails, festoons, wheels, razors, pieces of coral, pearls, and other whimsical objects equally appropriate.*

In a judicious comparison of the figures of the different clusters of stars with any other object, for the purpose of a name or reference, the figure of the particular cluster ought first to be accurately considered, and then an object, having as near a relation to it as possible, should be fixed upon as its representation. But an order exactly the reverse of this seems to have been adopted by the ancients in their arrangement and nomenclature of the constellations. They first fixed upon the heroes, animals, and mythological figures which they intended to place in the celestial vault; and then attempted, if possible, to bend the clusters of stars to correspond with them—a most absurd, unscientific and unnatural procedure. And shall all succeeding astronomers in every nation tacitly give their approbation of such rude and injudicious arrangements, as if they were unqualified for forming a more scientific and definite outline of the sublime spaces of the firmament?

2. The figures now in use tend to convey a mean idea of the objects they are intended to represent. When the stars were considered as merely a number of tapers or studs fixed in the vault of heaven, solely for the purpose of shedding a few glimmering rays on the earth and adorning the canopy of our habitation, it might not appear quite so incongruous to represent their different groups by "corruptible men, and birds, and four-footed beasts, and creeping things." But now that the astronomer views the stars as so many suns and systems of worlds, dispersed through the immensity of space, the association of such august objects with representations so silly and whimsical as the mythological figures delineated on our globes, produces not only a ludicrous effect by the greatness of the contrast, but for the same reason, tends to lessen the idea of sublimity which naturally strikes the mind on the contemplation of such a stupendous scene. Every one knows how much things great and noble are debased by being placed in intimate connection with little and ignoble objects, and must feel the force of this association in the following lines of Hudibras:

> "And now had Phœbus in the lap
> Of Thetis taken out his nap;
> And like a lobster boil'd, the morn,
> From black to red began to turn."

Again—

> "Cardan believed great states depend
> Upon the tip of the Bear's tail's end;
> That as she whisk'd it toward the sun,
> Strew'd mighty empires up and down."

Again—

> "Who made the *Balance*, and whence came
> The *Bull*, the *Lion*, and the *Ram?*
> Did not we hear the *Argo* rig?
> Wake Berenice's Periwig?
> Whose livery does the *Coachman* wear?
> Or who made *Cassiopeia's* chair?
> And therefore as they came from hence,
> With us may hold intelligence."

Such an effect the celestial hieroglyphics have a tendency to produce, when placed in association with the august objects of the sky.

3. They tend to lead us back to the dark and rude ages of the world, and to familiarize our minds to those crude, chimerical, and absurd conceptions which ought now to descend into oblivion. The signs of the zodiac and most of the other constellations were invented by the Egyptians or Chaldeans to perpetuate the memory of some of their rude and barbarous heroes, to assist them in their absurd and idolatrous worship, or to serve the foolish and impious pretensions of astrology. In neither of these respects can the celestial hieroglyphics be interesting or instructive to the modern student of astronomical science, but they are, in almost every point of view, associated with opinions, practices, and representations, which deserve the most marked reprobation; they also distract the attention by turning it aside from the direct objects of the science to the investigation of their fabulous history. How ridiculous the story of Calisto and her son Arces, whom the rage of Juno turned into bears, which now circulate about the north pole!—the story of Medusa, whose golden hair Minerva turned into snakes, and of the winged horse which sprang from the blood which gushed out in striking off Medusa's head!—the story of Orion, who was produced from the hide

---

* See "Asiatic Researches," Vol. ii, Art. 16—Antiquity of the Indian Zodiac.

of an ox moistened with wine!—the story of the Dragon which guarded the golden apples in the garden of the Hesperides, and was taken up to heaven and made a constellation on account of his faithful services!—the story of Andromeda, of the Swan, of Perseus, and a hundred others of a similar description!

Such is the heaven of the pagans—a common receptacle of all ranks of creatures, real and imaginary, without distinction or order; a wild miscellany of everything that is false, grotesque, and chimerical. Such fantastical groups, which occupy the "houses of the Zodiac," and other compartments of the sky, may comport with the degrading arts of the astrologer, but they are not only incompetent to the purposes, but completely repugnant to the noble elevation of modern astronomical science. How incongruous, then, is it that such representations, the wildest hallucinations of the human mind, should be blazoned in such brilliant colors upon our globes, and that a considerable portion of our astronomical treatises should be occupied in detailing their mythological history? Because a few shepherds in the plains of Babylon, or on the banks of the Nile, arranged and delineated the heavens according to the first crude conceptions which arose in their minds, are these chimerical representations to guide the astronomers of every nation, and throughout all succeeding generations? It becomes the astronomers of the present day to consider, whether they intend to transmit to the enlightened generations of the twentieth or thirtieth centuries the sublime discoveries of modern times, which have transformed the heavens into an immense assemblage of suns and worlds,—incorporated and disfigured with hydras, gorgons, flying-horses, three-headed dogs, and other "dire chimeras;" or whether they might not be as well qualified as the shepherds of Chaldea to reduce the starry groups, in the concave of the firmament, to a more natural, simple, and scientific arrangement.

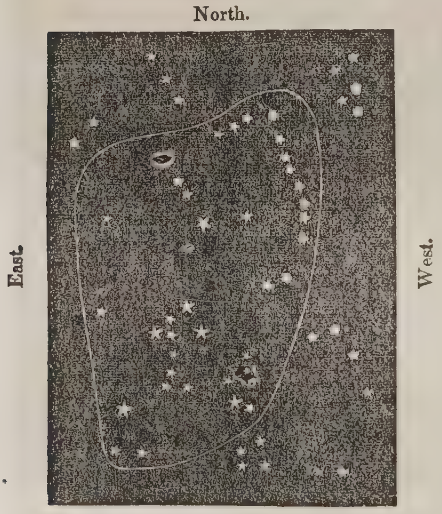
4. The constellations, as presently depicted on our globes and planispheres, convey an *unnatural* and complex representation of the heavens, which tends to confuse the imagination of the juvenile student. On some celestial globes which I have inspected, the natural and hieroglyphic figures are so prominently engraved, and the colors with which they are bespattered so deep and vivid, that the stars, appeared not only as a secondary object, but were almost invisible, except on a very minute inspection. The animals were so nicely drawn, and exhibited such a glare of variegated colors, that the sphere appeared more like a young miss's plaything than a delineation of the starry heavens. It seems as if the engraver had been afraid lest his pretty little dogs, and serpents, and scorpions, and flying-horses, and crabs, and lizards, should have been disfigured by the radiated groups of stars which spotted the pretty creatures; and therefore he threw them into the shade, in order that the artificial globe, which a late philosopher calls "a philosophic toy," might prove nothing more to the fair one, who occasionally twirled it round its axis, than a beautifully-colored ball to fill up a niche in her parlor or bed-room. The same thing appears in many of our planispheres of the heavens, on the first opening of which one would imagine he was about to inspect the figures connected with the natural history of animals, or the fantastical representations illustrative of the system of pagan mythology. Whatever may be said of the utility of such delineations it is evident they present a very awkward and *unnatural* representation of the beautiful and variegated scenery of a starry sky; and hence it is that a young person who wishes to acquire a general knowledge of the positions of the principal stars finds it extremely difficult to recognize them by our present maps and planispheres, on account of their being so much interwoven with extraneous objects, and on this account, presenting appearances so very different from what they do in the heavens.

For these and many other reasons, it appears expedient that some change or modification should be adopted in the arrangement and delineation of the celestial orbs. Were any scheme of this kind attempted, it would be proper to proceed on the following principle, among others—namely, *to give names to the starry groups from objects which bear the nearest resemblance to the actual figures which appear in the heavens.* I shall not presume at present to determine what are the particular objects which might be selected for representing the constellations; as it would require a combination of astronomers to enter particularly into the discussion. It is evident, however, that a number of clusters might be reduced to mathematical figures and diagrams; and in so far as these were found to resemble the starry groups they would form a *natural* representation. For there actually appear in the heaven—triangles, squares, parallelograms, pentagons, crosses, trapeziums, perpendicular and parallel lines, and various combinations of geometrical schemes, some of which might be selected for the purpose proposed. It would be expedient that as many as possible of the old constellations should be preserved entire; such as Orion, Ursa Major, and others; and that those which behooved to be somewhat deranged should be so divided as that two or more of the new-formed constellations should exactly correspond to one of the old, and *vice versa.*

To any proposal of this kind, however, I am aware that many objections would be raised, particularly that it would introduce confusion into the science of astronomy, especially when references are made to ancient catalogues and observations. It is well known however that a similar difficulty has been overcome in reference to the science of *chemistry.* The new nomenclature, which was intended to express the *nature* of the substance by the *name* which is attached to it, though at first scouted by many eminent chemists and philosophers, is now universally adopted, and has introduced both simplicity and precision into the science. The same may be said of the departments of geology, botany, zoology, mineralogy, and meteorology. The principle now proposed in reference to the constellations is materially the same as that which led to the adoption of a new chemical nomenclature; and, with regard to the inconveniences attending a new set of terms, it may be observed, in the words of M. Bergman, that "those who are already possessed of knowledge cannot be deprived of it by new terms; and those who have their knowledge to acquire will be enabled, by an improvement in the language of the science, to acquire it sooner."

The opposition, however, which is generally made to every innovation, whether in science or religion, the high respect in which everything is held which has the sanction of antiquity, the difficulty of forming such an arrangement as would combine simplicity with accuracy, and meet the approbation of astronomers, will probably postpone the attempt to some distant period. I would therefore propose, in the meantime, as matters now stand, one or other of the following plans for adoption:—1. That the stars be depicted on celestial globes and planispheres in their true positions, and apparent magnitudes, without being connected with any hieroglyphic delineations; the different constellations still retaining their former names. By this plan, the different clusters, not being encumbered and buried, as it were, in a medley of grotesque and extraneous representations, would appear in their natural simplicity, without distortion and confusion, so that the globe, being rectified to any particular position of the heavens, would appear a *natural* as well as accurate representation of the corresponding orbs of the firmament. To distinguish the boundaries of the constellations, a dotted line might be drawn around them, and each of them receive a very slight tint of coloring, so that their shape and limits may be distinguished at a glance. Or, 2. Instead of engraving the stars on a white ground, as is always done on the globes, let them be engraved on a black or a dark-blue ground, so that the several stars may appear as so many white specks, varying in size according to their apparent magnitudes, with a white border (which might be colored if deemed expedient) around each constellation, to mark its boundaries. On this plan the principal stars in the constellation *Orion*, with its boundary, would appear nearly as represented in the following cut.

Fig. 4.



This mode of delineation would exhibit the most *natural* representation which can be made, on a convex surface, of the appearance of the starry sky. I am fully persuaded that globes, with either of these modes of delineation, particularly the last, would be prized by a numerous class of individuals; as I have seldom conversed with any person on this subject who would not have preferred such a simple and natural delineation to those which are bespattered with the mythological figures. Should it, however, be deemed necessary, in cases of particular and minute reference, to have globes and planispheres on the common plan, a number of delineations of both kinds might be engraved to suit the taste of different individuals· and those to whom money is no great object would furnish themselves with one of each description, so that the one globe would prove a mutual assistance to the other.*

That the opinions I have now expressed on this subject are not altogether singular will appear from the following extract from Sir J. Herschel's "Astronomy." "Of course we do not here speak of those uncouth figures and outlines of men and monsters which are usually scribbled over celestial globes and maps, in a rude and barbarous way, to enable us to talk of groups of stars, or districts in the heavens, by names which, though absurd or puerile in their origin, it would be difficult to dislodge them. In so far as they have really any slight resemblance to the figures called up in imagination by a view of the more splendid 'constellations,' they have a certain convenience; but as they are otherwise entirely arbitrary, and correspond to no *natural* subdivisions or groupings of the stars, astronomers treat them lightly, or altogether disregard them, except for briefly naming particular stars, as α Leonis, β Scorpio, &c., by letters of the Greek alphabet attached to them." And again,—"This disregard is neither supercilious nor causeless. The constellations seem to have been almost purposely named and delineated to cause as much confusion and inconvenience as possible. Innumerable snakes twine through long and contorted areas of the heavens, where no memory can follow them; bears, lions and fishes, large and small, northern and southern, confuse all nomenclature, &c. A better system of constellations might have been a material help as an artificial memory."†

---

* The above remarks are abridged from two papers on this subject, which the author communicated twenty years ago to the London "Monthly Magazine" for October, 1818, and January, 1819, Vol. 46, pp. 201, and 500.

† Since the above was written in April, 1838, I am happy to learn that the "British Association for the advancement of Science" has had its attention directed to this subject. At the meeting at New-Castle in August, 1838, it was resolved, "That it is desirable that a revision of the nomenclature of the stars should be made, with a view to ascertain, whether or not a more correct distribution of them among the present constellations, or such other constellations as it may be considered desirable to adopt, may be formed." At the meeting at Birmingham, August, 1839, the committee appointed to report on this subject stated, "That some progress has been made in reforming the nomenclature of the northern constellations; and that the stars in the southern have been commenced laying down on a planisphere, according to their observed actual magnitudes, for the purpose of grouping them in a more convenient and advantageous manner." It is hoped, therefore, that we shall soon be presented with an arrangement and nomenclature of the starry groups, accordant with the sublime conceptions and discoveries of modern astronomy, and which shall present, on our globes and planispheres, a more perspicuous and natural representation of the heavens.

CHAPTER IV.

ON THE DISTANCES OF THE STARS.

To measure the length and breadth of an extensive kingdom, and to compute its dimensions, or to determine the distances between two large islands or continents, was formerly reckoned an achievement of considerable magnitude; but to measure the whole earth, to compute its area, and to determine its exact figure and magnitude, were considered as the most astonishing enterprises ever attempted by man, and almost beyond the reach of the powers with which he is endowed. Confined to a small spot in the world in which he dwells, having no scale of measurement, in the first instance, but his own dimensions, or the length of a rod or chain formed from these dimensions, how can he measure spaces hundreds of times greater than the extent of his whole visible horizon? how can he compute the distance and dimensions of places which he has never visited, and some of which he never can visit, and embrace the whole amplitude of a world which has never been thoroughly explored? The hight of his body is but a fathom, and the length of his chain but a score of fathoms, and such measures dwindle into mere points when compared with the dimensions of the earth. Hence it happened that many ages elapsed before the figure and dimensions of the world in which we dwell were nearly ascertained. The powers of the human mind, however, when called into action and properly exercised, are not only capable of such enterprises, but adequate to the performance of still more elevated achievements. When the mind of man is determined on the pursuit of knowledge, and bent upon improvement, difficulties, however great, only serve as incitants to action and perseverance, and to stimulate his energies to their highest pitch of exertion. He multiplies small measures until he arrives at greater; he combines units into tens, tens into hundreds, hundreds into thousands, and thousands into millions. He combines lines into angles, angles into triangles; compares triangles, squares, and circles together; ascertains their peculiar properties and relations; and, from the conclusions he deduces, constructs instruments and ascertains principles which enable him not only to measure the dimensions of this lower world, but the magnitudes and distances of the globes which roll around him in the heavens.

There is no saying at what point the human faculties will stop when once they are aroused to active operation, and stimulated to exert all their energies. We have not only ascertained the bulk of the terraqueous globe, its spheroidal figure, its diurnal and annual motions, and the relation in which it stands to other bodies in the universe, but we have determined the dimensions of the solar system, and the distances and magnitudes of most of the bodies it contains, so that we can now speak with as much certainty of the distance of the sun, or of Jupiter and Saturn, as we can do of the distance of London from Paris, or of the distances of any two places on the surface of the earth. This is an achievement which at first view might have appeared beyond the power of human genius to accomplish; but by the unwearied observations of modern astronomers, and the application of mathematical principles to such observations, they have been enabled to trace the exact movements of the machinery which is in operation around us, and to determine with precision the relative distance and position of every planet within the system of the sun. There are limits, however, beyond which it is difficult for the human faculties to penetrate. The planetary system comprises an area so vast that imagination is almost lost in the conception. A circle drawn around its circumference would measure more than eleven thousand millions of miles; and a body moving at the rate of thirty miles an hour would require above forty-two thousand years to complete the circuit; still these vast dimensions are within the limits of measurable distance. But when we attempt to pass beyond the boundaries of this system into the illimitable spaces which lie beyond, all our usual modes of computation begin to fail, and the mind is overpowered and bewildered amidst boundless space, and the multiplicity of orbs which fill the regions of immensity. We can tell that some of the nearest of these orbs are not within a certain distance, but how far they may lie beyond it the most expert astronomer has never yet been able to compute.

The principal mode by which the distance of the fixed stars has been attempted to be determined is by endeavoring to ascertain whether any of them have an *annual parallax*. I have already explained the mode by which the distances of the sun, moon, and planets is determined by means of the *horizontal parallax*, or the angle under which the earth's semi-diameter is seen at any of these bodies.* But such a mode is altogether inapplicable to the fixed stars, whose distances from the earth is so great that the horizontal parallax is quite imperceptible. Astronomers have therefore attempted to find a parallax by using the whole diameter of the earth's annual orbit as a *base line*,—namely, one hundred and ninety millions of miles,—and endeavoring to ascertain whether any of the fixed stars appear to shift their position when viewed from the opposite extremities of this line. The nature and mode of this investigation will appear from the following explanations:

The axis of the earth extended, being carried parallel to itself during its annual revolution round the sun, describes a circle in the sphere of the fixed stars equal to the orbit of the earth. Thus (fig. 5), let *A B C D* be the orbit of the earth, *S* the sun, the dotted lines the axis of the earth extended; this axis, when the earth is at *A*, points at *a* in the sphere of the heavens; when the earth is at *B*, it points at *b*; when at *C*, it points at *c*; and when at *D*, it points at *d*; so that in the course of a year it describes the circle *a b*

---

* "Celestial Scenery," pp. 110, 111.

c d in the sphere of the heavens, equal to the circle *A B C D*. But although the orbit of the earth, and consequently the circle *a b c d*, be immensely large, no less than many millions of miles in diameter, yet it is but a point in comparison of the boundless sphere of the heavens. The angle under which it appears to an inhabitant of the earth is insensible by any instruments or observations that have hitherto been made, and therefore the celestial poles appear in the same points of the heavens during the whole of the earth's annual course. The star *H* is nearer the point *a* than it is to the point *c* by the whole length of the line *a c*, yet if this line *a c*, great as it is when viewed from the earth, should occupy no *sensible* space in the sphere of the heavens, the star will appear at the same distance from the pole throughout every portion of the annual revolution, and consequently will have no parallax,—which is found to be the fact.

If the annual parallax of a fixed star were sensible, the star would appear to change its place so as to describe a small ellipsis in the sphere of the heavens in the course of a year, or an annual revolution of the earth. Thus, let *G E F I* (fig. 6) be the orbit of the earth, and *K* the star to be observed,—if we imagine a straight line to be drawn from the earth at *G* through the star to a point in the heavens, as at *i*, that visual line *G i* being carried along with the earth in its annual motion, will describe the ellipse *h n i*; in other words, the motion of the earth round its orbit *G E F I* will make the star appear to go round the ellipse *h n i*. If the star *K* were in the pole of the ecliptic, the ellipse it described would have the same eccentricity as the orbit of the earth, and consequently would differ very little from a circle; if it were at any distance from the pole of the ecliptic,* the greater that distance, the more oblong would be the ellipse. If the star were in the plane of the ecliptic, the ellipse would become a straight line, as *i h*, in which the star would appear to move one-half of the year according to the order of the signs, and contrary to the order of the signs during the other half,—somewhat similar to the appearance which the moons of Jupiter present when moving between the opposite points of their orbits. If therefore the stars were at a moderate distance from the earth, so that the diameter of the earth's orbit, *G F*, bore a sensible proportion to that distance, the star would be found at one time of the year, suppose the month of December, at the point *i*, and at the opposite season, in the month of June, at the point *h*; and if the angle *i K h*, which is equal to the angle *G K F* could be found, it would constitute what is termed the *annuul parallax;* and having obtained this parallax, and knowing the extent of the base line *G F*, or the diameter of the earth's orbit, the distance of the stars whose parallax was ascertained could then be determined by an easy process in trigonometry; for as radius: is to the sine of the angle $i\ K\ h = G\ K\ F$: : so is the diameter of the orbit of the earth, 190,000,000 of miles : to a fourth number, which would express the distance of the particular stars from our globe.

Fig. 5.

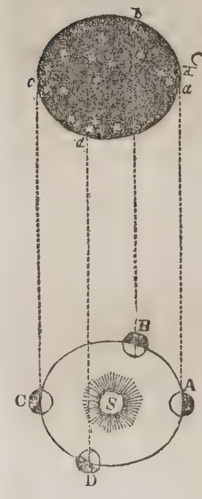


Fig. 6.

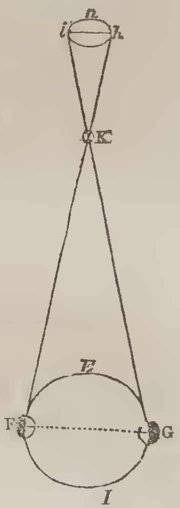


But this angle, in respect to any of the stars, has never yet been ascertained; although astronomers for more than a century past have used the most accurate instruments which ingenuity could contrive, and the most unwearied observations in order to determine it.

Galileo appears to have been the first who thought of trying whether the annual parallax of the stars were discoverable. Taking for granted that the stars are placed at different distances from the earth, and that those stars which are nearest will appear the largest, he suggested that, by observing with a telescope two stars very near each other, one of the greatest and the other of the least magnitude, their apparent distance from each other might perhaps be found to vary as they were viewed from different parts of the earth's orbit at different times of the year; but no change of position whatever was at that period perceived

If any change of this kind were perceptible, it behooved to be a change either in the longitude or latitude of the stars fixed upon as the subject for observation. These are found, not directly, but by first determining their declination and right ascension. The declination of a star is found by taking its meridian altitude, and subtracting the hight of the equator; the right ascension is found by the time of its coming to the meridian.* We have thus two methods pointed out of attempting to determine the annual parallax of the stars: *one*, by observing if any change can be discovered in the meridian altitudes of the same star at different times of the year; the *other*, by examining whether the intervals of time between any two stars coming to the meridian are equal throughout the year. If there be any sensible change of declination in any of the stars, it must be greatest in those which are near the poles of the ecliptic; but the change of right ascension must be greatest in stars in the solstitial colure, and nearest the pole of the equinoctial.

---

* The *pole* of the ellipse is that point in the heavens which is farthest distant from the plane of the earth's orbit, or 90° from every part of it, as the north pole of the earth is the point distant 90° from the equator. The pole of *any circle* is a point on the surface of the sphere 90° distant from every part of that circle of which it is the pole

* The *latitude* of a star is its distance from the *ecliptic*, either north or south, counted toward the pole of the ecliptic. Its *longitude* is its distance from the first point of Aries, reckoned eastward on the *ecliptic*. The declination of a star is its distance from the *equinoctial* north or south, and the greatest declination it can have is 90°. Its *right ascension* is its distance from the first point of Aries, reckoned on the *equinoctial* eastward round the sphere of the heavens, or that degree of the equinoctial which comes to the meridian with the star By the right ascension and declination the situation of stars in the heavens is determined, as that of places on the earth by longitude and latitude.

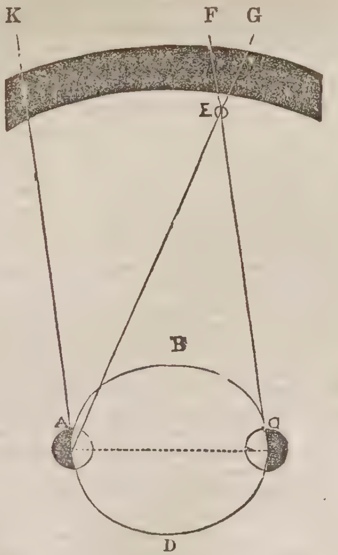
The following is the plan by which the discovery of the annual parallax, by the *change of the declination* of the stars, may be attempted. Let a telescope be placed perpendicular to the horizon, and through this instrument, when accurately adjusted, observe some star in or near the solstitial colure,* which passes through the zenith, or very near it. If the parallax of the star be sensible, there will appear a difference in its altitudes at different periods of the year, and its altitudes at the two solstices† will differ most from each other. In the month of *June* a star that passes through the zenith of any place, in north latitude, will in *December* pass *south* of the zenith, and a star that in December passes through the zenith will in June pass to the north of it, if there be any sensible parallax.

The celebrated Dr. Robert Hook was among the first who suggested this method of attempting to find the parallax of the stars. In the year 1669 he endeavored to put it in practice at Gresham College, with a telescope thirty-six feet in length. His observation was made on the 6th of July, on the bright star in the head of *Draco* marked *Gamma.* On that day it passed 2′ 12″ north of the zenith. On July 9th it passed at the same distance as before. On the 6th of August the star passed north of the zenith 2′ 6″, and on the 21st of October it passed 1′ 48″ north of the zenith. But at that period astronomical instruments were not constructed with such accuracy as to enable the observer to determine with precision the quantity of so small angles; and even Dr. Hook himself could place no great reliance on such observations. In the year 1689, Flamstead, the astronomer royal, commenced similar observations with an instrument adapted to a refracting telescope seven feet long, and, after numerous observations, he supposed that he found the pole-star nearer the pole in December than in the months of April, May, July, August, or September; and that its apparent distance from the pole was greater in April than in September, and greater in July and May than in April; and from the whole of his observations he deduced that its apparent distance from the pole in June must be forty-six seconds different from that in December. But even Flamstead himself speaks of these observations with a great deal of diffidence, owing to his doubts about the regular divisions of his instruments.

From these observations of Hook and Flamstead, supposing them to be nearly correct, Mr. Whiston computed that the greatest annual parallax of a star in the pole of the ecliptic is forty-seven seconds; and hence he calculated the distance of such stars to be about 9000 *semidiameters* of the earth's orbit, then estimated at eighty millions of miles, or about 700,000,000,000, that is seven hundred thousand millions of miles, —a distance so great that it would require a cannon ball, moving 500 miles an hour, more than 160,000 years to move across this immense interval. But we have reason to believe that the distance of the nearest stars from our globe is at least forty times the distance now stated; for modern astronomers would long since have determined the annual parallax had it been nearly so great as Hook and Flamstead supposed; nay, had it amounted to 2″ instead of 47″ this grand problem, as it respects the nearest stars, would have been resolved.

The human mind, when ardently engaged in the pursuit of any object, is seldom deterred by difficulties; and astronomers in particular, notwithstanding the intricacies and difficulties connected with many of the objects of their investigation, have persevered in their observations and researches, and have not unfrequently arrived at the most important and unexpected results. In the year 1725, Mr. Molyneux, doubtful of the accuracy of the observations of Hook and Flamstead, began a series of observations, to ascertain, if possible, the true annual parallax. Assisted by Dr. Bradley, he placed a telescope of twenty-four feet long perpendicularly at his house at Kew, and began to observe the same bright star in Draco as Hook had done. From the 3d of December that year it was found that the star did not sensibly change its distance from the zenith for several days. On December 17th it passed a little more southerly, and continued gradually to pass more and more southerly at every transit over the meridian until the beginning of March, when it was found to pass twenty seconds more southerly than at the time of the first observation. About the middle of April it appeared to be returning toward the north, and at the beginning of June it passed the meridian at the same distance from the zenith as in December, when it was first observed. From that time it appeared more and more northerly at every transit until September following, being then twenty seconds more *northerly* than in June, and no less than thirty-nine seconds more *northerly* than in March. From September the star returned toward the south until it arrived, in December, at the same situation in which it was found a twelvemonth before.

Fig. 7.



The result of these observations, so different from what was expected, was a matter of great surprise to the observers; for it appeared that the star was thirty-nine seconds more northerly in

---

* The *colures* are two great circles passing through the poles of the world; one of them passes through the equinoctial points Aries and Libra, which is called the *equinoctial colure;* the other through the solstitial points Cancer and Capricorn, called the *solstitial colure.* They are drawn on all celestial globes and planispheres.

† The *solstitial* points, or solstices, are where the ecliptic touches the first points of Cancer and Capricorn. The summer solstice is on the 21st of June; the winter solstice is on the 21st of December.

September than in March, *just the contrary to what it ought to appear by the annual parallax of the stars.* This may be illustrated by the foregoing figure:

Let *A B C D* represent the orbit of the earth, and *A* and *C* the place of the earth at two opposite periods of the year; then a fixed object at *E* will be seen from the earth at *A*, in the line *A E*, which will point out its apparent place at *G* in the concave expanse of the sky. But at the opposite period of the year it will be seen from the earth at *C* in the line *C E*, which will project its place in the heavens at *F;* so that while the earth has passed from *A* to *C* the object will appear to have moved from *G* to *F*, through the space *G F*, provided there be any sensible parallax. Now, in the case of the observations stated above, the observers who in *September* saw the star at *F*, did in *March* following observe it at *K*, in the right line *A K*, parallel to *C F*, and not at *G*, where it ought to have appeared by the parallactic motion; so that, instead of finding a parallax, they found a result directly opposite to what they expected, which exceedingly perplexed the observers, and one of them, Mr. Molyneux, died before the true cause of it was discovered.

Some time afterward, Dr. Bradley repeated the same observations with an instrument of great accuracy, to which was appended a telescope twelve and a half feet long. With this instrument, which was so nicely adjusted that he could depend upon it even to half a second, he continued his observations for more than two years, not only on the bright star in Draco, above alluded to, but on many other stars, and always observed the same appearances and arrived at the same results. At last, after many reflections and conjectures on the subject, he arrived at the following conclusion—namely, that the phenomenon he had observed was owing to "the progressive motion of light, and the sensible proportion which its velocity bears to the velocity of the annual motion of the earth." In other words, that *the motion of light, combined with the progressive motion of the earth in its orbit, causes the stars to be seen in a different position from what they would be if the eye were at rest.* This position, after it was explained and demonstrated, was considered as one of the most brilliant discoveries which had been brought to light during the last century. It agrees with the velocity of light which had been deduced from the eclipses of Jupiter's satellites, and it amounts to a *sensible* demonstration of the *annual* motion of the earth. The observations which led to this discovery likewise prove the immense distance of the stars from the earth; for Dr. Bradley assures us, from the accuracy with which they were conducted, that if the annual parallax had amounted to so much as *one second,* he should have discovered it.

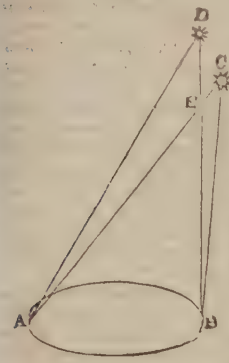
If, then, the greatest annual parallax of the nearest stars does not amount to one second, their distance must be immense. Supposing the parallax to be exactly one second, the distance of a star having this parallax will be found by the following trigonometrical proportion:—As the sine of 1″: is to radius :: so is the semidiameter of the earth's orbit: to a fourth number, which expresses the distance of the star. Now, a parallax of one second determines the object to be 212,000 times farther from the earth than is the sun. The distance of the sun is 95,000,000 of miles, which, multiplied by 212,000, produces 20,140,000,000,000, or more than *twenty billions* of miles. This distance is absolutely certain: it follows, as a matter of course, if the annual parallax were determined to be one second, it is the *very least distance* at which any of the fixed stars can be situated from our globe; but as the parallax does not amount to this quantity, their distance must be much farther than what is here stated, perhaps not less than double or treble that distance. We may acquire some faint idea of the immense distance stated above by considering that a cannon ball, flying with uniform velocity 500 miles every hour, would require *four millions, and five hundred and ninety five thousand years* before it could reach an object at the distance we have stated. Such are the ample and inconceivable dimensions of the spaces of the universe.

Several other methods have been resorted to by astronomers in order, if possible, to determine the distance of the stars, but most of them are founded upon assumptions which have not yet been proved. The celebrated Huygens, as recorded in his "Cosmotheoros," despairing of being able to find an annual parallax, resorted to the following method:—supposing that the star *Sirius*, one of the brightest fixed stars in the heavens, to be equal in luster and magnitude to the sun, he endeavored to diminish the apparent diameter of the sun to the eye, so that it should appear no larger or brighter than Sirius appears to a common observer. For this purpose he closed one end of a twelve feet tube with a very thin plate, in the middle of which he made so small a hole that a very minute glass globule being put into it, so very small did the sun appear to the eye placed at the other end of the tube, that the light transmitted to the eye seemed not more splendid than that which we behold transmitted from Sirius with the naked eye. Having calculated, on the principles of optics, the quantity of diminution of the sun's apparent diameter, he found it to be only the 1-27664th part; or, the light and diameter of the sun appeared 27,664 times smaller than what we daily see. Hence he concluded that were the sun at 27,664 times his present distance from us, he would appear as small as Sirius; and consequently, if Sirius be of the same magnitude as the sun, the distance of that star must be 27,664 times greater than the distance of the sun from the earth, or 2,628,080,000,000,—that is, two billions, six hundred and twenty eight thousand, and eighty millions of miles. This method of determining the distance of the stars depends upon two assumptions:—1st, that the sun and Sirius are equal in magnitude; and 2d, that the eye judged correctly of the equality of the small intercepted portion of the sun to Sirius; both of which must be considered as uncertain. But it corroborates the general position of the very great distance of the stars.

On a principle somewhat similar, but by experiments conducted with far greater accuracy, Dr Wollaston endeavored to determine the same problem in relation to the stars. "This gentleman," Sir J. Herschel remarks, "by direct photometrical experiment, open, as it would seem, to no objections, has ascertained the light of Sirius, as received by us, to be to that of the sun as 1 to 20,000,000,000. The sun, therefore, in order that it should appear to us no brighter than Sirius, would require to be removed 141,400 times its actual distance. We have seen, however, that the distance of Sirius cannot be so small as 200,000 times that of the sun. Hence it follows that, upon the lowest possible computation, the light really thrown out by Sirius cannot be so little as *double* that emitted by the sun; or that Sirius must, in point of intrinsic splendor, be equal to *two suns*, and is in all probability, vastly greater."

The late Sir William Herschel proposed another method of determining the annual parallax by means of *double stars*, which he supposed would be free from the errors of other methods, and of such a nature that the parallax, even if it should not exceed the tenth part of a second, may still become visible. The following figure and description will convey a general idea of this method:

Fig. 8.



Let *A* and *B* (fig. 8) represent the earth at two opposite points in its orbit, and *C* and *D* two stars of different magnitudes. Then, if when the earth is at *B*, the two stars appear to us near each other, as at *C* and *E*, it was thought that when the earth arrived at *A* the two stars might appear farther apart, as at *C* and *D;* in other words, that the angles at which they would appear to us in the two cases would be different, the angle *D A C* being larger than the angle *D B C* in which case the angle of parallax might be computed. But it does not appear that any difference in the angles referred to has yet been found, or that any definite conclusions respecting parallax have hitherto been deduced from this method, excepting the general position that the stars are at too great a distance to be subjected to our calculations, or that our angular instruments are still in too imperfect a state to detect so small an angle as that of the annual parallax.

While writing the above (December, 1838), I perceived an announcement in certain literary journals, that Professor Bessel, of Konigsberg, had addressed a letter to Sir John Herschel, which was immediately communicated to the Royal Astronomical Society, containing an account of the discovery of the annual parallax and the observations on which it was founded. In the introduction to this communication Professor Bessel says—"After so many unsuccessful attempts to determine the parallax of a fixed star, I thought it worth while to try what might be accomplished by means of the accuracy which my great Fraunhofer heliometer gives to the observations. I undertook to make this investigation upon the star 61 *Cygni*, which, by reason of its great proper motion, is perhaps the best of all, which affords the advantage of being a double star, and on that account may be observed with greater accuracy, and which is so near the pole that, with the exception of a small part of the year, it can always be observed at night at a sufficient distance from the horizon." The professor began his observations in September, 1834, but various circumstances prevented them from being regularly continued at that period. They were resumed in 1837 with certain hopes of success. He selected among the small stars which surrounded the double star 61 *Cygni* two stars between the ninth and tenth magnitudes, of which one (*a*) is nearly perpendicular to the line of direction of the double star, the other (*b*) nearly in this direction. He measured with the heliometer the distances of these stars from the point which bisects the distance between the two stars 61 Cygni, and generally repeated the observations sixteen times every night, and when the atmosphere was unusually steady he made more numerous repetitions. The places of both stars, referred to the middle point of the double star, he calculated, for the beginning of 1838, to be—

	Distance.	Angle of Position.
a	461″.617	201° 29′ 24″
b	706″.279	109° 22′ 10″

In these observations, he concentrated his attention as far as he could on the *distance* of the small stars from the double star, as being the most important point to be ascertained. His communication contains tables of all his measures of distance, freed from the effects of refraction and aberration, and reduced to the beginning of 1838.

It would be uninteresting to the general reader to enter into all the details of observations, corrections, and calculations which Professor Bessel's communication contains, as they can only be understood by practical astronomers. I shall therefore only state his general conclusion, which seems to be legitimately deduced from his observations and reasonings, and may be considered at least as a very near approximation to the point, if not perfectly correct. The result then is, that the annual parallax of the star 61 *Cygni* is 0″.3136; that is, somewhat less than *one-third of a second* It follows that the distance of this star from the sun is 657,700 times the mean distance of the earth from the sun; and as the distance of the sun from the earth is 95,000,000 of miles, this number multiplied by the former produces 62,481,500,000,000, or *sixty-two* BILLIONS, *four hundred and eighty-one thousand five hundred* MILLIONS of miles, which is the distance of the star 61 *Cygni* from the sun, and which of course is nearly about the same distance from the earth; the earth being in one part of its course ninety-five millions of miles nearer the star than this distance, and in the opposite part of it ninety-five millions of miles beyond it. This, I have no doubt, will be considered as one of the most interesting and splendid discoveries which have been made in astronomy for a century past. It lays a foundation for precise and definite conceptions of the distances of some of the starry orbs, of the amplitude of the celestial regions, and of the magnitude and grandeur of those countless orbs which diversify the spaces of immensity. It likewise proves to a demonstration the annual motion of the earth round the sun, and all the principles and phenomena with which it is connected, as well as corroborates the general views of former astronomers respecting the immense distance of the fixed stars.

Professor Bessel concludes his communication in these words:—"As the annual proper motion of *α Cygni* amounts to 5″.123 of a great circle, the *relative* motion of this star and the sun must be considerably more than sixteen semidiameters of the earth's orbit [that is, one thousand, five hundred and twenty millions of miles], and the star must have a constant aberration of more than 52″. When we shall have succeeded in determining the elements of the motion of both the stars forming the double star, round their common center of gravity, we shall be able to determine the sum of their masses. I have attentively considered the preceding observations of their relative positions, but I consider them as yet very inadequate to afford the elements of the orbit. I consider them as sufficient only to show that the annual angular motion is somewhere about two-thirds of a degree, and that the distance at the beginning of this century had a minimum of about 15″. We are enabled hence to conclude that the time of a revolution is more than 540 years, and that the semi-major axis of the orbit is seen under an angle of more than 15″. If, however, we proceed from these numbers, which are merely *limits*, we find the sum of the masses of both stars less than half the sun's mass. But this point, which is deserving of attention, cannot be established until the observations shall be sufficient to determine the elements accurately. When long-continued observation of the places which the double star occupies among the small stars which surround it shall have led to the knowledge of its center of gravity, we shall be enabled to determine the two masses separately; but we cannot anticipate the time of these further researches. I have here troubled you with many particulars; but I trust it is not necessary to offer any excuse for this, since a correct opinion as to whether the investigation of the parallax of 61 *Cygni* has already led to an approximate result, or must still be carried further before this can be affirmed of them, can only be formed from a knowledge of these particulars. Had I merely communicated to you the result, I could not have expected that you would attribute to it that *certainty* which, according to my own judgment, it possessed."

The distance inferred from the parallax ascertained by Bessel is more than three times greater than what was formerly considered the *least distance* of any of the fixed stars. In order to acquire some rude conceptions of this distance, it may not be inexpedient to illustrate it by the times which certain moving bodies would require to move along such a space. *Light* is the swiftest moving body with which we are acquainted; it flies from the sun to the earth, a distance of ninety-five millions of miles, in about eight minutes, or at the rate of 192,000 miles every moment of time; yet light, incomprehensively swift as its motion is, would require ten years and 114 days to fly across this mighty interval; so that if the star 61 *Cygni* were supposed to be only just now launched into existence, it would be more than ten years before its light could reach the distant globe on which we dwell, so as to appear like a small star twinkling in our sky. Suppose a cannon ball to move 500 miles every hour without intermission, it would require fourteen millions, two hundred and fifty-five thousand, four hundred and eighteen years before it could move across the same interval. But to come to motions with which we are more familiar: suppose a steam-carriage to set out from the earth with a velocity of twenty miles an hour, or 480 miles a day; at this rate of motion, continued without intermission, it would require 356,385,466, or three hundred and fifty-six millions, three hundred and eighty-five thousand, four hundred and sixty-six years before it could pass from our globe to the star alluded to above — a number of years sixty-one thousand times greater than the whole period which has elapsed since the Mosaic creation.

Such distances are amazing, and almost terrifying to the human imagination. The mind is bewildered, confounded, and almost overwhelmed, when attempting to form a conception of such portions of immensity, and feels its own littleness, the limited nature of its powers, and its utter incapacity for grasping the amplitudes of creation; but although it were possible for us to wing our flight to such a distant orb as that to which we have referred, we should still find ourselves standing only on the extreme verge of the starry firmament, where ten thousands of other orbs, a thousand times more distant, would meet our view. We have reason to believe that a space nearly equal to that which we are now considering intervenes between most of the stars which diversify our nocturnal sky. The stars appear of different magnitudes; but we have the strongest reason to conclude that in the majority of instances this is owing, not to the difference of their real magnitudes, but to the different distances at which they are placed from our globe. If, then, the distance of a star of the first or second magnitude, or those which are nearest us, be so immensely great, what must be the distance of stars of the sixteenth or twentieth magnitudes, which can be distinguished only by the most powerful telescopes? Some of these must be several thousands of times more distant than the star 61 Cygni, whose distance now appears to be determined. And what shall we think of the distance of those which lie beyond the reach of the most powerful telescopes that have yet been constructed, stretching beyond the utmost limits of mortal vision, within the unexplored regions of immensity? Here even the most vigorous imagination drops its wing, and feels itself utterly unable to penetrate this mysterious and boundless unknown.

The vastness of the spaces and greatness of the distances to which we have adverted ought not, however, to prevent any one from acquiescing in the statements we have now made; for space is boundless,—absolutely infinite. A seraph might wing its flight with the swiftness of light for millions of years through the regions of immensity, and never arrive at a boundary where it might be said, "Hitherto mayest thou approach, but no farther;" and we have reason to believe, from what we already know of the Creator and his works, that during the whole course of such an excursion, new objects and new scenes of glory and magnificence would be continually rising to his view. To suppose otherwise would be to set boundaries to space, and to prescribe limits to the infinite perfections of the Divinity. That incomprehensible Being who formed the universe fills immensity with his presence; his power and wisdom, and all his other perfections, are *infinite;* and therefore we should expect that the plans on which he has constructed the systems of the universe should be like himself, vast, boundless, and inconceivable by mortals. Were we to find the plans of the universe circumscribed like those which were represented by the ancient astronomers, — who imagined the firmament a solid sphere with a number of tapers whirled round the earth,—we should be apt to think that the Creator of the world was a limited being; but when we contemplate the vast amplitude of planetary systems, and the immense spaces by which they are separated from each other, we behold plans and operations which are in perfect unison with the immensity of his nature, with his boundless power, his uncontrollable agency, and his universal presence. Wherever we turn our eyes throughout the scene of nature, and fix our attention on its plans and movements, we uniformly find the Creator *acting like Himself;* and in no case is this more strikingly displayed than in the grandeur and magnificence of the orbs of heaven, and *the immense spaces with which they are surrounded*.

This is likewise the representation which the Scriptures give us of the immensity and incomprehensible nature of the Deity. "Great is Jehovah and of great power; his understanding is infinite; his greatness is unsearchable." He is not only "high above all nations," but "his glory is *above the heavens*." "He dwelleth on high, and humbleth himself to behold the things" not only that are "on the earth," but even "the things that are in the heavens." Vast as the celestial spaces are, "he meted out heaven with the span," and "stretched forth the heavens alone." "Among the gods there is none like unto thee, neither are there any works like unto thy works." "Canst thou by searching find out God? Canst thou find out the Almighty to perfection? Who can utter the mighty operations of Jehovah? Who can show forth all his praise? Lo, these are but parts of his ways, but the thunder of his power, or the full extent of his omnipotence, who can comprehend?" In relation to a Being who is thus described, we can expect nothing but what is wonderful and incomprehensible by finite minds. The declarations of inspired men bear testimony to the discoveries of astronomy as in perfect unison with the attributes of the Divinity, so that science and revelation completely harmonize in the views they unfold of the plans and arrangements of the Deity, and of the immense spaces which intervene among the systems of the universe.

Whether man will ever be permitted to traverse any of the vast spaces of the universe, to which we have now adverted, is a question which is at present beyond our province to resolve. In our present state of corporeal organization it is impossible to wing our flight even to the nearest celestial orb in that system of which we form a part, much less to the distant starry regions. How pure spirits, disconnected with material vehicles, may transport themselves from one region of creation to another, it is impossible for us, in the present state, to form a conception. But it is possible to conceive of a system of organization far more refined than the present, and susceptible of a power of motion far surpassing what we have an opportunity of witnessing in this terrestrial sphere—a locomotive power which might enable an intelligent agent to keep pace with the rapid motions of the celestial orbs. We have only to suppose organical vehicles constructed with matter far more subtile and refined than hydrogen gas, or the ethereal fluid, and approximating to the tenacity of light itself. As we find animalculæ many thousands of times less than the least visible point, their bodies must be constructed of materials extremely subtile and refined; and hence we may infer that the same Allwise Intelligence who formed such minute and refined structures, can with equal ease construct a material organization for the residence of a rational soul out of the finest materials which creation can supply, and endow it with a capacity of rapid motion superior to that of some of the celestial globes which roll around us. It is not improbable that angelic beings are connected with such a system of material organization, which enables them to move with rapidity from one part of creation to another; and it is possible that man, in a future world, may be invested with such vehicles and such powers of rapid motion. At the same time, even with such locomotive powers, only a small portion of the universe could be supposed to be visited or explored, even after a lapse of ages. It is highly probable that, at this moment, there is not a single subordinate intelligence, even of the highest order of created beings, who is acquainted with every region of universal nature and the objects it contains, and that the greater part of the vast universe, with its scenery, movements, and inhabitants, is known only by Him who formed it by his power and fills it with his presence.

CHAPTER V.

ON THE MAGNITUDE OF THE STARS.

In our attempts to ascertain the *magnitudes* of any of the heavenly bodies, we must first endeavor to determine the distances at which they are placed from our abode; and in the next place we must measure, as accurately as possible, the *apparent diameters* of the bodies whose magnitudes we wish to determine. The extreme difficulty of determining these two points, in certain instances, on account of the smallness of the angles which require to be measured, has hitherto prevented us from ascertaining with precision the real magnitudes of the bodies connected with the sidereal heavens. We formerly were led to conclude on good grounds, that their distances were almost immeasurably great, and consequently that, as they emit a certain degree of splendor to our eye, even from such remote distances, their *bulk* must be immensely great. But no precise conceptions could be formed as to this point so long as the annual parallax of some of the stars remained undetermined.

The annual parallax of the star 61 *Cygni* being now in all probability ascertained (as stated in the preceding chapter), we are in possession of certain *data* which may lead to the determination of the *real magnitude* of that body. But a difficulty still remains. The stars are found to have no sensible diameters. When viewed through telescopes of the greatest power, they present no visible discs, or well-defined surfaces to the eye, as the planets do, when viewed through such instruments, but appear only as so many shining and undefined points. When they are viewed through a telescope of moderate size, their diameter appears less than when examined by the naked eye, but considerably more brilliant. When we view them with a telescope of greater power, the apparent diameters will be somewhat increased, but not according to any regular proportion, as happens in the case of the planets; and even when seen with the same power, through different telescopes, their apparent magnitudes are not precisely the same. Sir William Herschel, who viewed these bodies under almost every aspect, uniformly found that their diameter was less in proportion as the higher powers were applied; and the smallest proportional diameter he ever obtained was when he employed the extraordinary power of 6450 times. From such observations it appears that the apparent diameters of the fixed stars do not arise from any sensible disc, but from other causes with which we are not acquainted. Dr. Halley remarks that "the diameters of Spica Virginis and Aldebaran (two stars of the first magnitude) are so small, that when they happen to immerge behind the dark edge the moon, they are so far from losing their light gradually, as they must do if they were of any sensible magnitude, that they vanish at once with all their luster, and emerge likewise in a moment, not small at first, but at once appear with their full light, even although the emersion happen when very near the cusp, where, if they were four seconds in diameter, they would be many seconds of time in getting entirely separated from the limb. But the contrary appears to all those who have observed the occultations of those bright stars." Every one who has been in the habit of viewing the starry firmament with good telescopes will at once admit that, although that instrument brings to view numerous stars which the unassisted sight cannot perceive, yet they appear only as luminous points with no well-defined sensible diameters, although their light is much more brilliant than to the naked eye.

Hence the difficulty of determining, with precision, the real magnitudes of any of the fixed stars. From their immense distance we are perfectly certain that they are bodies of immense size, otherwise they would be altogether invisible from our terrestrial sphere, or from any part of the solar system. But we have hitherto obtained no sufficient data for estimating their exact size, as we have done in relation to the globes which compose the planetary system. Since, then, the apparent diameters of the stars, even those of the *first* magnitude, are so small as not to amount to a single second, we cannot hope, in the meantime, to determine their measure with any degree of certainty. We may assign them a measure which we certainly know they do not exceed, but we cannot be sure that that measure is not too great. All luminous objects appear larger than those of the same dimensions which are opaque. The planet Mercury, when in its greatest brightness, appears larger than when it is seen to pass, like a dark spot, across the disc of the sun, although it is nearest the earth in this last position. The apparent diameters of the fixed stars are much smaller than they have generally been supposed by those who have attempted to measure them. Yet small as they are, their real magnitude must be *very great*, since they are visible to our sight at the immense distance at which they are placed. In proportion to the greatness of their distance, and the smallness of their apparent diameters, will be their real magnitudes. If we suppose the apparent diameters of any of the stars observed by Dr. Bradley to be equal to the 400,000th part of the sun's apparent diameter or $\frac{1}{200}$th of a second—which is a probable supposition for a star of the second magnitude,—it will follow that such a star is equal to the sun in magnitude. For, if the sun were removed to the distance at which such a star is situated, he would appear no larger than those twinkling points, nay, would perhaps disappear altogether from our view. From all the observations and reasonings that have been entered into on this subject, we have no proofs that any of the stars are less than the sun, but it is more probable that many of them equal and even far surpass that luminary in their real dimensions and splendor. Having obtained the parallax of 61 *Cygni*,* if we could find the exact apparent diameter of that star, its real bulk could be calculated with as much ease and certainty as the bulk of the sun, or moon, or any of the planets. But as this important element in the calculation is still a *desideratum*, we must resort to other methods by which we may arrive at the nearest approximation to the truth.

I have already alluded to the photometrical experiments of Dr. Wollaston, in relation to the comparative quantity of light emitted to our eye from the star Sirius and from the sun. In reference to these experiments, Sir John Herschel, in a marginal note, remarks:—"Dr. Wollaston assuming, as we think he is perfectly justified in doing, a much lower limit of *possible* parallax in Sirius than we have adopted in the text, has concluded *the intrinsic light of Sirius to be nearly that of* FOURTEEN SUNS." Sir William Herschel informs us that, with a magnifying power of 6450, and by means of his new micrometer, he found the apparent diameter of *Vega* or *α* Lyræ to be 0″. 355: this will give the real diameter of the star about *thirty-eight* times that of the sun, or 33,440,000 miles, supposing its parallax to be one second. Were this its true estimate its solid contents would be 19,579,357,857,382,400,000,000,* or, above nineteen thousand five hundred and seventy-nine *trillions* of miles; which is, *fifty-four thousand eight hundred and seventy-two times* larger than the solid contents of the sun. The magnitude of such a globe is altogether overpowering to the human imagination, and completely baffles every effort to approximate to a distinct conception of an object of such amazing amplitude and splendor. We have formerly shown† that the *sun* is a body of so vast dimensions that the human mind, in its present state, can form no adequate conceptions of it; that it is more than 500 times greater than all the planets, satellites, and comets of our system; that it is equal to thirteen hundred thousand globes as large as the earth; that its surface contains an amplitude fifty-three millions seven hundred and seventy-thousand times larger than the view from Mount Etna, which comprises an extent of 45,000 miles; and that, were a landscape on the sun of this extent to be contemplated every two hours, it would require twenty-four thousand five hundred years before the whole surface of this luminary could be in this manner surveyed. What, then, shall we think of the probable existence of a luminous globe fifty-four thousand times greater than the expansive globe of the sun!

However amazing the magnitude of such a body may appear, we ought not on this account to consider the existence of such an orb as either improbable or incredible. Prior to the first discoveries of modern astronomy two or three centuries ago, no one could have believed that the sun is a body of such an immense size as he is now found to be, or that the planetary system occupies so extensive a range as astronomers have now determined it. And we are not to conceive that even the immense amplitude of the sun is the highest scale of magnitude which the Creator has prescribed to himself in his arrangements of the universe. From the knowledge we have already acquired of the vastness of the scale on which creation is constructed, we have reason to believe that bodies exist in it far surpassing, in magnitude and grandeur, any of the globes to which we have alluded. There are certain lucid specks in the heavens which can only be perceived by the most powerful telescopes, which we are quite certain, from their immense distance, must comprise a mass of matter thousands of times larger than our sun,—either a distinct mass of materials or a congeries of shining globes so near each other that the separate bodies cannot be distinguished. As the distance between the great globes of the universe is incomprehensible by limited intellects, so the *magnitude* of some of these bodies may be so great as to surpass every estimate and every conception we may have hitherto formed on this subject. Such views of the magnitudes of creation are quite in accordance with the ideas we ought to entertain of a Being who is eternal, omnipresent, omnipotent, and incomprehensible.

---

* This star belongs to the constellation *Cygnus*, or the Swan. Its right ascension for January 1, 1839, was 20h. 59′ 41″, and its declination 37° 57′ 42″ north. In places of 52° of N. latitude, this star passes the meridian within two or three minutes of the zenith. It is a star of about the fifth magnitude. It is 28 degrees nearly due east from the bright star *Vega* or *a* Lyræ, in the constellation of the Harp, and nearly nine degrees south by east of *Deneb*, or *a Cygni*, the principal star in the Swan.

* In some editions of the "Improvements of Society," this number is inaccurately stated, the cube of the diameter having been by mistake substituted for the solid contents of the body, but the general result of the comparative magnitudes of the two bodies is the same.

† "Celestial Scenery," chap. iii, sect. 10

But, without going beyond the strict deductions of science, we may fairly conclude that there are few stars in the concave of our sky that do not equal, and even surpass, our sun in size and in splendor; and if so, what a glorious and overwhelming scene does creation present to an intelligent and contemplative mind! Here we are presented with a scene on which the highest order of created beings may expatiate for myriads of ages, and objects, ever wonderful and ever new, may still present themselves to the astonished mind throughout the whole length of its immortality; so that the most expansive intellects shall never want subjects of sublime investigation during all the revolutions of an interminable existence.

We are not to imagine that all the stars, even those which appear with the same brilliancy, are of the same size. We have reason to believe that a *variety*, in this respect, exists among those distant orbs, as well as among the bodies which compose the planetary system, and in other departments of nature. Various considerations tend to show that "one star differeth from another star in glory," not only as they appear to the naked eye, but in *reality*, as to their intrinsic magnitude and splendor. Some of the telescopic stars appear of very different colors, one exhibiting rays of an orange or ruddy hue, another blue, another yellow, and another green, indicating a difference in their constitution and in the nature of the light they emit. Among the double stars, the one which is found revolving round the other is evidently the smaller body, as its light is not distinguishable without a high magnifying power, and yet its distance from the earth must be nearly the same as that of the larger star around which it revolves. Recent observations tend to prove that some of the smaller stars have not only a greater annual parallax than those which are most brilliant, but an absolute motion in space much greater than those of the brightest class, which indicates that there is a difference in the real size of those bodies, and that some of the stars which appear smallest to our eye may be the largest in real dimensions; but the smallest of them are, undoubtedly, bodies of such magnitudes as surpass our distinct comprehension.

Some readers, from their ignorance of the mathematical principles of astronomy, and from being incapable of appreciating the observations to which we have referred, are apt to view with a certain degree of skepticism the conclusions which astronomers have deduced respecting the distances and magnitudes of the stars. Perhaps the following consideration, level to the capacity of every man of common sense, may have a tendency to convince even the most skeptical that the stars are situated at an almost incalcuable distance from the earth.

Suppose a telescope to magnify 400 times, that is, makes a distinct object appear four hundred times nearer, and four hundred times larger in diameter, than to the naked eye With an instrument of this description I have been enabled to read a person's name, the letters of which were not above half an inch in length or breadth, at the distance of more than two miles. When this telescope is directed to the moon, it enables us to perceive the shadows of its mountains, and other minute portions of its scenery, and even to distinguish rocks and cavities less than a mile in diameter. When directed to the planet Venus, it exhibits it as a large splendid body, with either a gibbous, a half moon, or a crescent phase. When directed to Jupiter and Saturn, it makes these orbs appear several times larger than the moon does to the naked eye, and enables us to perceive the dark belts which run across the one, and the rings which surround the other. Now, if this same instrument be directed to the fixed stars, it shows them only as so may luminous *points*, without any well-defined diameters. It brings to view hundreds and thousands of stars which the naked eye cannot discern; but although they appear somewhat more brilliant, they appear, on the whole, no larger in diameter than the stars in general do to the unassisted sight. This circumstance I consider as a palpable and *sensible* evidence of the immense distance of the fixed stars; for bodies at the distance of nine hundred, and even of eighteen hundred millions of miles, appear magnified in proportion to the power of the instrument; and why should not the fixed stars appear magnified in the same proportion, and present to the eye large discs like the planets, were it not on account of their incalculable distance? Were they only at a moderate distance from the planetary system—suppose ten times the distance of Saturn, or nine thousand millions of miles,—this would undoubtedly be the case; but observation proves the contrary. When we view a planet —for example *Saturn*, which is distant nine hundred millions of miles—through a telescope magnifying 400 times, we contemplate it as if we had been carried to a point only the four-hundreth part of its distance; that is, we view it as if we were brought within little more than *two millions* of miles of its surface. In other words, we see it of the same magnitude, and nearly with the same distinctness, as if he had surmounted the law of gravitation, and been transported more than 897 millions of miles from our present abode in the direction of that orb.

When such an instrument is directed to the fixed stars, it does not lose its power as a telescope; this is proved by its presenting the *nebulæ*, which are invisible to the naked eye, as large, well-defined spaces in the firmament. It carries us within the four-hundreth part of their actual distance, and enables us to contemplate them just as we would do if we were 400 times nearer them than we are. Let us suppose, as formerly, the distance of the nearest stars to be 20,000,000,000,000, or twenty billions of miles, we contemplate such stars by this instrument, as if we were carried to a station nineteen billions nine hundred and fifty millions[*] of miles from the place we now occupy, where we should still be fifty thousand millions of miles.

---

[*] The following is the calculation expressed in figures:
400) 20,000,000,000.000, dist. of the star.
50,000,000,000, dist. as viewed by the telescope.
19,950,000,000,000, dist. from the earth at which we view it

distant from these bodies. Supposing the sun were removed to a point fifty thousand millions of miles from the point he now occupies—which is 526 times his present distance,—he would appear 526 times less in diameter than at present, or under an angle of little more than 3½ seconds, which is less than the apparent diameter of Uranus, a body which is generally invisible to the naked eye; so that if a star be distant twenty billions of miles, and equal to the sun in magnitude, it should appear no more than a point when viewed with a telescope magnifying 400 times. Supposing, then, that we were transported through the immense space of 19,950,000,000,000 miles, we behooved to be carried forward several thousand millions of miles farthe before those distant orbs would appear to expand into large discs like the moon, or like Jupiter and Saturn, when viewed through telescopes.

The above considerations prove to a demonstration that the nearest stars are removed from us at immense and inconceivable distances; and if their distance be so great, their *magnitudes* must likewise be astonishing, otherwise they would be altogether invisible either to the naked eye or by the telescope; for a distant visible object must always be considered as having a magnitude proportional to its distance and its *apparent* diameter

CHAPTER VI.

ON NEW STARS.

To almost every eye but that of the astronomer, the starry firmament presents the same general aspect. To a common observer, the nocturnal heavens exhibit the appearance of a vast concave bespangled with countless numbers of shining points, of various degrees of brilliancy, and distributed over the sky apparently without any order or arrangement.—Whether the clusters of stars which are seen in summer and in winter are the same,—whether the stars which are seen in one region of the heavens at six o'clock in the evening are identically the same which are seen in the same quarter at midnight, or at three in the morning,—whether there be any stars which were seen by our forefathers which are no longer visible,—whether any stars unknown to former generations can now be traced in the firmament,—or whether any of those orbs which are visible at one time are invisible at another,—to such inquiries there is not one out of a thousand of those who have occasionally gazed at the starry heavens that could give a satisfactory reply. It is the industrious astronomer alone, who, with unwearied observations spends sleepless nights in surveying the various regions of the celestial vault, that can tell with certainty whether or not any changes occasionally take place in reference to any of the starry orbs.

The first account we have of any changes having been perceived among the stars is that recorded by Hipparchus, of Rhodes, a celebrated astronomer who flourished about 120 years before the Christian era. About this period, this accurate observer of the heavens perceived, in a certain part of the firmament, a star which he had never observed before, and of which he could find no record in the observations of his predecessors. Struck with this new and unexpected phenomenon, he began to doubt whether changes might not happen among the celestial orbs, as well as in the scene of nature here below. In order that such changes when they happen might be known to future generations, he began to form a catalogue of all the stars visible in that part of the world where he resided, noting down the place and apparent magnitude of each star, until he at length completed a list of all the visible stars in the heavens; which was the first catalogue of those luminaries of which we have any account in history. It is much to be regretted that we have no specific account of the particular part of the heavens where this new star appeared, as it might have led us to determine whether it be still visible, or whether it be subject to periodical changes, or have altogether disappeared.

In the year 130 after the Christian era, another new star is said to have made its appearance. In the year 389, a new star appeared near α Aquilæ, or Altair, in the constellation of the Eagle. Its appearance was sudden; it continued three weeks, emitting a splendor equal to that of Venus, and afterward entirely disappeared. In the ninth century, a new star appeared in the fifteenth degree of Scorpio, which is said to have emitted as much light as is reflected from one quarter of the moon. In 945, a new star appeared between the constellations of Cepheus and Cassiopeia; and another, in 1264, near the constellation Cassiopeia; but of these stars the accounts are so vague and imperfect that we can form no distinct conceptions of the phenomena they exhibited.

The most striking and wonderful phenomenon of this kind of which we have an authentic and distinct description occurred in the beginning of November, 1572, when a new star appeared in Cassiopeia, forming nearly a rhombus with the three largest stars, α, β, γ, of that constellation. Its appearance was sudden and brilliant. Its phenomena were so striking that the sight of it determined the celebrated Tycho Brahe to become an astronomer. He did not see it at half an hour past five, when he was returning from his house to his laboratory; but returning about ten, he came to a crowd of country people who were staring at something behind him. Looking round, he saw this wonderful object. It was so bright that his staff had a shadow; it was of a dazzling white, with a little of a bluish tinge. It had no tail or hair around it similar to comets, but shone with the same kind of luster as the other fixed stars. Its brilliancy was so great as to surpass that of *Lyra* and *Sirius*. It appeared even larger than Jupiter, which was then at its nearest approach to the earth, and by some was estimated to be superior to the planet Venus in its greatest luster. It was even seen by those who had good eyes at noonday; a circumstance which never happens in the case of any of the other stars, or even of the planets, except Venus, which has sometimes been seen in daylight in certain peculiar positions. During night, it was frequently seen through thin clouds which entirely intercepted the light of the other stars. In this state it continued to shine with undiminished brilliancy during the remaining part of November, or more than three weeks. It did not, however, continue much longer with this degree of brightness, but gradually diminished in its luster. In the month of December, it appeared to be only equal to Jupiter; in January, 1573, it appeared a little less than that planet, but still somewhat larger than stars of the first magnitude, to which it appeared about equal during the months of February and March; thus gradually diminishing in brightness, in April and May, it was like a star of the second magnitude; in the months of June, July, and August, it was equal only to the largest stars in Cassiopeia, which are mostly of the third magnitude; in September, October, and November, it was no larger than a star of the fourth magnitude; in December, it was about equal to the star called *Gamma*, which was nearest to it; toward the end of 1573, and during the month of January, 1574, it was but little superior to stars of the fifth magnitude; in February, it was no larger than a star of the sixth magnitude; and in the month of March it entirely disappeared, having continued visible from the beginning of November, 1572, to March, 1574, a period of about sixteen months. It was remarked that as it diminished in size it was likewise subject to certain changes in color and brightness. When it appeared largest, its light was *white* and brilliant; after which it appeared a little *yellowish;* and in the beginning of spring, 1573, it approached something to the color of Mars, being reddish like the star *Aldebaran*, or the Bull's Eye, and a little less bright than the star in the right shoulder of *Orion*. In the month of May that year, it was of a pale livid white, like Saturn; which color, as likewise its sparkling appearance, continued to the last, only growing more dim and faint as it approached the period of its disappearance.

Such were the appearances and changes of this wonderful star. These phenomena were particularly observed by several astronomers of that period, especially by Tycho Brahe, who wrote a treatise on the subject, in which he determined its longitude and latitude, and demonstrated that it was situated in the region of the fixed stars, at a much greater distance from the earth than the sun, moon, or any of the planets, as it had no sensible parallax, and remained in the same point of the heavens during the whole period of its appearance. This star was likewise diligently observed by Cornelius Gamma, who says that on the night of the 8th November, 1572, he viewed with some attention that part of the heavens, in a very serene sky, but saw nothing uncommon; but that the next night, November 9th, it appeared with a splendor surpassing all the fixed stars, and scarcely less bright than Venus. The longitude of this star, as determined by Tycho, was 9° 17′, and 53° 45′ of north latitude.

The point in the heavens where this star appeared may be ascertained from the following figure, which exhibits a representation of the principal stars in Cassiopeia. The general position of this constellation may be found from the map of the circumpolar stars, Plate III. It is almost directly opposite *Ursa Major*, or the Great Bear. A line drawn from the Bear through the pole-star meets Cassiopeia at nearly an equal distance on the other side of that star. When the Bear is at its lowest position below the pole, Cassiopeia is near the zenith, and *vice versa*. In the annexed representation (fig. 9) the large star toward the left points out the place which was occupied by the new star, which, with the three stars, α, β, γ, forms a kind of rhombus, or irregular square. The one on the left above the new star is β, and is also known by the name of *Caph.* The one to the right of Caph and a little higher is α, distinguished likewise by the name *Schedir.* Below Schedir, and a little to the right, is the star γ, or *Gamma*. About six degrees north-west of Caph, the telescope reveals to us a pretty large nebula of small stars, apparently compressed into one mass, with a number of loose stars surrounding it.

Fig. 9.

In the year 1604, about the end of September, another new star appeared near the heel of the right foot of *Serpentarius*. At that time, near the same part of the heavens, the planets Mars, Jupiter, and Saturn, were very near to each other, a phenomenon which so engaged the attention of astronomers that no uncommon appearance in that quarter of the heavens could long have escaped detection. On the 17th of September, Kepler, who wrote a treatise on this star, carefully observed the three planets; on the 23d, he again viewed Mars and Jupiter, then approaching to their conjunction; and one of his scholars made the same observation on the 27th. On the 28th, and on the 29th, which was the day when Mars and Jupiter were in conjunction, they were observed by *Mæstlinus* and others; but none of them as yet saw anything of the new star. On the 30th, the sudden breaking of the clouds afforded one of Kepler's friends an opportunity of having a very short view of it; for in looking for Mars and Jupiter, he saw a bright star near them, which he had not seen before, but it was soon obscured by clouds. On the 2d, 3d, 4th, and 6th of October, it was seen by several persons in different places. On account of cloudy weather at Prague, where Kepler resided, he did not see it until the 8th of that month. All the observers agreed in this,—that it was exactly round, without any beard or tail; that it was exactly like one of the fixed stars; and that in the vividness of its luster, and the quickness of its sparkling, it exceeded anything they had ever seen before. As to its *color*, it was remarked that it was every moment changing into the colors of the rainbow, as yellow, orange, purple, and red; but was generally white when at a little hight above the vapors near the horizon. At its first appearance, it seemed larger than any of the fixed stars, and even surpassed Jupiter, which planet was near it during the whole of October, and by its steady light was easily distinguishable from this vehemently sparkling star. It continued of the same size and brilliancy during the whole of October. About the end of this month the sun was approaching that part of the heavens in which the star appeared, yet on the 30th it was so much brighter than Jupiter that Kepler could see it distinctly when Jupiter was imperceptible, on account of the light of the sun, though he was farther from the sun's beams than the star. On the 6th and 8th of November it was seen by Kepler and others; and at Turin, on the 13th, which appears to have been the last time it was perceived before being overpowered by the solar rays. After emerging from the sun's rays, on the west, it was seen in the morning on the 24th December, and though it sparkled exceedingly, yet it was considerably diminished in magnitude, appearing however, larger than the bright star *Antares.* From the middle of January 1605, until the middle of March, it gradually diminished in brightness. In the beginning of April, it appeared like a star of the third magnitude, and continued nearly of the same size during the months of May, June, and July, and continued to sparkle more strongly than any other fixed star. On September 28th, a year after its first appearance, it was more brilliant than the star in the leg of Serpentarius, which is reckoned of the third magnitude. As it was at this time again approaching to the vicinity of the sun, it does not appear to have been seen after this period. In December, 1605, and January, 1606, cloudy weather prevented observations after it had emerged from the solar rays. Kepler concludes that it must have disappeared some time between October, 1605, and the following February, but on what day is uncertain. Like the former star which appeared in Cassiopeia, it had no parallax, and remained in the same point of the heavens.

None of the new stars whose phenomena we have described above have ever reappeared, the places which they occupied still remaining a blank. It is much to be regretted that the telescope was not invented at the periods when these stars appeared, as it might have been ascertained by their instrument whether they had any sensible diameters. At any rate, their gradual decrease of magnitude and luster might have been traced by a good telescope for a long period, perhaps for years, after they disappeared to the naked eye, which must have led us to draw some conclusions respecting the cause which produced so extraordinary phenomena. Were such a remarkable phenomenon to happen in our times, when telescopes, micrometers, and other astronomical instruments have received so many exquisite improvements, so as to enable us to penetrate deep into the profundity of space, and to measure the smallest angles, a variety of additional facts and circumstances would doubtless be discovered in relation to phenomena and events so striking and sublime.*

The subject of new stars, such as those now described, which blazed forth with so extraordinary a brilliancy and so soon disappeared, naturally gives rise to solemn and interesting reflections. There is a mystery that hangs over such sublime phenomena which produces in the mind an anxious desire to behold the vail removed, and to investigate the reasons and causes of such stupendous events. "It is impossible," says Mrs. Sommerville, when alluding to the star of 1572, "to imagine anything more tremendous than a conflagration that would be visible at such a distance." Whether there was anything in the existing state of the body alluded to similar to what we call a *conflagration* may be justly doubted, but there was a splendor and luminosity concentrated in that point of the heavens where the star appeared which would more than equal the blaze of *twelve hundred thousand worlds* such as ours, were they all collected into one mass, and all at once wrapt in flames. Nay, it is not improbable that were a globe as large as would fill the whole circumference of the earth's annual orbit to be lighted up with a splendor similar to that of the sun, it would scarcely surpass in brilliancy and splendor the star to which we refer; for during the whole period of its continuing visible, it never appeared in the least to shift its position, though it was carefully watched by the astronomers of that age; and, consequently, the whole diameter of the earth's orbit, while the earth passed from one extremity of it to another, appeared only as a point at the vast distance at which the star was situated. These may appear bold positions, but they are in some measure warranted by the facts of the case, and they are perfectly consistent with what we know of many of the other astonishing operations of that Almighty Being who is "wonderful in counsel and excellent in working," and "whose ways," in providence and creation "are past finding out."

It is natural to inquire what may have been the cause of phenomena so extraordinary and sublime; but our limited views of creation and of the plans and purposes of its Omnipotent Contriver and Governor prevent us from arriving at any satisfactory conclusions. La Place says, in reference to this subject—"As to those stars which suddenly shine forth with a very vivid light, and then vanish, it may be supposed, with probability, that great conflagrations, occasioned by extraordinary causes, take place on their surfaces; and this supposition is confirmed by their change of color, analogous to that which is presented to us on the earth by bodies which are consumed by fire."* But such an opinion, however great the astronomer who proposed it, appears quite unsatisfactory. We err egregiously when we attempt to compare the puny operations and conflagrations which happen on our globe with a scene so far transcending everything we behold in this terrestrial sphere. The greatest conflagration that was ever witnessed on earth cannot bear the smallest proportion or similitude to an object which must have occupied a space more than ten hundred thousand times the solid contents of our globe; nor is it likely that the agents or elementary principles which produced the respective phenomena were at all similar.

The late Professor Vince, one of the most learned astronomers of his age, has the following remark:—"The disappearance of some stars may be the destruction of that system at the time appointed by the Deity for the probation of its inhabitants, and the appearance of new stars may be the formation of new systems for new races of beings then called into existence to adore the works of their Creator."† The late Dr. Mason Good seemed to indulge in a similar opinion "Worlds, and systems of worlds," says, he, "are not only perpetually creating, but also perpetually disappearing. It is an extraordinary fact that, within the period of the last century, not less than thirteen stars, in different constellations, seem to have totally perished, and ten new ones to have been created. In many instances it is unquestionable that the stars themselves, the supposed habitation of other kinds or orders of intelligent beings, together with the different planets by which it is probable they were surrounded, have utterly vanished, and the spots which they occupied in the heavens have become blanks. What has befallen other systems will assuredly befall our own. Of the time and the manner we know nothing; but the fact is incontrovertible—it is foretold by revelation—it is inscribed in the heavens—it is felt through the earth. Such is the awful and daily text; what, then, ought to be the comment?" Similar to these were the sentiments of the late Professor Robinson, of Edinburgh:—"What has become of that dazzling star, surpassing Venus in brightness, which shone out all at once in November, 1572?"—"Such appearances in the heavens make it evident that, notwithstanding the wise provision made for maintaining that order and utility which we behold in our system, the day may come 'when the heavens shall pass away like a scroll that is folded up, when the stars in heaven shall fall, and the sun shall cease to give his light.' The sustaining hand of God is still necessary, and the present order and harmony which he has enabled us to understand and admire is wholly dependent on his will, and its duration is one of the unsearchable measures of his providence."

---

* Beside the above, the following instances of new stars may be noted:—In the year 1670, a new star was discovered by Hevelius and Anthelm, near the head of the Swan, which, after becoming invisible, reappeared, and after undergoing several singular fluctuations of light during two years, gradually vanished from the sight, and has never since been seen. Another new star is said to have been seen the same year at Paris, about the back of the Swan, which, after the space of fourteen days, vanished away.—Whiston's *Astronomical Lectures*, p. 45.

* *System of the World*, vol. 1, p. 101.

† Vince's "Complete System of Astronomy"

Such are the pious sentiments of the above-named respectable philosophers in reference to the subject under consideration; but it may be questioned whether they are altogether judicious, or correspondent to the perfections of the Creator and the arrangements he has made in the universe. They seem to take for granted that those stars which have blazed for awhile, and then disappeared, have been destroyed or annihilated. We are indeed informed that, in regard to our globe, a period is approaching when "the elements shall melt with fervent heat, and the earth and the works that are therein shall be burnt up." But such a conflagration cannot be justly compared to the splendor of those wonderful stars described above. At whatever period in the lapse of duration such an event may take place, it will be so far from being visible at the nearest star, that it would not be seen by such eyes as ours at the boundaries of our system. Beside, we are assured, in that revelation which announces it, that that awful event shall take place as one of the consequences of the sin and depravity of man; and therefore we have no reason to believe that it will extend to the sun or any of the surrounding planets of our system; nor have we any reason to conclude that the conflagration of our globe will issue in its entire destruction, or that the elementary principles of which it is composed will be annihilated. It is more probable, nay, almost certain, that this tremendous event will only tend to purify our globe from the physical evils which now exist, and to transform it into a new and happier world for the residence of renovated and pure intelligences. In regard to *annihilation*, we have no proof that any particle of matter which was ever created has yet been annihilated.* Incessant changes and transformations are going forward both in the scene of sublunary nature and throughout the celestial regions; but changes in material objects do not necessarily imply the *destruction* of the matter of which they are composed, but simply a new arrangement or mode of operation. We have no reason to believe that any portions of matter which now exist throughout the universe will ever be reduced to annihilation. On the other hand, we have palpable evidence, from several phenomena in the heavens, that the work of creation is still going forward, and that the Creator is gradually ushering into existence new suns, and systems, and worlds; and in all probability his creating energy will be continually exerting itself throughout all the succeeding ages of eternity.

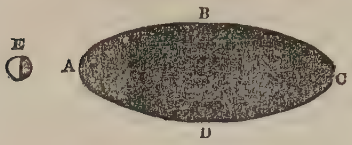
Again, if that grand and terrific event which is to put a final period to the present terrestrial system is to be viewed as a consequence of the introduction of moral evil and the depravity of man, then we are led to conclude that those intelligences which were connected with the systems which are supposed to have been destroyed must have been involved in the guilt of moral degeneracy, or, in other words, in rebellion against their Creator; otherwise, why were they subjected to such an awful catastrophe, and doomed to be blotted out of existence? We have no ground for entertaining any such supposition. Reasoning from the *benevolence* of the Deity, it is more probable to conclude that the inhabitants of our world are almost the only intelligences throughout the universe who have swerved from the path of original rectitude, and violated the moral laws of their Maker. Nor is it likely that the *whole inhabitants* of any system, consisting, perhaps, of thirty or even of a hundred worlds—would be found uniting in rebellion against the moral government of their Benefactor, so as to warrant the *entire* destruction of the system with which they were connected. Beside, were the views of the philosophers to which I allude to be adopted, then we must admit that the systems which in their opinion were destroyed or annihilated must have been continued in existence only for a year or two; for no luminous bodies occupied the places of the new stars before they burst on a sudden to the view, and no twinkling orbs have been seen in these points of the heavens since they disappeared; but it is surely not at all probable that the Almighty would launch into existence systems of such amazing magnitude and splendor, and suffer them to rush into destruction within a period of so very limited duration.

For the reasons now stated, and others which might have been brought forward, I cannot acquiesce in the views of the respectable philosophers to which I have adverted; but it is easier to set aside an untenable hypothesis than to attempt an explanation of the real causes of so sublime and wonderful phenomena. In investigating the distant wonders of the universe and the arrangements of the Divine government, it becomes us to express our sentiments with modesty and caution. Whatever may have been the causes which produced the sudden splendor and the rapid disappearance of the new stars, I entertain not the least doubt that those bodies are still in existence, and subserving important purposes in the economy of God's universal government. Almost any hypothesis is to be preferred to that which supposes their destruction or annihilation. What should hinder us from concluding that the extraordinary phenomena of the star of 1572 was owing to a luminous orb of immense magnitude, accompanied with a retinue of worlds, *moving with inconceivable velocity in an immense elliptical orbit, the longer side of which was nearly in a direction to our eye;* that its most brilliant appearance was when it was nearest our system, as at *A*, (fig. 10), supposing *E* the relative position of the earth, or of our system; and that, as it gradually declined in its brightness, it was passing along the curve from *A* toward *B* and *C*, until its rapid flight at length carried it beyond the limits of human vision? Had telescopes been in use at that period, there is little doubt it would have been seen, though still diminishing, for a much longer period than that in which it was visible to the unassisted eye; in which case it would have fully corroborated the opinion now stated. In confirmation of this explanation of the phenomena it has been supposed, with a high degree of probability, that it is the same star which appeared in the year 945 and in 1264, which, of course, would have a period of revolution of about 319 years, which period might vary two or three years in the course of its revolutions, from causes with which we are unacquainted, as we find sometimes happens in the case of comets. This opinion is rendered the more probable from the consideration that the stars of 945 and 1264 appeared in the constellation of *Cassiopeia*, where likewise the star of 1572 was observed; and if these be identical, then it is probable that it will again make its appearance about the year 1891 or 1892; and if so, astronomers will then have a better opportunity of marking its aspects and motions, and determining its size and its period of revolution.

---

* See "Philosophy of a Future State," chap. i, sect. 10; and "Christian Philosopher."

Fig. 10.



If this explanation appear the most probable, it presents to the mind a most magnificent and overwhelming idea, without supposing anything so tremendous and terrific as a sudden conflagration. It presents before us a luminous globe of astonishing magnitude—perhaps not less than a hundred times the size of our sun—winging its course over a circuit perhaps a thousand times more expansive than the orbit of Uranus, and carrying along with it a hundred worlds in its swift career. The motion of such a body must have been rapid in the extreme, when we consider the rapid diminution of its apparent magnitude. In the month of November it first appeared; in December its brightness was sensibly diminished; in the month of April following it had diminished to the size of a star of the second magnitude; in July, to one of the third magnitude; in October, to one of the fourth; in the following January, to one of the fifth; in February, to one of the sixth magnitude; and in March it disappeared.

Now, according to Sir W. Herschel's experiments, the light of a star of the *first* magnitude being supposed 100, the light of one of the second magnitude is 25, one of the *third* magnitude, 12, &c. (see p. 22). If, then, we suppose these classes of stars to be nearly of equal magnitudes, and that their distance is in an inverse proportion to the diminution of their light, it will follow that a star of the second magnitude is four times the distance of a star of the first; a star of the third magnitude, four times the distance of the second, or eight times the distance of the first magnitude, &c. Supposing, then, the star of 1572 to have been twenty billions of miles from the earth at its nearest approach to our system; from December, 1572, to April, 1573, when it was diminished to the apparent size of a star of the second magnitude, it must have moved four times that distance, or eighty billions of miles during these four months, which is at the rate of six hundred thousand millions of miles a day, and four hundred and sixty-two millions a minute, a velocity of which we can have no adequate conception.

If the above explanation be unsatisfactory, I know not to what hypothesis to resort for a solution of this mysterious and wonderful phenomenon. Whatever view we may be disposed to take of such striking events, we are lost in admiration and wonder. We behold a display of magnitude, of motion, and of magnificence, which overpowers the human faculties, which shows us the littleness of man and the limited nature of his powers, and which ought to inspire us with reverence of that Almighty Being who sits on the throne of the universe, directing all its movements for the accomplishment of his wise and righteous designs, and for the diffusion of universal happiness throughout all the ranks of intelligent existence. However astonishing the conclusions we are led to deduce from the phenomena under consideration, the facts to which we have adverted are not beyond the energies of Him whose perfections are strictly *infinite*. Nay, from such a Being, who is self-existent and omniscient, who fills the immensity of space with his presence, and whose power is boundless in its operation, we should naturally expect that displays of creating and sustaining energy would be exhibited, altogether overwhelming and incomprehensible by mortals. "Canst thou by searching find out God? Canst thou find out the almighty to perfection? In the hights of heaven he doth great things past finding out, yea, and wonders without number. By his spirit he hath garnished the heavens. The pillars of heaven tremble and are astonished at his reproof. Lo, these are but parts of his ways; but the thunder of his power who can understand?"

CHAPTER VII.

ON VARIABLE SIGNS.

WHEN the starry firmament is attentively surveyed, and the aspects of the numerous orbs it contains particularly marked, it is found that several of these bodies are subject to periodical changes in the brilliancy of their light and their apparent diameters, indicating in some instances motions and revolutions of considerable extent. The following sketches contain descriptions of the more remarkable phenomena connected with this class of the heavenly bodies, generally known by the name of *variable*, or *periodical* stars:

The first star of this kind which seems to have been particularly noticed is one in the neck of the Whale, whose right ascension is 2h. 8′ 33″, and south declination, 3° 57′ 25″. It was first observed on August 13th, 1596, by David Fabricius, when it appeared like a star of the third magnitude, but disappeared after the month of October in the same year. It was again observed by Holwarda in the year 1637; and after having disappeared during a period of nine months, it again became visible; since which time it has been found every year pretty regular in its period, except from October, 1672, to December, 1676, during which time Hevelius could not perceive it, though it was a particular object of his attention. Bullialdus, a Frenchman, having compared together the observations that had been made on it from 1638 to 1666, determined the periodical time between its appearing in its greatest brightness and returning to it again to be 333 days. He found also that about 120 days elapse between the time that it is first seen of the sixth magnitude and its disappearing; that it continues in its greatest luster for about fifteen days; that after its first reappearance of the sixth magnitude it increases in size much faster until it comes to be of the fourth magnitude, than it does from that period to its being of the third; and that from its being of the third it increases to the second magnitude by still slower degrees. Modern astronomers give the following description:—"It remains in its greatest brightness about a fortnight, being then nearly equal to a star of the second magnitude; it decreases during three months, until it becomes completely invisible, in which state it remains about five months, when it again becomes visible, and continues increasing during the remaining three months of its period; but it does not always return to the same degree of brightness, nor increase and diminish by the same gradations." It appears about twelve times in eleven years. Cassini determined its period to be 334 days; but Sir W. Herschel makes it 331 days, 10 hours, 19 minutes. It appears, then, that this star passes through all the gradations of light and magnitude from a star of the second to a star of the sixth magnitude and under; but after it has disappeared to the naked eye it may be traced to its lowest magnitude by a telescope of moderate power. It is sometimes distinguished by the name of *Stella Mira*, or the wonderful star, and *Omicron Ceti*.

In 1704, Maraldi observed a variable star in the constellation *Hydra*. This star had been described by Montanari in 1670, but was not visible in April, 1702. Maraldi saw it for the first time in the beginning of March, 1704, in the same place where it had been seen thirty-four years before. It appeared of the fourth magnitude, and continued nearly in the same state until the beginning of April. It then gradually diminished until the end of May, when it could no longer be seen by the naked eye, but was visible through the telescope for a month longer. It could not be seen again until the end of November, 1705, when that part of the heavens began to emerge from the sun's rays. It was then very faint, and grew less and less until the end of February, 1706, and could then be scarcely perceived even with a telescope. It did not reappear until the 18th of April, 1708, when it was larger than a star of the sixth magnitude, and increasing in luster. It was seen by the same observer afterward, in the years 1709 and 1712. From the observations of Maraldi, Mr. Pigot concludes that its period was then 494 days; but from observations made by himself he thinks that *now* it is only 487 days; so that from the time of Maraldi it has shortened seven days. The following are the more prominent particulars relating to this star:—1. When at its full brightness it is of the fourth magnitude, and does not perceptibly change for the space of fourteen days. 2. It is about six months in increasing from the tenth magnitude and returning to the same; so that it may be considered as invisible during that time. 3. It is considerably more quick, perhaps one-half more so, in its increase than in its decrease. 4. Though, when at its full, it may always be styled a star of the fourth magnitude, it does not constantly attain the same degree of brightness, but the differences are very small. 5. Its right ascension for 1786 is 31h. 18′ 4″; and its south declination, 22° 9′ 38″. It is marked No. 30 in Hevelius' Catalogue of the Stars; from which data, its place may easily be found on a planisphere, or on the celestial globe.

In the year 1600, G. Jansonius discovered a variable star in the breast of the Swan, which was afterward observed by different astronomers, and supposed to have a period of about ten years. The results of Mr. Pigot's calculations from the observations of former astronomers are—1. That it continues in full luster for five years. 2. It decreases rapidly for two years. 3. It is invisible to the naked eye for four years. 4. It increases slowly during seven years. 5. All these changes are completed in eighteen years. 6. It was at its minimum at the end of the year 1663. 7. It does not always increase to the same degree of brightness, being sometimes of the third, and at others only of the sixth magnitude. "I am entirely ignorant," says Mr. Pigot, "whether it is subject to the same changes in this century, having not met with any series of observations upon it; but if the above conjectures are right, it will be at its minimum in a very few years. Since November, 1781, to the year 1786, I have constantly seen it of the sixth magnitude, though I suspect that in 1785–6, it had rather decreased." This star is near *Gamma* in the Swan's breast; it varies from the third to the sixth, seventh, &c. magnitudes. Its right ascension is 20h. 9′ 54″; north declination, 37° 22′ 37″.

One of the most remarkable of these changeable stars is that called *Algol*, in the head of Medusa, in the constellation *Perseus*. It had long since been known to appear of different magnitudes at different times; but its period was first ascertained by John Goodricke, Esq., of York, who began to observe it in the beginning of the year 1783. It changes continually from the first or second to the fourth magnitude; and the time which elapses from one greatest diminution to the other was found in 1783 to be, at a mean, 2 days, 20 hours, 49 minutes. The change is thus—during four hours it gradually diminishes in luster; during the succeeding four hours it recovers its first magnitude by a like gradual increase; and during the remaining part of the period, namely, 2 days, 12 hours, 42 minutes, it invariably preserves its greatest luster; after the expiration of which its diminution again commences. According to Mr. Pigot, who has made many observations on such stars, and paid particular attention to the subject, the degree of brightness of this star when at its *minimum* is variable at different periods; and he is of the same opinion in regard to its brightness when at its full; but whether these differences return regularly or not has not been determined. The right ascension of Algol, or *β Persei*, for 1786, is 2h. 54′ 19″; and its north declination 40° 6′ 58″. It is situated 12° east of *Almaach*, in the foot of Andromeda, and may be known by means of three stars of the fourth magnitude lying a few degrees south-west of it, and forming a small triangle. It comes to the meridian on the 21st of December, about nine o'clock in the evening; but as it continues above the horizon at least twenty hours out of the twenty-four, it may be seen every evening from August to May.

Another variable star is to be found in the neck of the Swan. The period of this star has been settled by Maraldi and Cassini at 405 days; but from a mean of the observations of Mr. Pigot, it appears to be only 392, or at most 396 7-8 days. The particulars relating to it are,—1. When at its full brightness, it undergoes no perceptible change for a fortnight. 2. It is about three and a half months in increasing from the eleventh magnitude to its full brightness, and the same in decreasing; for which reason it may be considered as invisible during six months. 3. It does not always attain the same degree of luster, being sometimes of the 5th, and sometimes of the seventh magnitude. The right ascension of this star is 19h. 42′ 21″; and its north declination, 32° 22′ 58″. It is situated in the neck, and nearly equidistant from *Beta* and *Gamma*, and south by west from *Deneb*, at the distance of about twelve degrees, and is marked *Chi*.

The star *Eta* Antinoi is another star of this description, whose variation and period were discovered by Mr. Pigot in 1785. From his corrected observations, he concludes that it continues at its greatest brightness forty hours without decreasing; it is sixty-six hours after it begins to decrease before it comes to its full diminution; after which it continues stationary for thirty hours more; and then increases for thirty-six hours. In every period it seems to acquire its full brightness, and to be equally decreased. Its period therefore is seven days, four hours; and its greatest and least variation is from the third to the fifth magnitude. Its right ascension is 19h. 41′ 34″; and its north declination 0° 28′ 14″. It is about eight degreees south from *Altair*, the principal star in the constellation Aquila.

The above descriptions may suffice as specimens of the phenomena of variable stars. There are about seven or eight other stars which have been observed to be certainly variable, among which are the following:—A star in the Northern Crown, whose right ascension is 15h. 40′ 11″; north declination, 28° 49′ 30″; and period, 10½ months. A star in Hercules, whose right ascension is 17h. 4′ 54″; north declination, 14° 38′; and period of variation 60¼ days. A star in Sobieski's Shield, whose right ascension is 18h. 36′ 38″; south declination, 5° 56′; and period 62 days. The star *Beta* Lyræ—right ascension, 18h. 42′ 11″; north declination, 33° 7′ 46″; greatest and least variation, 3, 4, 5; supposed period, 6 days, 9 hours. The star *Delta Cephei*, whose period is 5 days, 8½ hours; right ascension, 22h. 21′; and north declination, 57° 50′. With several others.

Beside these, whose variations and periods have been determined, there are about thirty-seven other stars, which are, with good reason, suspected to be variable, but whose periods of change have not yet been ascertained, on account of the want of a sufficient number of observers, who might devote their attention more particularly to this department of astronomical observation. For example, the star *Pollux*, or *Beta* Gemini, is suspected to change from the first to the third magnitude.

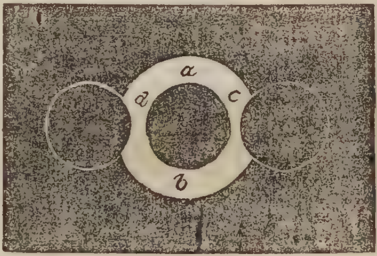
When contemplating such changes among bodies so immensely distant, and of so vast magnitude, we are naturally led to inquire into the causes which produce these phenomena. Our ignorance, however, of the precise nature and constitution of those remote bodies, and of the scenes and circumstances in which they may be placed, prevent us from forming any definite or satisfactory conclusions. The following are some of the opinions which have been thrown out on this subject. It has been supposed that portions of the surfaces of these stars are covered with large black spots, which, during the diurnal rotation of the star, present themselves under various angles, and thus produce a gradual variation in its brilliancy. Sir W. Herschel says "Such a motion may be as evidently proved as the diurnal motion of the earth. Dark spots, or large portions of the surface less luminous than the rest, turned alternately in certain directions, either toward or from us, will account for all the phenomena of periodical changes in the luster of the stars so satisfactorily, that we certainly need not look for any other cause." Sir Isaac Newton thought that the sudden blaze of some stars may have been occasioned by the "falling of a comet into them, by which means they would be enabled to cast a prodigious light for a little time, after which they would gradually return to their former state." But we know too little about the nature of comets to be able to determine what effect they would produce in such a case, nor are we certain that such bodies are connected with other systems. If the fixed stars be nearly of the same nature as the sun, it is highly improbable that any such effect would be produced even although a comet were to fall into its luminous atmosphere, as that atmosphere appears to have nothing in it that would take fire by the approach of any extraneous body, or that would "blaze" like combustible substances on the earth. The blaze, if such an effect were to take place, would scarcely be distinguishable from our globe, and much less from a distant system. Maupertius, in a "Dissertation on the Figures of the Celestial Bodies," is of opinion that some stars, by their prodigious quick rotation on their axes, may not only assume the figures of oblate spheroids, but that, by the great centrifugal force arising from such rotations, they may become of the figures of millstones, or be reduced to flat circular planes, so thin as to be quite invisible when their edges are turned toward us, as Saturn's ring is in such positions. And when any eccentric planets or comets go round any fixed star, in orbits much inclined to its equator, the attraction of the planets or comets in their perihelions must alter the inclination of the axis of that star; on which account it will appear more or less large and luminous, as its broadside is turned more or less toward us. This opinion, at best, I consider as having a very small degree of probability, and almost quite untenable. Mr. Dunn, in a paper in vol. 52 of the "Philosophical Transactions," supposes that the interposition of some gross atmosphere may solve the phenomena under consideration. "The appearance of new stars," says he, "and the disappearance of others, possibly may be occasioned by the interposition of such an ethereal medium within their respective orbs as either admits light to pass freely or wholly absorbs it at certain times, while light is constantly pursuing its journey through the vast regions of space."

Whatever opinions we may adopt on this subject, it is evident that *the regular succession of the variations* of periodical stars preclude the idea of their being destroyed. It is likewise evident that *motion* of some kind or other, either in the stars themselves or in some bodies either directly or remotely connected with them, must be one of the causes of the phenomena in question; and it is not improbable that different causes in different instances may operate in producing the effects. It does not appear to me probable that the cause which produces the variation in the case of *Delta Cephei*, whose period is only 5 days, 8½ hours, is the same which produces all the variety of change which happens in the star *Gamma* in the Swan's breast, whose periodical changes are completed only in eighteen years. It is not unlikely that a rotation round an axis, which has the effect of presenting different sides of the star of more or less degrees of obscurity or brightness to the eye of a spectator, will account for the phenomena of such stars as *Eta* Antinoi and *Delta Cephei;* but it does not appear probable that a motion of rotation is so slow in any of these bodies as to occupy a period of eighteen years, as in the case of the star in the breast of the Swan.

I am disposed to consider it as highly probable that *the interposition of the opaque bodies of large planets revolving around such stars*, may, in some cases, account for the phenomena. It is true that the planets connected with the solar system are so small in comparison of the sun that their interposition between that orb and a spectator at an immense distance would produce no sensible effect. But we have no reason to conclude that in all other systems the planets are formed in the same proportion to their central orbs as ours; but, from the variety we perceive in every part of nature both in heaven and earth, we have reason to conclude that every system of the universe is in some respect different from another. There is no improbability in admitting that the planets which revolve round some of the stars, may be so large as to bear a considerable proportion (perhaps one-half or one-third) to the diameters of the orbs around which they revolve; in which case, if the plane of their orbit lie nearly in the line of our vision, they would in certain parts of their revolutions interpose between our eye and the stars, so as to hide for a time a portion of their surfaces from our view, while in that part of their orbits which is next the earth. Such a supposition is by no means inconsistent with the operation of the law of universal gravitation; for although such planets bore a considerable portion of the size of their central luminaries, yet we have only to suppose that their *density* is *very small.* They may be globes whose central parts are devoid of solid matter, consisting only of a solid external shell for the support of inhabitants, as is probably the case with the planet Saturn, whose density is only equal to that of cork.

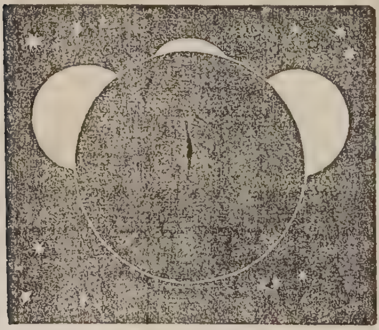
A planet about the size we have now supposed revolving around a star would, in a great measure, account for the phenomena presented by *Algol.* This star accomplishes the period of its variations in 2 days and nearly 21 hours. During 3½ or 4 hours it gradually diminishes in luster, and during the succeeding four hours it gradually recovers its first magnitude. Throughout the remaining part of the period—namely, 2 days, 12 hours, 42 minutes,—it invariably preserves its greatest luster; so that the time of its being diminished in luster is only about the ninth part of its whole period of variation. Now supposing a planet about half the diameter of the star revolving around Algol, it would intercept a large portion of its surface when it passed between our eye and the star, as at *a*, *b* (fig. 11), where the white circular ring represents the surface of the star partly covered by the planet. Its luster would begin to diminish when the planet entered on its edge at *d*, and it would again resume its full brightness when going off at *c*, the dark side of the planet being of course turned to our eye; and during the remaining part of its revolution it would appear in its brightest luster. The regularity of the changes of this star admits of the supposition now made, and evidently requires a regular motion of some kind or other, either in the star itself or in some body connected with it, in order to produce the phenomena. Perhaps, in the case of some of the variable stars, we might suppose several large planets in succession to pass between our eye and the star to account for the appearance they present—a supposition which perfectly agrees with the idea of a *system* of revolving bodies.

Fig. 11.



As it is not probable that the changes of all such stars arise from the same cause, what should hinder us from supposing that *there are stars or suns that revolve around planets of a size immensely greater,*—the planets, for example, bearing a similar proportion to the stars as the sun bears to Jupiter? Considering the immense variety of celestial mechanism throughout the universe, there can be no great improbability in such a supposition. The case of *double stars* demonstrates that one sun actually revolves round another; and why may not a sun revolve around a central planet, whose surface may contain forty times the area of all the planets of our system, in order to distribute light and heat, and other beneficial influences, to its numerous population? No violation of the law of universal gravitation is implied in such a supposition; and the Almighty is not confined to one mode of arranging systems and worlds. Supposing, then, such an arrangement to exist, it might account for the phenomena of some of the variable stars, particularly those which remain invisible for a certain period. Such are some of those formerly noticed, as the star in Hydra, and that in the breast of the Swan, and particularly a star in the Northern Crown, whose right ascen. is 15° 40′, north declin. 28° 49½′, and period 10½ months, and which decreases from the sixth to the ninth and tenth magnitude. It attained its full brightness about the 11th of August, 1795, and continued so for three weeks; in 3½ weeks it decreased to the tenth magnitude, and a few days afterward disappeared. After being a considerable time invisible, in April, 1796, it again appeared; on the 7th of May, it reached the ninth magnitude, and then gradually attained its full brightness. If, then, such a star was revolving round a very large central planet, it is easy to conceive that in the more distant part of its course it might be hid from our view, either in whole or in part, by the interposition of the opaque central body, as is obvious from an inspection of figure 12. And as the star now alluded to never exceeds in luster a star of the sixth magnitude, it is not improbable that it is one of the inferior order of those luminous orbs which may revolve round an opaque body of superior magnitude.

Fig. 12.



Such, then, are some of the conceivable causes which may produce the phenomena of variable stars, although other causes may in some cases exist of which we have no conception. These phenomena evidently indicate that motions and revolutions of various kinds are going forward throughout the stellar regions; that the Almighty is superintending the movements of those provinces of his empire, and that all his agencies have a respect to the order and the happiness of intelligent existence.

Beside the periodical variations to which we have now adverted, there are several other striking changes which have been observed in the starry regions which deserve our attention, and which I shall briefly notice.

1. Several stars which were formerly distinctly visible, and are marked in different catalogues, are now wholly lost. The following are a few instances. M. Montanere, professor of mathematics at Bononia, in a letter to the Royal Society, of date April 1670, gives the following statement:—"There are now wanting in the heavens two stars of the second magnitude, in the stern and yard of the ship Argo. I and others observed them in the year 1664, upon occasion of the comet that appeared that year. When they disappeared first I know not: only I am sure that, in the year 1668, upon the 10th of April, there was not the least glimpse of them to be seen, and yet the other stars about them, of the third and fourth magnitudes, remained the same. I have observed many more changes among the fixed stars, even to the number of a hundred, though none of them are so great as those I have showed." In 1670, Anthelm discovered a star of the third magnitude in the head of the Swan, which after becoming completely invisible, reappeared, and after undergoing one or two singular fluctuations of light during two years, at last died away entirely, and has not since been seen. Sir William Herschel gives a list of thirteen stars, most of which are supposed to be lost. Of these are the following:—Nos. 80 and 81 of Hercules, both of the fourth magnitude; the 19th of Perseus, of the sixth magnitude; and the 108 Pisces, are judged to be wholly lost. The stars 73, 74 Cancer, in the southern claw of the Crab, of the sixth magnitude, are either lost or have suffered such great changes that they can no longer be found. On this subject Sir John Herschel states—"The star 42 Virginis is inserted in the catalogue of the Astronomical Society from Zach's Zodiacal Catalogue. I missed it on the 9th of May, 1828, and have since repeatedly had its place in the field of view of my twenty feet reflector without perceiving it, unless it be one of two equal stars of the 9th magnitude very nearly in the place it must have occupied."

2. Some stars have changed their magnitudes since the beginning of last century. A considerable number of stars marked by Flamstead, in his *Historia Cœlestis*, are now found to be of different magnitudes since the period in which he observed the heavens and formed his catalogue. For example; the 1st and 2d of *Hydra* are now only of the eighth or ninth magnitude instead of the fourth, as they are marked by Flamstead. The 31st and 34th of *Draco* have changed greatly; the 31st has increased from the seventh to the fourth, and the 34th has diminished from the fourth to the sixth or seventh magnitude. The 38th Perseus, instead of the sixth, has now increased to the fourth magnitude. About thirty stars of this description are reckoned by Sir W. Herschel to have changed their magnitudes.

3. There are stars unknown to the observers of former times which have recently become visible. The following, among others of this description, have been marked by Sir W. Herschel:—1. A star in the end of the Lizard's tail, of the fourth or fifth magnitude, which is not recorded by Flamstead, although he notices one in that constellation less conspicuous. 2. A star near the head of Cepheus. 3. A considerable star in a direction from the 68th to the 61st of Gemini. 4. A star of considerable brightness preceding the 1st of the Little Horse. 5. A remarkable star between β and δ Hydræ. 6. A star near δ Hercules, of the fourth or fifth magnitude, with several others. Similar observations appear to have been made about the end of the seventeenth and the beginning of the eighteenth centuries, by Cassini and others. Cassini discovered a new star of the fourth, and two of the fifth magnitude in Cassiopeia; two in the constellation Eridanus, one of the fourth the other of the fifth magnitude; and four of the fifth

and sixth magnitude near the north pole, which had not been perceived at a former period.

Such changes in bodies so far removed from our system, and of magnitudes so enormous as the least of them must be, naturally lead to the conclusion that revolutions of vast extent, and operations conducted on a most magnificent scale, are incessantly going forward in those remote and unexplorable regions. In the case of stars which have totally disappeared, we are led to conclude, either that some vast and important change has taken place in the *constitution* of certain worlds or systems, or that the central luminaries of such systems, with all their surrounding planets, have been transported by some unknown and almighty agency into more distant regions of space, where they may remain forever hid from our view. As to those stars which have changed their magnitudes within the last century, they may either be approaching to or receding from the system to which we belong, or their native brightness may be either increasing or diminishing from causes with which we are unacquainted; or some ethereal mediums of a peculiar nature may be interposed between our sight and those distant orbs. With respect to stars unknown to former observers which have recently become visible, it is not unreasonable to suppose that these are *new systems* recently launched from the creating hand of the Omnipotent, to diversify his creation and augment the glories of his empire, as well as to distribute happiness among new orders of sensitive and intelligent existence. We ought not to imagine that the work of creation, considered as a whole, is yet finished, or ever will be finished during an indefinite lapse of ages. When it is stated by the inspired writer of the book of Genesis that "God rested from all his work," we are to understand the expression only in reference to the formation or *arrangement* of the world in which we reside into the form and order in which we now behold it; for to this arrangement chiefly, if not solely, the descriptions of the sacred historian in the first chapter of Genesis refer. It is in perfect accordance with the idea of a Being possessed of omnipotent power, boundless goodness, and endless duration, that his creating energies should never cease in their operation throughout all the periods of an interminable existence; and the phenomena to which we refer are a strong presumption, if not a demonstrative evidence, of a continued series of creations. These new creations may be bursting forth in the remote spaces of the universe, in various degrees of splendor and magnificence, to an extent of which we have no conception; and from the character and perfections of the Divinity, we have reason to believe that such processes will be incessantly going forward throughout all the ages of eternity.

Whatever opinions we may be disposed to form as to the phenomena to which we have adverted, they tend to convey to the reflecting mind magnificent views of the physical energies of the Almighty, in arranging the different departments of his boundless dominions, and accomplishing the purposes and plans of his moral government, and they naturally excite in the mind a desire of future existence, and an ardent wish to behold the vail which now intercepts our views of these glorious orbs withdrawn, and to contemplate the scene of divine operation in all its splendor and magnificence.

At first view, it may appear a circumstance of comparative insignificance to behold a small star, scarcely distinguishable to the eye, waxing brighter, or growing dimmer, or vanishing altogether from the view; or a star appearing in a point of the heavens which was unoccupied before. The distant blaze of a field of furze, the falling of a tower, or the conflagration of a cottage, may to some appear events of far greater interest and importance; but such events in the heavens as those to which we refer may be connected with scenes as astonishing—though perhaps not so tremendous—as if the sun were shorn of his rays and turned into darkness, and this earth and all the planetary globes shattered to their centers and wrapped in flame; or, as if a new sun of superior magnitude were to appear in our system, and to illuminate our globes with a new species of light and colors. Objects at a great distance from the observer make little impression on the organs of vision, and seldom affect the mind. A fleet of the largest ships of war viewed from the top of a tower at fifty miles distance appears only like a few almost undistinguishable specks on the verge of the horizon, while the fate of individuals, families, communities, and even empires, may depend upon the encounter in which they may be engaged. The conflagration of a city of ten hundred thousands of inhabitants may appear at a distance as only a faint glimpse of light in one point of the horizon, while palaces, and temples, and thousands of splendid fabrics are turned into smoking ruins, and multitudes are thrown into the utmost consternation, and perishing in the flames. The burning of the city of Moscow, as beheld from the moon when the dark side of the earth was presented to that orb, would appear only like a dim lucid speck, scarcely distinguishable from the other parts of the earth's surface. And if this be the case in respect to objects within such limited distances, what astonishing scenes may be the result of what we perceive in bodies many thousands of millions of miles distant, when we behold them disappearing to our view, or even when we perceive their light only increasing or diminishing? Here imagination is left to fill up the picture which the organs of vision so dimly perceive. We are to consider that the orbs to which we allude are luminous globes of immense size,—that they are doubtless encircled with a retinue of worlds replenished with inhabitants,—that what to us appears a slight change of aspect may to them be the commencement of an era of new glory and splendor,—that the Almighty rules over those distant regions as well as "among the inhabitants of the earth,"—and that all the changes which happen among them are in unison with his eternal designs, and subsreve the ends of his universal government.

CHAPTER VIII.

ON DOUBLE STARS AND BINARY SYSTEMS.

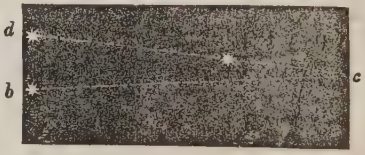
In whatever part of creation we survey the operations of the Almighty, we uniformly find the characteristic of *variety* impressed upon all his works. This is evident in all the kingdoms of nature connected with our globe, where the multitude and diversity of animals, vegetables, and minerals, cannot but strike the eye even of the most superficial observer. Though the same general laws appear to pervade the material universe, so far as our observation extends, yet these laws are so comprehensive and so endlessly modified as to produce an immense variety of minute and wonderful effects. It is more difficult to trace the operation of these laws in the remote spaces of the universe than in our terrestrial sphere. But even in regions of creation immeasurably distant we can perceive the agency of the same powers which are at work in conducting the movements of our planetary system; and not only so, but we can trace these powers, while operating with their native energy, wonderfully modified, and producing effects altogether different from those which we experience in the system of which we form a part, evidently indicating that a *variety*, analogous to that which we behold in the scene around us, marks the operations of the Creator throughout the immensity of his works. This will more clearly appear in the descriptions we shall now give of the phenomena of double and multiple stars.

The phenomena of double stars do not seem to have been much attended to until Sir W. Herschel commenced his extensive observations on the sidereal heavens. About a century ago, the astronomers of that period seem to have been aware that "several stars which appear single to the bare eye are by the telescope discovered to be double." The principal stars of this description which they mention are,—the head of Castor, the first in the head of the Ram, the star *Gamma* in the breast of Virgo, and the middle one in the sword of Orion. Conceiving the fixed stars as bodies precisely of the same nature, and that no specific or diversified arrangements prevailed among them, they do not appear to have entered upon any minute surveys, by the telescope, of particular stars; and their idea respecting the double stars they had detected was merely this;—that a small star, at a very remote distance from another, might happen accidentally to lie nearly in the same line of vision as the larger one; and, on this ground, Dr. Long, in his "Astronomy," shows how the annual parallax would be discovered by a star appearing single at one time of the year, and double at another. It appears to have been chiefly with an object of this kind in view that Sir William Herschel commenced his numerous observations in this department of sidereal investigation. But, as we are informed by his son, who has distinguished himself in an eminent manner by similar observations, he had hardly entered on the measurements of the angles of position, and the distances of double stars, before he was diverted from the original object of his inquiry by phenomena of a very unexpected character, which at once engrossed his whole attention. The circumstances alluded to, shall be particularly described in the sequel, after I have given a brief sketch of the phenomena of double stars.

When a telescope of considerable power is directed to certain stars which appear single to the naked eye, another star, generally much smaller than that which appears to the unassisted eye, is seen quite adjacent to it, and in some cases the interval between the two stars is so small that it requires a very high degree of light and magnifying power to be able to perceive that they are two distinct bodies. Only a few, perhaps not exceeding six or eight, of these stars were known to the astronomers of the age preceding that of Herschel; but this illustrious astronomer, with unwearied perseverance, detected no less than 500 double stars, and presented to the Royal Society a list in which their situation and relative positions are distinctly marked. These observations of the elder Herschel were followed up by other observers, particularly by Sir J. Herschel and Sir James South, who, in the year 1824, soon after Sir W. Herschel had ceased from his labors, produced a catalogue of 380 double stars, whose distances and angles of position they had determined with the utmost accuracy and precision.—Sir J. South afterward produced a *distinct* catalogue of 480, and Sir J. Herschel a list of upward of 3300 of double and triple stars, from his own solitary observations, accompanied with all the micrometrical measurements. Strüve, the celebrated astronomer of Dorpat, has arranged a catalogue of no less than 3000 double stars; and before he determined the characteristics of each of these, he examined about 120,000 stars—a laborious process, which none but an astronomical observer can duly appreciate. Mr. Dunlop has formed a catalogue of 250 double stars in the *southern* hemisphere; and Sir J. Herschel, during his late residence at the Cape of Good Hope, has added considerably to their number; so that we may now reckon about 6000 of these interesting objects as having already been discovered, even making allowance that many of these objects are common to the lists of the observers now specified.

It is not at all improbable that the phenomena of some of the double stars now alluded to may arise from ***accidental proximity***, the one star, though far remote and unconnected with the other,

Fig. 13.



lying nearly in the same visual line. Thus, the star *a*, fig. 13, might appear nearly in contact with the star *b*, placed at an immense distance beyond it, when viewed nearly in the same straight line by the eye at *c*, so as to produce the phenomena of a double star at *d b*. But, reasoning *a priori*, it appears in the highest degree improbable that such coincidences should happen in the case of all, or even of the greater part of the double stars which have now been discovered; and therefore Mr. Mitchell, so early as the year 1783, in a paper inserted in the "Philosophical Transactions" for that year, states it as his opinion that they are binary systems intimately connected. "The very great number of stars," says he, "that have been discovered to be double, treble, &c., particularly by Mr. Herschel, if we apply the doctrine of chances, as I have done in my 'Inquiry into the probable Parallax of the Fixed Stars,' published in the Philosophical Transactions for 1767, cannot leave a doubt with any one properly acquainted with the force of those arguments, that by far the greatest part, if not all of them, are systems of stars so near each other as probably to be liable to be affected sensibly by their mutual gravitation; and it is therefore not unlikely that the periods of the revolutions of some of these about their principals may some time or other be discovered."

The prediction here announced by this ingenious gentleman has now been fully realized by Sir William Herschel and other astronomers, and is no longer a subject of conjecture, but *an ascertained fact*. This is the discovery to which I have alluded above, one of the most important and interesting discoveries which astronomy has unfolded during the present age, and which opens to our view a new prospect of the plans and arrangements of Infinite Wisdom.

Having made these preliminary remarks, I shall now proceed to a more particular detail of the facts which have been ascertained respecting binary systems.

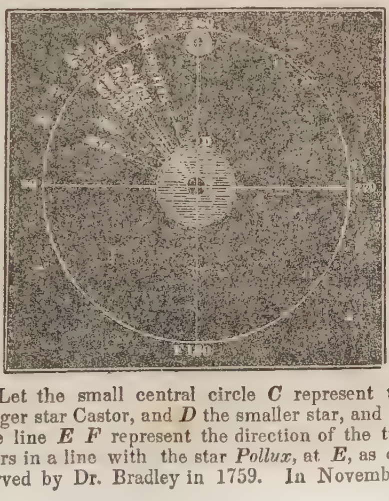
When Sir W. Herschel first directed his attention to this subject, in order if possible to determine the annual parallax, he was not a little surprised that, instead of finding, as he expected, a regular annual change of the two stars, by one alternately shifting its position with respect to the other, which a parallax would have produced, he observed in many instances "*a regular progressive change*, in some cases bearing chiefly on their distance, in others on their position, and advancing steadily in one direction, so as clearly to indicate either a real motion of the stars themselves, or a general rectilinear motion of the sun and whole solar system, producing a parallax of a higher order than would arise from the earth's orbital motion." In an elaborate paper on this subject, read before the Royal society, June 9, 1803, he considers specifically all the motions and combinations of motion that can possibly be supposed, in order to account for the phenomena, particularly of the double star *Castor*, and satisfactorily demonstrates that nothing but the idea of the smaller star revolving around the larger in a circular or elliptical orbit will solve the phenomena in question; and this conclusion has been amply confirmed by all succeeding observations. Such stars, therefore, must be considered as *physically connected* by the law of mutual gravitation, so that they describe orbits around each other and around their common center of gravity, and bear a relation to each other similar to that which the planets bear to our sun.

From the paper of Sir W. Herschel now referred to, I shall select, as a specimen of the motions of double stars, some of his observations of *Castor*, or *α Geminorum*. It appears that Dr. Bradley in the year 1759 had observed the position of the two stars which form this double star, and communicated it to Dr. Maskelyne, who made a memorandum of it, of which the following is a copy:—"Double star Castor. No change of position of the two stars; the line joining them at all times of the year, *parallel to the line joining Castor and Pollux* in the heavens, seen by the naked eye."—The object of Dr. Bradley in observing the exact position of these stars was, to determine if any change happened in their position at opposite periods of the year, so as to indicate an annual parallax. The angles of position observed by Sir W. Herschel are as follow:

Times of the observations.	Angles of Position.	
November 1, 1759	56°	32
November 5, 1779	35	29
February 23, 1791	23	36
December 15, 1795................	18	32
March 26, 1800	14	3
December 31, 1801................	12	12
February 28, 1802	12	1
March 27, 1803................	10	53

From these observations it appears that from the year 1759, when Dr. Bradley observed the positions of the two stars, to the year 1803, there has been a portion of an orbit described by the smaller star around the greater equal to forty-five degrees and thirty-nine minutes; and from the time that Herschel commenced his observations in 1779 until 1803, an arch of twenty-four degrees and thirty-six minutes had been passed over.—Hence Sir W. Herschel concludes—"The time of a periodical revolution may now be calculated from the arch 45° 39′, which has been described in 43 years and 142 days. The regularity of the motion gives us great reason to conclude that the orbit in which the small stars moves about Castor, or rather the orbits in which they both move round their common center of gravity, are nearly circular and at right angles to the line in which we see them. If this should be nearly true, it follows that *the time of a whole apparent revolution of the small star round Castor will be about* 342 *years and two months*." This subject may be illustrated to the general reader by the following diagram:

Fig. 14.



Let the small central circle *C* represent the larger star Castor, and *D* the smaller star, and let the line *E F* represent the direction of the two stars in a line with the star *Pollux*, at *E*, as observed by Dr. Bradley in 1759. In November, 1779, they were found in the position *C H*, twenty-one degrees from the position they occupied twenty years before; in February, 1791, they were thirty-three degrees from the same position, &c.; and in March, 1803, forty-six and a half degrees; giving evident indication of a regular progressive motion in a circle. Since 1803 its motion has been regularly traced by Strüve, Sir J. Herschel, and Sir J. South; and in 1816 it was found about 57° from its first position, and in 1830 about 68°, still regularly progressing. In 1819, the distance of the small star from Castor was five seconds and a half, and in 1830 it was little more than four seconds and a half. Although Sir W. Herschel, as above stated, conjectured the period of revolution to be about 342 years, yet later astronomers, from a comparison of all the observations recently made, are disposed to conclude that its period is little more than 250 years.

More than fifty instances of changes in the angles of position of double stars were observed by Sir W. Herschel, beside those which have been more recently observed by his son and other astronomers, most of which indicate motions which are regularly *progressive;* but a considerable number of years must elapse before their periods can be determined with any degree of accuracy. The following double stars are considered as demonstrative instances of circular progressive motion:—γ Virginis, ξ Ursæ Majoris, 70 Ophiuchi, σ and η Coronæ, ξ Bootis, η Cassiopeiæ, γ Leonis, ζ Herculis, δ Cygni, μ Bootis, ε 4 and ε 5 Lyræ, λ Ophiuchi, μ Draconis, ε Bootis, and ζ Aquarii. The periodic times of some of these have been determined to a near approximation. One of the stars of *Gamma* Virginis is reckoned to revolve about the other in the space of 629 years; the small star of *Gamma* Leonis, in 1200 years; the star connected with *Epsilon* Bootis, in 1600 years; that of 61 Cygni, in 452 years; that of *Sigma* Coronæ, in 287 years; that of 70 Ophiuchi, as ascertained by Professor Encke, in 80 years; that of *Xi* Ursæ, in 58 years; that of *Zeta* Cancri, in 55 years; and that of *Eta* Coronæ, in 43 years.

A whole revolution of some of these stars has been nearly completed since observations began to be made on such objects. The motion of the small star of *Xi* Ursæ began to be traced about the year 1781; in 1819, it had moved 219° from its position in 1781; in 1830, it was 303 from that position, progressing in a circle; and about this time, or the beginning of 1840, it has probably finished its orbital revolution. The star *Eta* Coronæ, whose period is forty-three years, has not only accomplished a complete revolution, but is actually considerably advanced in its second period. Sir J. Herschel, during his late sojourn at the Cape of Good Hope, is said to have discovered in the southern skies, binary stars, whose periods of revolution are even shorter than those now stated, their change of position having been quite perceptible during the three or four years of his residence in that quarter. Sir W. Herschel, in the paper to which I have already referred, states observations which furnish us with a phenomenon which is new in astronomy—namely, *the occultation of one star by another.* With a power of 460, in July, 1782, the stars of *Zeta* Herculis were then half the diameter of the small star asunder; in 1795, he found it difficult to perceive the small star with the same power; in 1802, the small star could no longer be perceived, but the apparent disc of the large star seemed to be a little lengthened one way. With his ten feet telescope, and a power of 600, he found it to have the appearance of a wedge-formed star. On the 11th of April, 1803, he examined the apparent disc with a power of 2140, and found it, as before, a little distorted, but there could not be more than about three-fourths of the apparent diameter of the small star wanting to a complete occultation. "Most probably," he observes, "the path of the motion is not quite central; if so, the disc will remain a little distorted during the whole time of the conjunction." This phenomenon evidently demonstrates the fact of circular orbital motion, performed in a plane nearly parallel to our line of vision.

The star *Gamma* Virginis has presented phenomena nearly similar to that of *Zeta* Herculis This star is remarkable both for the length of its period, the rapid increase of the angular motion of the two stars of which it is composed, and particularly *the great diminution of their apparent distance.* It has been known as a double star for at least 120 years. The two stars of which it is composed, and which are nearly equal, were so far apart about the middle of the last century that they were marked in Mayer's catalogue as two distinct stars, so that any moderately good telescope would have shown their separation, being at that period about seven seconds distant from each other. Since that time they have been constantly approaching, and in 1833 were scarcely more than a single second asunder; so that a common telescope was insufficient to show their separation, and even telescopes of very superior power could show them no otherwise than as a single star somewhat elongated. According to Sir J. Herschel's computations, the small star must have arrived at its perihelion on the 18th of August, 1834. He also determined *the inclination of the orbit to the visual ray* to be 22° 58′, *and the angle of position of the perihelion* projected on the heavens, 36° 24′. The small star of *Eta* Coronæ reached its perihelion in 1835; and it is calculated that the revolving star of Castor will reach the same point during the year 1855.

From the observations that have been made on binary stars, it now appears demonstrable that the law of gravitation extends its influence to the starry regions; that the same laws of motion which direct the planets in their courses, and connect them with the sun as their center, likewise operate in these binary systems in carrying one star around the center of gravity of another. It has often been surmised that gravitation is a power which is universal in its influence; and here we have a proof that it extends not only beyond the range of the planetary system and the orbits of the most eccentric comets, not only to stars reckoned the nearest to our globe, but to those of the third, fourth, and even tenth magnitudes, which may be supposed many hundreds of billions of miles farther distant; thus rendering it highly probable that it is a fundamental law of matter, and extends its energies throughout the amplitudes of creation, combining in one vast system all the operations of the Eternal.

The orbits in which the one star moves around the other are found to be *elliptical*, which is the same kind of curve in which the earth and the other planets move round the sun, in which the satellites of Jupiter, Saturn, and Uranus perform their revolutions round their respective primaries—another proof that the same general law operates in both cases. Some of these orbital motions are *retrograde* and others are *direct*, or in the same direction as the motions of the planets of our system. In some cases it happens that the edge of the orbit of the revolving star is presented to the earth, or in a line nearly parallel to that of our vision, as is found in the star π Serpentarii; in which case the star appears to move in a straight line, and to oscillate on each side of the larger star around which it revolves, in a manner similar to that of the satellites of Jupiter, which appear to pass from the one side to the other of the planet in nearly straight lines, because the plane of their orbits is nearly in a line with our eye. At the time when Sir W. Herschel first observed this binary system, the two stars were distinctly separate, but at present the small star is so completely projected on the other that even Strüve, with his powerful telescope, cannot now perceive the least separation between the two bodies—a fact which evidently demonstrates that to our eye the one is passing across the disc of the other, and that a number of years hence it will appear on the other side of the larger star. On the other hand, the two stars of *Zeta* Orionis are now separated by a small interval, although they appeared as one star in the time of Sir W. Herschel; all which phenomena demonstrate a motion in a circular or elliptical orbit, the plane of which lies *oblique* to our eye; and it has been calculated, from the apparent motions of these bodies, that the ellipses in which they move are in general more elongated than the orbits of the solar planets. On the whole, to use the words of Sir John Herschel, "we have the same evidence of their rotations about each other that we have of those of Uranus and Saturn about the sun; and the correspondence between their calculated and observed places in such very elongated ellipses must be admitted to carry with it proof of the prevalence of the Newtonian law of gravity in their systems, of the very same nature and cogency as that of the calculated and observed places of comets round the central body of our own."

Having stated the above general facts respecting binary stars, I shall now present to the reader a few telescopic views of these objects.

Fig 15 represents a telescopic view of *Epsilon* Bootis, with a magnifying power of about 200 times. This is reckoned a very beautiful double star on account of the different colors of the stars of which it is composed, and has an appearance somewhat similar to a planet and its satellite, both shining with innate but differently colored light. The small star is of a bluish color, and is separated from the other by a space equal to the diameter of the larger star, and its apparent size is one-third of the other. It is sometimes called *Mirac*, and it is situated about ten degrees north-east of *Arcturus*. The large star has a *reddish* tinge.

Fig 16 is α Herculis: the small star is of a bluish color, separate from the other two diameters of the large star; the blue star is one-third the size of the other. It is situated in the head of Hercules, about thirty degrees south-west from the bright star α Lyræ, and six degrees north-west from *Ras Alhague*, a star of nearly the same magnitude. It comes to the meridian about the middle of July, at nine o'clock in the evening, at an elevation of about fifty-two degrees. This star is also distinguished by the name *Ras Algethi*, and may be seen marked in Plate II, which contains a map of stars which are seen near the meridian about the beginning of September.

Fig. 17 is a view of γ Andromedæ: the small star is of a fine greenish-blue color, separate from the large star about nine seconds, or four diameters of that star; the larger star is of a reddish white. It is situated in the left foot of Andromeda, and is distinguished by the name *Almaack*. It is a star of the second magnitude, about forty-two degrees of north declination, and passes the meridian, in the beginning of December, about half past ten in the evening, about ten degrees south from the zenith. It is about twelve degrees nearly due west from the variable star *Algol*.

Fig. 15

16

17

Fig. 18 is *Zeta* Cygni: the smaller star is blue, and they are separated about ten diameters. This star is situated in the eastern wing of the Swan—right ascension, 21h. 4′, north declination, twenty-eight degrees, and is about twenty degrees south-east of Denib, the principal star of this constellation.

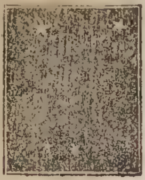


Fig. 18

19

Fig. 19 represents *Zeta* Aquarii. The two stars are nearly equal in apparent magnitude, and one diameter and a half separate from each other; both stars are of a whitish color. It is in the middle of three other stars, which together form a figure resembling the letter Y. Its right ascension is 22h. 20′, and its south declination about two degrees. It is a star of about the third magnitude, and comes to the meridian at nine o'clock in the evening about the middle of October.

Fig 20 represents the ***Pole-star***. The accompanying star is a very faint point, and requires an accurate telescope with considerable power to distinguish it. The large star is white, and the small star somewhat of a ruddy appearance, and is distant from the larger seventeen seconds, or about three or four of its diameters.

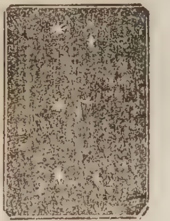

Fig. 20

21

22

Fig. 21 is the double star *Castor*. The smaller star is nearly half the size of the larger, and they are distant about five seconds, or two diameters of the principal star. They are both of a whitish color. Their situation may be found on Plate I. Castor and Pollux lie to the north-west of Orion, at a considerable distance from it. They are very conspicuous, are within five degrees of each other, and rise to a very high elevation when passing the meridian, and may be seen throughout the whole winter and spring months. *Castor* is the more elevated of the two.

Fig. 22 represents *Rigel*, a splendid star in the left foot of Orion. The small star is a mere point, and very difficult to be distinguished, and is three or four diameters of the large star from it. The large star is white, the small one of a reddish hue.

Fig. 23 shows the double star Castor, with a magnifying power of 300. It likewise shows the angular position of the small star at the present time in respect to *Pollux*, (fig. 24), by which it appears that it is nearly at a right angle to a line joining Castor and Pol-

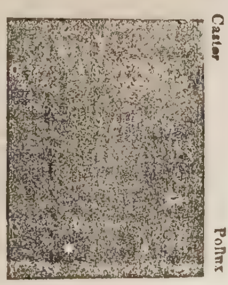

Fig. 23

24

lux, whereas in the time of Dr. Bradley it was *parallel* with a line joining these two stars.

Fig. 25

26

27

28

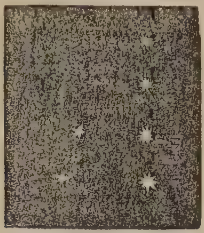

Fig. 25, 26, 27, and 28, exhibit views of the double star *Epsilon* Bootis, with four magnifying powers. Fig. 25 is its appearance with a power of 227; fig. 26, with a power of 460; fig. 27, with a power of 900; and fig. 28, with a power of 1100.

Fig. 29

30

31

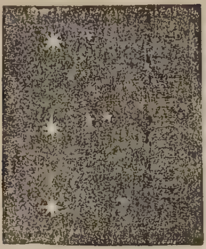

Fig. 29, 30, and 31, represent telescopic views of the triple star in the left fore-foot of the constellation *Monoceros,* or the Unicorn, which forms a very beautiful object in this class of stars. This star appeared at first double, but with some attention, one of the two is discovered to be also double; the first of them is the largest. The color of these stars is white. With a small power they appear as in fig. 29; with a power of 220, as in fig.30; and with a power of 450, as in fig. 31. There is a beautiful object of this description, but somewhat different in the configuration of the three stars of which it is composed, to be seen in the tail of the great Bear; it is the star *Zeta* Ursæ, called also *Mizar,* and is the middle star in the tail.

Such are a few specimens of the telescopic appearances of this class of celestial objects. Some of these objects, in order to be distinctly seen, require telescopes of considerable magnifying power. All the objects, however, referred to above may be seen with a good three feet and a half achromatic telescope, whose object-glass is two inches and three quarters aperture. The double star Castor may be seen with powers of 80, 140, and 180. I have frequently distinguished the separation of the two stars with a terrestrial power of only 45; but the higher powers of course are much preferable. In order to perceive the very small star or point of light adjacent to the pole-star, a power of 140 at least is requisite with such a telescope; but it is more distinctly seen with a power of 190 or 200. It is considered as a fair test of the goodness of a telescope of this description when this minute object is perceptible with such powers. The small star connected with *Epsilon* Bootis is likewise an object which requires a considerable degree of magnifying power and distinctness to perceive the separation of the two stars; and it is more difficult to perceive the small star adjacent to *Rigel* than any of these objects.

In the phenomena I have now described, we have a new and interesting scene presented before us, which leads the mind into a train of thought very different from what could have been conceived by astronomers of a former age. To some minds, not accustomed to deep reflection, it may appear a very trivial fact to behold a small and scarcely distinguishable point of light immediately adjacent to a larger star, and to be informed that this lucid point revolves around its larger attendant; but this phenomenon, minute and trivial as it may at first sight appear, proclaims the astonishing fact, that SUNS REVOLVE AROUND SUNS, AND SYSTEMS AROUND SYSTEMS. This is a comparatively new idea, derived from our late sidereal investigations, and forms one of the most sublime conceptions which the modern discoveries of astronomy have imparted. It undoubtedly conveys a very sublime idea, to contemplate such a globe as the planet Jupiter—a body thirteen hundred times larger than the earth—revolving around the sun, at the rate of twenty-nine thousand miles every hour; and the planet Saturn, with its rings and moons revolving in a similar manner round this central orb in an orbit of five thousand, six hundred and ninety millions of miles in circumference. But how much more august and overpowering the conception of a sun revolving around another sun—of a sun encircled with a retinue of huge planetary bodies, all in rapid motion, revolving round a distant sun, over a circumference a hundred times larger than what has been now stated, and with a velocity perhaps a hundred times greater than that of either Jupiter or Saturn, and carrying all its planets, satellites, comets, or other globes along with it in its swift career! Such a sun, too, may as far exceed these planets in size as our sun transcends in magnitude either this earth or the planet Venus, the bulk of any one of which scarcely amounts to the thirteen-hundred-thousandth part of the solar orb which enlightens our day. The farther we advance in our explorations of the distant regions of space, and the more minute and specific our investigations are, the more august and astonishing are the scenes which open to our view, and the more elevated do our conceptions become of the grandeur of that Almighty Being who "marshaled all the starry hosts," and of the *multiplicity* and *variety* of arrangements he has introduced into his vast creation. And this consideration ought to serve as an argument to every rational being, both in a scientific and a religious point of view, to stimulate him to a study of the operations of the Most High, who is "wonderful in counsel and excellent in working," and whose works in every part of his dominions adumbrate the glory of his perfections, and proclaim the depths of his wisdom and the greatness of his power.

In order to form a comprehensive conception and a proper estimate of such binary systems, we have to consider, in the first place, the distances of the stars or *suns* from each other. These distances, in the meantime, cannot be accurately ascertained until something more definite be determined respecting the parallaxes of these bodies. Some have supposed that the distance between some of these binary stars may be as great as the distance between the earth and any of these stars. But such a supposition is highly improbable, if we admit, what is now completely ascertained, that these bodies are intimately connected by the law of gravitation. Their distance, however, must be very great, notwithstanding their apparent nearness to each other, as a few seconds of interval, at the distance of the nearest star, must comprise an immense space. I shall suppose this distance in the case of some of these bodies to be only the one-hundredth part of what is reckoned the distance (namely, twenty billions) of the nearest star. On this supposition, the distance of the revolving star from its primary would be 200,000,000,000, or two hundred thousand millions of miles. The circumference of its orbit would therefore be 1,256,640,000,000 of miles. The small star of ξ Ursæ completes its revolution in fifty-eight years, and consequently, if at the distance now supposed from its primary, must move at the rate of two millions four hundred and seventy-one thousand miles every hour, which is eighty-five times the velocity of the planet Jupiter, and more than twenty-three times the velocity of Mercury in its orbit, which is the swiftest moving planet in our system. This motion would be still more swift in the case of some of the other stars to which we have alluded. The small star of 6 *Eridani*, as determined by Mr. Dunlop, revolves around the larger at the rate of somewhat more than ten and a half degrees per annum, and consequently accomplishes a revoluion in little more than thirty years. Its motion, then, at the distance supposed, would be equal to four millions seven hundred thousand miles an hour, which is 162 times the velocity of Jupiter, and about forty-four times that of Mercury. Even the small star of γ Leonis, which takes 1200 years to accomplish its revolution, would, on the same supposition, move at the rate of 119,000 miles an hour, which is a greater velocity than that of the swiftest planets of our system. These are immense velocities, especially when we consider the enormous size of the bodies thus impelled; for the least of these suns may be considered as *ten millions* of times larger than the planet Mercury, yet moving with a velocity so much superior.

What, then, would be the velocities of such bodies were we to suppose them as far distant from each other as we are from the nearest star! In the case of *Xi* Ursæ, the velocity would be two hundred and forty-seven millions, one hundred and sixty thousand miles every hour, and four millions, one hundred and fifty thousand every minute; and in the case of 6 *Eridani*, the velocity would be 477,800,000 miles an hour, and 132,735 in a *second*, which is more than sixteen thousand times the velocity of Jupiter. That bodies may move with such velocity is perhaps not impossible, but it is highly improbable that such rapid motions actually exist among bodies of such astonishing magnitudes; and therefore we must suppose that the binary stars are within a moderate distance of each other. Still, that distance must be very considerable, and it is not unlikely may be as great as I have supposed, and if so, it presents to our view motions more rapid and sublime than any which are known to exist within the limits of our planetary system.

In the next place, we must consider the *system of planets* connected with the binary stars. These stars are evidently suns or self-luminous bodies, otherwise their light would never reach our distant sphere. But we can never admit that suns were created merely to diffuse a useless splendor over the waste spaces of infinity, where there are no sentient beings with visual organs to be cheered with their radiance. In this case they might be said to be created in vain. Hence we must necessarily conclude that these suns are attended with a retinue of planetary bodies, which revolve around them as the centers of light and attractive influence, and we can scarcely conceive a more sublime and astonishing object than that of magnificent suns revolving around still more magnificent and luminous centers, and conveying along with them in their swift career a numerous train of mighty worlds, all in regular and rapid motion around their respective orbs. In such sublime sidereal arrangements we behold a combination of motions and effects of gravitation which are not to be traced throughout any part of the system to which we belong. For while the planets which perform their revolutions around the revolving sun, are affected by the power of attraction from that body with which they are more immediately connected, they must likewise be attracted by the larger central sun, and their motions sometimes retarded, sometimes accelerated, and variously modified, by its powerful influence, which combined influences must produce a diversity of phenomena and effects unknown in the system of our sun. For the sake of some readers, not accustomed to such views and contemplations, I have given a rude sketch of a binary system in fig. 32, in which the central circles represent the larger sun with its attendant planets, and the other circles the revolving sun and its planets, in four different positions.

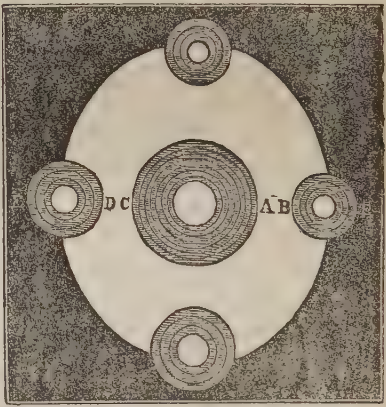
Again, in contemplating these binary systems, we perceive a great diversity in the periods of their revolutions. The period of revolution of the small star of ι Bootis is calculated to be not less than 1600 years. An inhabitant of that system would be considered by us an old residenter were he to survive the period of a year, or a single revolution. But in such systems it is not likely that the lapse of duration is marked by so short periods as in our own sublunary abode, nor is it probable that disease and death cut short the existence of its inhabitants, as in the world in which we dwell. Another of these suns takes 1200 years to complete a revolution; another, 629 years; and another, 452; while several others finish their circuits in the comparatively short periods of 55, 43, and even 30 years. Whether these diversities in the periods of revolution be owing to the different magnitudes of the respective bodies, their distances from each other, the amplitudes of the orbits in which they move, or the comparative velocities with which they are carried forward in their career, we have as yet been unable to determine; and a long-continued series of the most delicate and minute investigation is still requisite before such points can be ascertained with any degree of precision. But such striking differences in their periodic revolutions evidently indicate that the characteristic of *variety* is impressed upon all the arrangements connected with those distant systems; which lead us to conclude that there is no system of suns or worlds in the universe exactly resembling another, although they may be all subject to the operation of the same general and fundamental laws. From such circumstances we are likewise led to infer that among bodies in the more distant regions of creation there may be motions and arrangements altogether different from anything we yet know, which produce scenes of beauty, sublimity, and grandeur, far surpassing what the mind of man can yet conceive.

In regard to the *number* of such binary systems, no precise estimate has yet been made. We have, however, every reason to believe that their number is very great. I have already stated that about 6000 double stars have been detected by M. Strüve, the two Herschels, Mr. Dunlop, and Sir James South. On the doctrine of chances, it is in the highest degree improbable that the greater part, or even any considerable number of these bodies, appear double by their accidental proximity, or being so placed one behind another as to be nearly in the same line of vision. We may therefore conclude that at least 4000 of these stars are binary systems connected by the law of mutual gravitation. Between forty and fifty of these bodies have been ascertained beyond doubt to form revolving systems, and time must be allowed for further investigations. It is but lately that the attention of astronomers has been directed to such observations; and on account of the very minute distances of the revolving stars from each other, and the slight variation of the angle of position which can be traced for a series of years, an age or two is requisite in order to determine with precision the degree or progress of their revolutionary movements. Some of their orbits, too, may be so extensive, or their motions so comparatively slow, that several thousands of years may elapse before the periods of some of these bodies be completed; and if so, we have no reason to conclude that they are *not* binary systems, although half a century should elapse without any change being perceived in their angular positions. In the course of fifty or sixty years hence, we have reason to believe many important discoveries will be made in reference to the bodies in question, and what is at present doubtful or obscure will be rendered definite and precise. In the meantime, we may safely take for granted that several thousands of those revolving suns and systems lie within the range of our telescopes, whose revolutions will ere long be determined. But as our most powerful instruments can carry us only a very small way, comparatively, beyond the outward boundaries of those mighty heavens which surround us, ten thousands of such systems may exist in those remoter regions, which will forever remain inexplorable by mortals.

There is another interesting view which may be taken of these binary systems, and that is—*the contrast of colors which some of the stars composing these systems exhibit.* I have already alluded to some of these stars being of different colors, and any observer who is possessed of a good telescope may easily satisfy himself on this point. "Many of the double stars," says Sir J. Herschel, "exhibit the beautiful and curious phenomena of contrasted or complementary colors. In such instances, the larger star is usually of a ruddy or orange hue, while the smaller one appears blue or green; probably in virtue of that general law of optics which provides that when the retina is under the influence of excitement by any bright-colored light, feebler lights, when seen alone would produce no sensation but of whiteness, shall for the time appear colored with the tint complementary to that of the brighter. Thus a yellow color predominating in the light of the brighter star, that of the less bright one in the same field of view will appear blue; while if the tint of the brighter star verge to crimson, that of the other will exibit a tendency to green, or even appear as a vivid green under favorable circumstances. The former contrast is beautifully exhibited by *Iota Cancri*, the latter by *Gamma* Andromedæ, both fine double stars. If, however, the colored star be much the less bright of the two, it will not materially affect the other. Thus, for instance, *Eta* Cassiopeiæ exhibits the beautiful combination of a large white star and a small one of a rich ruddy purple. It is by no means, however, intended to say that in all such cases one of the colors is a mere effect of contrast; and it may be easier suggested in words than conceived in imagination, what variety of illumination *two suns*, a red and a green, or a yellow and a blue one, must afford a planet circulating about either; and what charming contrasts and 'grateful vicissitudes'—a red and a green day, for instance, alternating with a white one and with darkness—might arise from the presence or absence of one or other, or both, above the horizon. Insulated stars of a red color, almost as deep as that of blood, occur in many parts of the heavens, but no green or blue star (of any decided hue) has, we believe, ever been noticed unassociated with a companion brighter than itself."

The fact of *colored suns*, of suns belonging to the same system, diffusing light of opposite or contrasted colors presents a novel and interesting idea, and a splendid scene, in which a lively imagination may luxuriate while depicting the diversity of aspects under which ojects will appear in those worlds which are alternately illuminated by such a variety of irradiation. It is somewhat difficult, however, to form a distinct conception of the particular beauties, sublimities and contrasts which will be produced by such admirable arrangements. We are unacquainted with the nature and qualities of the substances which are thus illuminated, and therefore can not determine the peculiar hues or splendor which will result from the reflection of such irradiations; but we may easily conceive there will be a considerable difference in the variety and splendor of such illuminations, and in the contrast of colors which will be exhibited when the revolving planets are in different parts of their orbits. When in such positions as *A*, *B*, *C*, *D* (fig. 22), they will be more directly under the influence of both suns than when at *E* and *F*, and of course the effect of the contrasted colored rays will be most remarkable. One hemisphere of a planet may be illuminated with a yellow sun, while the other is at the same time enlightened by a green, and both suns may occasionally shine in the same hemisphere, producing such a blending of hues, and a contrast of coloring over the whole landscape, as to render the aspect of the scene completely different at one time from what it is at another. In different parts of the planets' courses around their primary suns these effects will be variously modified, so as to produce an almost perpetual variety in the scenery of such worlds. A sun of a brilliant white color may perhaps be seen rising, while a sun of a ruby hue is descending below the horizon, and when both suns are absent, the starry firmament will appear in all its splendor, and every object around present a contrast to its previous appearance.

Fig. 32.



The science of optics, and particularly the experiments which have been made on *polarized light*, show us what a variety of combinations of vivid and beautiful colors may be produced by certain modifications of light, which may easily lead us to conceive of the sublime and diversified brilliancy of coloring which must be the result of the irradiation of suns of different hues. The light of the stars in general is greatly diversified, although on a cursory view of the firmament they appear nearly of the same aspect. The rays of *Sirius*, for example, are not only strikingly different from those of *Aldebaran*, but from those of many other stars which seem to bear a nearer resemblance. In tropical climates, where the sky is clearer than with us, and almost of a dark ebony color, the different hues of the stars are more striking and perceptible to the naked eye than when seen through our comparatively hazy atmosphere. In this respect then, as well as in several others, the declaration of the inspired writer is literally true, that "one star differeth from another star in glory." Milton, in the eighth book of his "Paradise Lost," utters a sentiment on this subject which seems to be almost prophetic, when he represents Raphael in his address to Adam as saying—

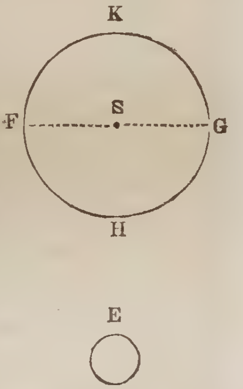
> "Other suns, perhaps,
> With their attendant moons thou wilt descry,
> *Communicating male and female light,*
> Which two great sexes animate the world,
> Stored in each orb, perhaps, with some that live."

In these phenomena we have another proof of the infinite *variety* which the Creator has introduced into the systems of the universe—a variety in regard to *color* as well as to magnitude, motion and other arrangements,—which leads us to conclude that although we were permitted to make the tour of universal nature, we should meet with no worlds, or systems of worlds, in which the scenery and arrangements are exactly the same, but that each would display its own peculiar harmonies, beauties, and sublimities, and the enraptured spectator, at every stage of his excursion, would behold a new manifestation of "the manifold wisdom of God."

It would be an important and interesting acquisition in astronomy could we determine exactly, or even to a near approximation, the *distances* of any of these binary systems, and the *actual dimensions* of the orbits of the revolving stars. It appears from what has been formerly stated (pp. 31, 32,) that the parallax, and consequently the distance, of 61 *Cygni* has been determined by Professor Bessel. Now this is a double star, or binary system, ana one of the stars is found to have an annular angular motion of about two-thirds of a degree; from which it is inferred that the period of its revolution may be about 540 years, and that the semi-major axis of its orbit is seen under an angle of more than 15″. Were these and other correlative points accurately settled, we might soon determine to a near approximation the extent of its orbit, the space through which it moves in the course of a revolution, and consequently its rate of velocity; but as the motion of revolution of this star is so extremely slow, a considerable period of years may elapse until all the elements of its orbit be accurately ascertained.

A few years ago, a method was pointed out by M. Savory, a French Astronomer, by which the dimensions of the orbit of a revolving star might be determined. This method depends upon the fact that light moves with a certain known rate of velocity. Suppose that one of the double stars moves round another in an orbit which is nearly parallel to our line of vision, it is evident that the one half of its orbit will be nearer to us than the other, and that at the most distant point of its course the star will be removed from us to a distance equal, or nearly equal, to the whole diameter of its orbit farther than when at the point which is nearest the earth. As the light which proceeds from the star takes a certain time in moving across the interval which separates us from that body before it reach our eye, we must necessarily see the star in a point of its orbit different from that in which it is actually placed. Let *S* (fig. 33) represent the central star, *E* the earth, and *H F K G* the orbit of the revolving star. When the star is at *H* it is nearest the earth; and when at *K* it is farther distant by the whole diameter of its orbit. Now, when the star proceeds from *H*, the nearest point of its orbit, its light will take a longer period to reach the earth in proportion as it moves on in its course from *H* to *G* and from *G* to *K*, and consequently will appear to take a longer time than in reality it does in moving along that portion of its orbit; but in returning through the other half of its orbit, *K F H*, it will appear to pass through it in a less space of time than it actually does, since the light which proceeds from it takes less and less time to reach our eye as it approaches in its course toward *F* and *H*. If, therefore, we could accurately determine the difference of time between these two half revolutions of the star, we should have *data* sufficient for determining, to a near approximation, the dimensions of the orbit in miles, or other known measures; and having found these dimensions, the distance of the star from the earth could likewise be found by an easy trigonometrical calculation.

Fig. 33.



This method of finding the dimensions of binary systems is entitled to the praise of ingenuity; but it will be difficult, in many instances, to put it in practice. Its accuracy will depend upon our knowing the *position* of the orbit with regard to our eye, and our ascertaining exactly when the star is in *H* or at *K*, or the two opposite points of its orbit. Beside, a very long time must intervene before observations of this kind can be completed, since most of the periods that have been determined in regard to double stars extend to several hundreds of years, and the shortest period yet known of any of these revolving bodies is above thirty years. It is generally taken for granted, by those who have adverted to this subject, that the distance between the revolving and the central star is as great, or nearly as great, as that which intervenes between us and the nearest star; and hence, in their illustration of this point, they have supposed light to take at least one year in crossing the orbit of a revolving star, which of course would make the diameter of such an orbit above *six billions* of miles. But there appears no reason for forming such extravagant suppositions, as in such a case the binary stars could scarcely be supposed to have an intimate connection. We might almost as soon suppose that the star Sirius might revolve around our sun, or the sun around Sirius. It is not likely that the double stars in general are much farther from each other than the distance I formerly supposed; namely, 200,000,000,000, and consequently the diameter of their orbits about 400,000,000,000, of miles. Through this space light would pass in the course of 24 days and 2⅔ hours; and therefore it would require very accurate determinations indeed of the points *H* and *K*, or the nearest and remotest points of the orbits, before any precise conclusions could be deduced, if the stars be not farther distant than I have supposed, and it is perhaps as probable that they are considerably within that distance. It is not improbable, however, that the dimensions of the orbits of some of those stars whose periods are shortest may in this way be determined; but a considerable period must elapse before the requisite operations can be made.

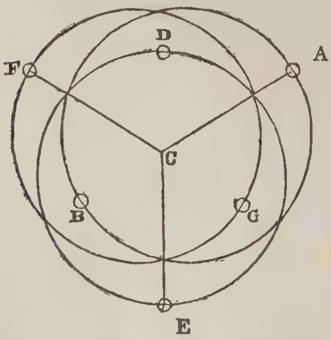
CHAPTER IX.

ON TREBLE, QUADRUPLE, AND MULTIPLE STARS.

Beside the combinations of double stars described in the preceding chapter, treble, quadruple, and multiple stars have been discovered, many of which appear to be ultimately connected, and to be formed into regular systems, whose motions and phenomena must of course be more diversified and complicated than those of binary systems. Without entering into particular discussions on this subject, I shall present to the reader only two or three general remarks, with a short list of some of the treble and multiple stars to which I allude.

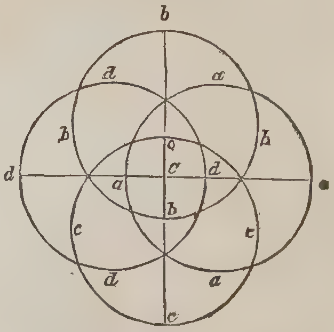
The more profound and minute our investigations are into the scenery of the heavens, the more do we discover of the endlessly diversified modes by which the system of universal nature is arranged and conducted, and the more clearly do we perceive a display of the infinite wisdom and intelligence of its Almighty Author. Who could have previously conceived of one sun and system revolving round another, had not recent observations demonstrated the astonishing fact? As one discovery naturally leads to another, so the facts which have already been ascertained may lead to discoveries in future generations still more wonderful and sublime than those which have hitherto been brought to light. The discovery of binary systems leads to the conclusion that almost all the close groups, or clustering stars, visible to the naked eye or descried by telescopes, are multiple systems, or suns and planetary worlds linked together by a universal law or principle, acting in different modes, and producing an immense variety of physical phenomena and effects. Guided by principles and facts recently brought to light, astronomers have only to direct their attention more particularly to such objects, to watch with care the slightest movements in the sidereal heavens, and take their measurements of distances and angular positions with the utmost precision; and then we may expect that succeeding generations will have unfolded to their view a more sublime and comprehensive prospect of the arrangements of the universe.

Fig. 34.



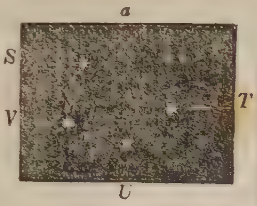
In certain cases it has already been ascertained that treble stars form one connected system. The star marked ξ Cancri is a treble star of this description. Two of the stars are considerably unequal; the largest of these is larger than the single star, and the least of the two is less than the single star. The first and second largest, as described by Sir W. Herschel, are pretty unequal, and the second and third pretty unequal. The nearest are pale red. They require very favorable circumstances to be distinctly seen; they are just separated by a power of 227, and with 460 their distance is ¼ the diameter of the smaller one. This is considered a case in which three suns revolve around a common center. Observation has not yet afforded a sufficient data for determining the particular motions or arrangements of such complex systems; but we may conceive them as arranged in a manner somewhat similar to what we have delineated in fig. 34, where the point *C* may represent the common center of gravity around which the three bodies revolve. The circles *A B*, *D E*, *F G*, represent the orbits of the revolving bodies, which may be conceived as lying in different planes oblique to each other, to prevent any occasional collision or too near an approach.

Fig. 35.



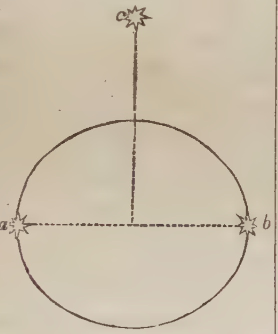
A *quadruple* system may be represented by fig. 35, where *C* is the center of gravity round which the four bodies revolve, and the circles ***a a a a***, *b b b b*, &c., the respective orbits in which they move. The star ε Lyræ is probably a system of this kind. It is a star of the fifth magnitude, situated about two degrees north-east from the bright star *Vega*, or α Lyræ. The stars of which it is composed are easily distinguishable by a telescope of moderate power, and it is easily found from its vicinity to the very bright star adjacent to it. The small stars of which it is composed are situated nearly as represented in fig. 36. We might conceive of such a system of bodies revolving in a still more complex manner,—the star *V* revolving round *S*, the star *U* revolving round *T*, the system of *V* and *S* revolving round a point *a*, and the system of *U* and *T* round the same point or center in a separate but more expansive orbit. But it is difficult to form diagrams of such complex systems.

Fig. 36.



There are many different combinations by which we may conceive treble, quadruple, and multiple stars to revolve round their common center of gravity, which it would be too tedious to describe, particularly as such motions have not yet been accurately ascertained. Sir W. Herschel describes one of these possible combinations which is not a little singular. Suppose two equal stars, *a* and *b* (fig. 37), moving in a circular orbit round their common center of gravity, which will be the center of the circle. From the center of the circle, draw a line perpendicular to the plane of their orbit, extending to equal distances above and below this center. Let us now suppose a third star, *c*, to fall from one extremity of this perpendicular, from a state of rest; it will obviously descend with a gradually accelerated motion until it reaches the center of gravity; and passing onward with a motion gradually retarded, it will move to the other end of the perpendicular, where it will arrive at a state of rest, and again return and continue to oscillate between these two points The two stars which move in a circular orbit may describe equal ellipses of any degree of eccentricity. In this case, however, the perturbations will affect not only the planes of their orbits, but also their figures; and the length of the oscillations of the third will be sometimes increased and diminished.

Fig. 37.



A sun oscillating in a line perpendicular to the orbit of other two suns, and continuing its motion for ages in that line, is certainly a very strange idea; and yet, from the variety we perceive in the arrangements of the universe, it is not at all improbable that such combinations may exist among treble stars. The idea here intended to be conveyed may be illustrated by suspending a ring, and placing a wire perpendicular to it in its center. The ring will represent the plane of the orbit in which the two equal stars move, and the perpendicular wire the line or course of the third star moving backward and forward with different degrees of accelerated and retarded motion. The motions connected with quintuple and multiple stars must be still more complex than those to which we have adverted; but it is difficult in the meantime to form any distinct ideas on the subject, until actual observation in the course of succeeding ages shall pave the way for deducing definite conclusions. The discoveries already made open to view new scenes of celestial mechanism, and new views of the diversified and admirable contrivances of Divine Wisdom, so that, in reference to such objects, we may apply to the almighty architect the language of the sacred writer—"How unsearchable are thine operations and thy ways past finding out!" When we consider that around each of these moving suns a retinue of planets must be supposed to wheel their courses, at different distances and in different periods of time, we cannot but feel astonished at the *complexity* of motions, perturbations, and other effects which must necessarily follow; yet we are bound to believe that everything moves onward, not only without confusion, but in the most perfect order and harmony, for He who at first arranged the plan of the material world, and impressed upon matter the laws which now operate, is possessed of boundless intelligence, and foresees at one glance all the effects which those laws can possibly produce; and, so far as our observation extends, every object and movement in nature appears to be adjusted with the most perfect regularity.

The solution of the "problem of three bodies" was considered as a work of so great nicety and difficulty that none but such profound mathematicians as Clairaut, D'Alembert, and Euler, could undertake such a delicate and laborious investigation. This problem was, "to determine the curves described by three bodies projected from three points given in position, and with velocities given in quantity and direction—the force with which they gravitate being directly as their quantities of matter, and inversely as the squares of their distance." If the resolution of such a problem required so great acuteness of intellect, and so eminent skill in the science of analysis, what perspicacity of intellect, and what profound knowledge of everything connected with physical and mathematical investigations must be requisite to determine the courses described and the perturbations produced by the complex motions of five, six, or seven suns all connected together, yet moving in different curves and in different directions, along with hundreds of planets, each connected with its own sun and pursuing its own distinct course, yet acted upon in succession with different degrees of force by the attractive influence of other suns! All our boasted powers of analysis are completely incompetent for such determinations. The faculties of an archangel, or of intelligences of a higher order than that of man, are alone adequate to such investigations; and this circumstance affords a presumptive evidence that such superior intelligences actually exist in the universe, and that man, in the present improvement of his powers, may be in the act of training for the employments and the society of such intellectual beings in a future scene of existence.

The following brief list of treble and multiple stars, selected chiefly from Sir W. Herschel's catalogue, is given for the sake of those who may be disposed to inspect them with their telescopes.*

π, or 42 *Aries, in the ham,* sixth magnitude.—The three stars, which are all in a line, are excessively unequal; the largest is white, and the two smallest are mere points. With a power of 460, the two nearest are 1½ diameter of the largest star. The third is about 25″ from the largest.

ε, or 4 or 5 *Libra.*—This is a remarkable double-double star—or a double star, each star itself being a double star. The first set consists of stars that are considerably unequal. The largest is very white, and the smallest reddish. Their distance with 227 is one diameter of the larger one; the second set are white and equal, the preceding being rather the largest; their distance 1½ diameter of either. The star appears of the fourth magnitude.

σ, or 48 *Orion,* a star of the fourth magnitude, *a little below the lowest of the three stars in the belt.* This is a double-treble star, or two sets of treble stars, almost similarly situated. The two nearest of the preceding set are equal; the third larger, and pretty unequal when compared with the latter two. With a power of 222, the distance of the two nearest is two diameters of either. The two nearest of the following set are very unequal. The largest of the two and the farthest are considerably unequal, the largest being white and the smallest bluish. With a power of 222, their distance is about 2½ diameters of the largest. The distance of the two farthest is 43″. Right ascension, 5h. 30′; south declination, 2° 43′.

θ, or 41 *Orion, the small telescopic trapezium in the nebula.* Right ascension, 5h. 26′; south dec., 5° 32′. The stars composing this quadruple star are considerably unequal. The most southern star of the following side of the trapezium is the largest; and the star in the opposite corner is the smallest, the other two being nearly equal. The largest is pale red; the star preceding the largest inclined to garnet; and the star opposite the largest, dusky. Distance of the two stars in the preceding side, 8¾ seconds; in the southern side, 12¾ seconds; in the following side, 15 seconds; and in the northern side, 20 seconds. The first star (in right ascension) is of the seventh magnitude, the second of the eighth magnitude, the third of the fifth magnitude, and the fourth of the sixth or seventh magnitude. M. Strüve found the angles of position, in 1819, to be as follows—

3d and 4th:
29° 45′ north following.

1st and 3d:
45° 9′ north preceding.

1st and 2d:
58° 8′ north fol.

2d and 4th:
31° 0′ north pre

2d and 3d:
74° 0′ north pre.

44 *Orion preceding the two ι's, or below* 1, 2, *θ—of the third or fourth magnitude.* The preceding set of this double-triple star consists of three equal stars, forming a triangle, and are all dusky. The distance of the two nearest with a power of 227 is about 3 diam. The following set consists of three stars of different sizes, forming a circle. The middle star is the largest; the one to the south is pretty large; and the third is very small. The two largest are white, and the smallest pale red. Distance 36¼″. These stars are east by north from the bright star *Rigel,* at the distance of about 5°.

12 *Lynx, below the eye; about* 18° *or* 19° *north-east of Capella and* 16° *north of ς Aurigæ.* The two nearest of this curious treble star are pretty unequal. The larger is white, and the smaller white inclining to a rose color. With a power of 227 their distance is ½ the diameter of the smaller one. The first and third are considerably unequal; the second and third pretty unequal; the color of the third being pale red, and its distance from the first 9″.

ξ, or 51 *Libra; of the fourth or fifth magnitude.* This star appears at first double, but the larger of the two will be found to consist of two stars. They are nearly unequal, and both white. With a power of 460 their distance is ¼ the diameter of the larger.

¾° *south of* 58 *Aurigæ, in a line parallel to β and θ, south-east of the bright star Capella.* This is a cluster of stars containing a double star of the second class and one of the third. The two of the second are very unequal, and both red. Their distance with 460 is 2½ diameters of the larger. Those of the third class are equal, and both red. Distance, 17″. Above 20 stars are in view with a power of 227.

A large star 1° *preceding ζ toward* 41 *of the Swan.* The two nearest are extremely unequal. The largest is white, and the smallest pale red. Their distance with 460 is 2½ diameters of the largest. The third and the largest are extremely unequal, and belong to the fifth or sixth class.

South preceding 27 *Swan, the middle of three, the most southern of which is the* 27. This star is quadruple and sextuple. In the quadruple of north preceding set, the two nearest are very unequal. Their distance with 678 is 11″. The two largest are almost equal, and both red. Distance, 29½″. In the sextuple or south following set, the two largest are pretty unequal, and both red. Their distance is 19″.—The other stars are as small as the smallest of the quadruple set.

⅔° *north preceding* H *Gemini* (of the fifth magnitude), *in a line parallel to the* 65 *Orion* (in the club, and of the fifth magnitude), *and ζ Taurus, the middle of the three.* The stars in this quintuple star are in the form of a cross. The two nearest, or the preceding of the five, are extremely unequal. Distance 20½″. There is a very obscure star of the third class near the last of the three, in the obscure star of the cross. Other five stars are dispersed about the quintuple one.

Between β and ζ Dolphin, but nearer to β. All the three stars are whitish red, and nearly equal. Distance of the two nearest with a power of 278, 21½″.

Near 27 *Cepheus, near δ.* The distance of the two nearest of this treble star is about 20″.

β, or 10 *Lyra* (of the third magnitude, and about 7° south-east of the bright star Vega). The stars of this quadruple star are all white, the second, third, and fourth, inclining to red. The first and second are considerably unequal; the first and third very unequal; and the first and fourth unequal. Distance of the first and second, 44″.

ς, or 78 *Gemini* (Pollux). The stars of this multiple star are extremely unequal. The nearest distance is 1′ 57″; the next distance is 3′ 17.″

In the Unicorn's head. This multiple star consists of one star with about twelve around it. 16° west of Procyon.

ζ, or 16 *Cancer.* This very minute treble star requires very favorable circumstances to be distinctly seen. The two stars of which the preceding one consists are considerably unequal. The largest of these is larger than the single star, and the least of the two is less than the single star. The first and second largest and pretty unequal, and the second and third pretty unequal. The two nearest are pale red. They are just separated with a power of 278, and with 460 their distance is ¼ the diameter of the smaller one. *Zeta* Cancri is situated about 12 or 13 degrees south-east of Pollux, nearly in a line parallel to that which joins Castor and Pollux, and nearly the same distance north by east from Procyon. It appears as a star of the fifth or sixth magnitude, and is sometimes distinguished by the name of *Tegmine*. As a double star it is easily distinguished by a power of 140, with a 3½ feet achromatic telescope, whose aperture is 2¾ inches, and might perhaps be seen with a power of 100. But it requires a much higher power to distinguish it as a treble star.

---

* As the following and similar lists are inserted for the purpose of reference to amateur observers, the general reader, if he think proper, may pass over such lists and descriptions.

Most of the above stars may be found by consulting large planispheres of the heavens, or a common celestial globe. To facilitate the finding out of their positions, I have inserted in the above list some special directions, which may perhaps be of use to the astronomical tyro who is furnished with a moderately good telescope. It is to be regretted that, even on some of our latest 18-inch celestial globes, several of the stars above referred to are not distinctly marked, either with their number or with the Greek letters by which they are generally distinguished, and some of them are altogether omitted; such, for instance, as the celebrated star 61 *Cygni*, which is a double star, and whose proper motion is greater than that of any other star yet discovered in the heavens.

CHAPTER X.

ON THE MILKY WAY.

As we advance in our survey of the distant regions of the universe, the astonishing grandeur and extent of the sidereal heavens gradually opens to our view. We have hitherto considered only a few objects on the outskirts of the heavens, in respect to their distance, magnitude, and the wonderful complication of systematic motions which prevails among them. Had we no other objects to engage our attention, ages might be spent in contemplating and admiring the economy and magnificence of those starry groups which appear to the unaided eye on the nearer boundary of our firmament. But all that is visible to man's unassisted vision is as nothing when compared with the immensity of august and splendid objects which stretch themselves in boundless perspective toward infinity. The discoveries of modern astronomy have enlarged the sphere of our conceptions far beyond what could formerly have been surmised, and opened to view a universe boundless as its Creator, where human imagination is lost and confounded, and in which man appears like a mere microscopic animalculum, and his whole habitation as a particle of vapor when compared to the ocean. In contemplating the visible firmament with the unassisted eye, we behold only the mere portals, as it were, which lead to the interior recesses of the vast Temple of Creation. When we direct our views beyond these outer portals, by means of the most powerful telescopes, we obtain a view of some of its more magnificent porches, and a faint glimpse of those splendid apartments which we shall never be able to explore, but which lead us to form the most august conceptions of the extent and grandeur of what is concealed from our view. In entering this Temple, "not made with hands," the splendor of its decorations, the amplitude of its scale, and the awfulness of infinitude, forcibly strike the imagination. There is sufficient to awaken into exercise all the powers and feelings of devotion, and to excite us to fall down in humility and adoration before Him whose word spoke into existence this astonishing fabric, and "whose kingdom ruleth over all." These reflections may not appear altogether inappropriate when entering upon a description of the *Milky Way*, which contains objects calculated to excite our highest admiration.

When we take a general view of the heavens about the months of August, September, and October, and during the winter months, we cannot fail observing a large, irregular, whitish zone stretching across the sky, with a few interruptions, from one end of the firmament to another. This mighty zone, thus stretching itself around us, is sometimes termed the *galaxy*, sometimes the *Via Lactea*, but more frequently, in plain English, the *Milky Way*, from its resemblance to the whiteness of milk. This luminous band is visible to every observer, and is the only real and sensible circle in the heavens. When traced throughout its different directions, it is found to encircle the whole sphere of the heavens, though in some parts of its course it is broader and more brilliant than in others. It forms nearly a *great circle* of the sphere, but it coincides neither with our equator, ecliptic, nor colures, nor with any other artificial circles which we conceive as drawn around the firmament. In all ages, so far as we know, this wonderful zone has retained the same position among the constellations as at the present day; and is frequently alluded to both by the astronomers and the poets of antiquity. Thus Ovid, on account of its luster, represents it as the high road to heaven, or the court of Jupiter

> "A way there is in heaven's extended plain,
> Which when the skies are clear as seen below,
> And mortals by the name of *Milky* know;
> The groundwork is of stars, through which the road
> Lies open to the Thunderer's abode."

And, Milton, in his "Paradise Lost" alludes to it in these lines:

> "A broad and ample road, whose dust is gold,
> And pavement stars, as stars to us appear;
> Seen in the galaxy, that Milky Way,
> Like to a circling zone powdered with stars."

This zone may be traced in the heavens as follows:—Beginning near the northern quarter of the heavens, at the head of Cepheus, or about 30° from the north pole, we may trace it through Cassiopeia, Perseus, Auriga, part of Orion, and the feet of Gemini. At this last point it crosses the Zodiac, and proceeding southward across the equinoctial into the southern hemisphere, it passes through the Unicorn and the middle of the ship Argo, where it is most luminous. It then passes through Charles's Oak, the feet of the Centaur, the Cross, the Altar, the tail of Scorpio, the bow of Sagittarius, and a part of Ophiuchus. Here it separates into two branches as it passes again over the Zodiac into the northern hemisphere. One branch runs through the tail of Scorpio, the bow of Sagittarius, the shield of Sobieski, the feet of Antinous, Aquila, Delphinus, the Arrow, and the Swan. The other branch passes through the upper part of the tail of Scorpio, the side of Serpentarius, Taurus, Poniatowski, the Goose, and the neck of the Swan, where it again unites with the other branch, and passes on to the head of Cepheus, the place of its beginning. After sending off the two branches above-mentioned, they unite again after remaining separate for the space of more than 100 degrees. There is another small separation of the Milky Stream between Cassiopeia and Perseus. The two streams appear to leave a blank about the head of Perseus, and a considerable space on each side of it, to the extent of about thirty degrees in length, and three in breadth, and are again joined into one stream in the sword of Perseus, adjacent to Cassiopeia.*

From the above description it will appear that the form, breadth, and general appearance of this zone are various in different parts of its circuit round the heavens. In some places it appears dense and luminous, in others faint and scattered; in certain points it appears broad, and in others narrow. Its breadth in some places, as between Auriga and Perseus, is only about four or five degrees; in other places, as in the southern parts of Scorpio, Ara, and the Cross, its breadth is from ten to fifteen or eighteen degrees. It assumes the appearance of a double path from the tail of the Scorpion, through the bow of Sagittarius, Antinous, Aquila, Taurus, Poniatowski, the Goose, and part of the Swan. It is more or less visible at every season of the year; but in Britain and in other northern latitudes it is most conspicuous during the months of August, September, and October, the latter part of July, and the beginning of November. About the middle of August, at nine o'clock in the evening, it may be seen stretching in an oblique direction over the heavens, from north-east to south-west, and its apparent motion along the heavens may be traced along with that of the other constellations. At other seasons of the year, and at other hours of the night, its position and form will appear somewhat different. It appears most brilliant in the southern hemisphere, particularly in the neighborhood of Argo, Ara, and the splendid constellation of the Cross. Between the tropics, where the atmosphere is clear and serene, it appears most vivid and brilliant. Mr. Brydon informs us that, from the top of Etna, it appeared "like a pure flame that shot across the heavens."

The ancients seem to have conjectured that the whiteness of this zone was owing to a confluence of stars; for Ovid, in the lines above quoted, says "Its groundwork is of stars." Soon after the invention of the telescope this conjecture was confirmed, and astronomers were astonished at the number of stars which appeared in this bright zone of the heavens; and their number appeared to be increased in proportion to the magnifying powers of their telescopes. But it was not before Sir W. Herschel applied his powerful instruments to this region of the heavens that its profundities were explored, and all its minute nebulous parts shown to consist of countless myriads of stars, of every apparent magnitude, stretching onward to the regions of infinity, until they appeared to be lost to the view, even when assisted by the largest telescopes. On first presenting telescopes of considerable power to this splendid zone, we are lost in amazement at the number, the variety, and the beautiful configurations of the stars of which it is composed. In certain parts of it every slight motion of the telescope presents new groups and new configurations, and the new and wondrous scene is continued over a space of many degrees in succession. In several fields of view, occupying a space not much more than twice the breadth of the moon, you perceive more of these twinkling luminaries than all the stars visible to the naked eye throughout the whole canopy of heaven. You seem to penetrate, as it were, to the remoter boundaries of creation, and feel bewildered and lost amidst the immensity of the universe. I have never been inspired with higher ideas of grandeur and sublimity, nor felt deeper emotions of humility and reverence, than when occasionally contemplating this stupendous scene through telescopes of considerable brilliancy and power. There is not another scene in creation, open to the view of mortals, calculated to fill the soul with more august conceptions, or to inspire it with more profound admiration and awe. In such surveys we behold "new heavens" and other firmaments rising to view, whose distances baffle the utmost stretch of imagination.

"O what a confluence of ethereal fire
From suns unnumbered down the steep of heaven
Streams to a point and centers on my sight."

The following contains a brief summary of Sir W. Herschel's observations on this region of the heavens, made with a Newtonian reflecting telescope of twenty feet focal length and an aperture of eighteen inches. He found that this instrument completely resolved all the whitish appearances into stars, which the telescopes he formerly used had not light enough to do. The portion he first observed was that about the hand and club of Orion, and he found in this space an astonishing number of stars, whose number he endeavored to estimate by counting many *fields*, that is, the apparent space in the heavens he could see at once through his telescope, and computing from a mean of these how many may be contained in a given portion of the milky way. In the most vacant place to be met with in that neighborhood he found 63 stars; other six fields contained 110, 60, 70, 90, 70, and 74 stars, a mean of all which gave 79 for the number of stars to each field; and then he found that, by allowing fifteen minutes for the diameter of his field of view, a belt of fifteen degrees long and two broad, which he had often seen pass through his telescope in an hour's time, could not contain less than 50,000 stars, large enough to be distinctly numbered; beside which he suspected twice as many more, which could be seen only now and then, by faint glimpses, for want of sufficient light. The reader may acquire some conceptions of this immense number of stars occupying so small a space, if he consider that it is fifty times more than all the stars which the naked eye can discern at one time throughout the whole heavens, and that the space they occupy is only the 1-1375th part of the visible canopy of the heavens; so that if every part of the firmament were equally rich in stars, there would be within the reach of such a telescope as Herschel's no less than 68,750,000, or sixty-eight millions, seven hundred and fifty thousand stars. And we are further to consider that it was only in the comparatively "vacant places" of this zone that the number of stars above stated were perceived.

---

* See the direction of this zone in the map of the stars on Mercator's projection.

In some of his observations of other parts of this zone, Sir W. Herschel informs us that he descried a much greater number of these luminaries in a similar extent of space. "In the most crowded parts of the Milky Way," he says, "I have had fields of view that contained no fewer than 588 stars, and these were continued for many minutes, so that in one quarter of an hour's time there passed no less than 116,000 stars through the field of view of my telescope." In order to appreciate this description, we are to suppose the telescope to have been fixed in one position at the time of observation, and that by the diurnal motion of the earth, or the apparent motion of the heavens, the first field of stars was gradually carried out of view, and other fields appeared in succession, until, in the space of fifteen minutes of time one hundred and sixteen thousand stars passed over the field of vision. Now, the field of view taken in by the telescope was only 15′ of a degree, a space which is less than the *one-fourth* part of the apparent size of the moon. In this narrow field were seen about as many stars as are generally beheld throughout the whole sky by the naked eye in a clear winter's night; for although nearly a thousand stars might be seen by a very acute eye in a clear atmosphere, yet there are few persons that in our climate could distinctly recognize above 600 or 700 stars even in a clear night. At another time, this indefatigable astronomer perceived no less than two hundred and fifty-eight thousand stars pass before his view in the course of forty-one minutes. In the space between ζ and γ of the Swan, the stars are found clustering with a kind of division between them, so that they may be considered as clustering toward two different regions. In this space, taking an average breadth of about five degrees of it, he found from observation that it contains more than 331,000 stars, which gives above one hundred and sixty-five thousand for each clustering collection.

Supposing the Milky Way to be, on an average, twelve degrees broad, the whole of it will contain an area of 4320 degrees $= 12 \times 360$. Now, if the space examined by Herschel between *Beta* and *Gamma* of the Swan be about fourteen degrees in length and five degrees in breadth, it will contain an area of seventy degrees, which is somewhat less than the 1-61st part of the space occupied by the Milky Way. Were we to suppose every part of this zone equally rich in stars as the space now referred to, it will contain no less than 20,191,000 stars, or more than twenty thousand times the number of those which are visible to the naked eye. The whole visible heavens, considered as a spherical plane, contains an area of 41,253 degrees. Now, could we suppose every portion of the firmament to be equally well replenished with stars as the milky zone, there would be more than 195,000,000* of stars in the heavens discernible by such a telescope as Herschel's; but as there are comparatively few other regions of the heavens so densely crowded with stars as the Milky Way, we must make a certain abatement from this estimate, though it is probable there are more than one hundred millions of stars within the reach of our best instruments were all the spaces of our firmament thoroughly explored; and future generations, with more powerful telescopes, may add indefinitely to the number. Had we taken the most crowded field of stars which Herschel perceived through his telescope (namely, 588) as our standard for estimating their number, the amount of stars in the Milky Way would have been forty millions, and in the whole heavens, 388 millions. In short, to use the words of Sir John Herschel—"This remarkable belt, when examined through powerful telescopes, is found (wonderful to relate!) *to consist entirely of stars scattered by millions*, like glittering dust, on the black ground of the general heavens."

In regard to the *distances* of some of these stars, we may easily conceive that they are immense, and consequently far removed from our distinct comprehension. Sir W. Herschel, in endeavoring to determine a "*sounding line*," as he calls it, to fathom the depth of the stratum of stars in the Milky Way, endeavors to prove, by pretty conclusive reasoning, that his twenty feet telescope penetrated to a distance in the profundity of space not less than 497 times the distance of Sirius; so that a stratum of stars amounting to 497 in thickness, each of them as far distant beyond another as the star Sirius is distant from our sun, was within the reach of his vision when looking through that telescope Now, the least distance at which we can conceive Sirius to be from the earth or the sun is 20,000,000,000,000, or twenty billions of miles; and consequently the most distant stars visible in his telescope must be four hundred and ninety-seven times this distance, that is, 9,940,000,000,000,000, or nearly ten thousand *billions* of miles! Of such immense distance, it is evident we can form nothing approaching to a distinct conception. We can only approximate to a rude and imperfect idea by estimating the time in which the swiftest bodies in nature would move over such vast spaces. Light, which is endowed with the swiftest degree of motion yet known, and which flies at the rate of nearly twelve millions of miles every minute, would require one thousand six hundred and forty years before it could traverse the mighty interval stated above; and a cannon ball, flying at the rate of 500 miles an hour, would occupy more than 2,267,855,068, or two thousand, two hundred and sixty-seven millions, eight hundred thousand years, in passing through the same space!—a period of years before which all the duration that has passed since man was placed on this globe appears only like a few fleeting hours, or "as an handbreadth or a span."*

---

* $4\frac{1}{7}\frac{2}{0}53 \times 58\frac{9}{7}\frac{2}{0}3 \times 331{,}000 = 195{,}067{,}757$

*The celebrated Schroeter, of Lilienthal, was a frequent observer of the stars which crowd the Milky Way. He was in the habit of observing with one of the largest reflecting telescopes to be found in Europe. This telescope was one of the finest ever constructed, and was the workmanship of Professor Schrader, of Kiel. The diameter of the speculum was about nineteen inches; it was about two inches in thickness, and toward the edge cast conical, so that the diameter of the polished surface is almost a quarter of an inch less than at the back, which circumstance was considered of the greatest utility in the finishing and polishing. It had a focus of twenty-six feet, and, without the frame, weighed eighty pounds. The large octangular tube was constructed with boards, made impenetrable to rain; and the instrument when ready for use was twenty-seven feet long. An immense quantity of apparatus and machinery was requisite for steadying and moving it. The figure of the speculum was so perfect, that it could bear a power of 800 or 1000 times without diminishing the aperture. Its capability of resolving the nebulosity of the Milky Way seems to have equaled that of the telescopes of Herschel. He allowed twenty degrees of its length from α Cygni to pass through the field, and the sight drew from him the natural exclamation, "What Omnipotence!" The power on the telescope in such observations was 179, and the diameter of the field, fifteen minutes; and the number of stars it contained at

Here, then, let us pause for a moment, and consider the august spectacle presented to view. We behold a few whitish spaces in the firmament, almost overlooked by a common observer when he casts a rude glance upon the evening sky; yet in this apparently irregular belt, which appears only like an accidental tinge on the face of the firmament, we discover, by optical instruments, what appears to be an amazing and boundless universe. We behold not only ten thousands, but *millions* of splendid suns, where not a single orb can be perceived by the unassisted eye. The distance at which these luminous globes are placed from our abode is altogether overwhelming; even the most lively imagination drops its wing when attempting its flight into such unfathomable regions. The scenes of grandeur and magnificence connected with such august objects are utterly overwhelming to such frail and limited beings as man, and perhaps even more exalted orders of intelligences may find it difficult to form even an approximate idea of objects so distant, so numerous, and so sublime.

On our first excursions into the celestial regions we are almost frightened at the idea of the distance of such a body as Saturn, which a cannon ball projected from the earth, and flying with its utmost velocity, would not reach in 180 years.—We are astonished at the size of such a planet as Jupiter, which could contain within its circumference more than a thousand globes as large as the earth. We are justly amazed at the stupendous magnitude of the sun, which is a thousand times the size of Jupiter, and which illuminates with its splendor a sphere of more than five thousand millions of miles in circumference. But what are all such distances and dimensions, vast and amazing as they are, compared with the astonishing grandeur of the scene before us? They sink into comparative insignificance, and are almost lost sight of amidst the myriads of splendid suns which occupy the profundities of the Milky Way. What is *one* sun and *one* planetary system in the presence of *ten millions* of suns perhaps far more resplendent, and of a hundred times this number of spacious worlds which doubtless revolve around them? Yet this scene, stupendous as it is, is not the universe. It is perhaps, as we shall see, only a comparatively small corner of creation, which beings at an immensely greater distance will behold as an obscure and scarcely discernible speck on the outskirts of their firmament; so that amidst this vast assemblage of material existence we may say, in the language of the inspired prophet, when speaking of the Almighty, that *even here* is but "the hiding of his power."—What then must the whole of creation be? and what must be the ineffable splendor and majesty of Him who laid the plan of the mighty fabric, whose breath kindled so many millions of suns, whose hands set in motion so many myriads of rolling worlds, who supports them in their ample and diversified courses, and whose moral government extends over all? And what is man, and the globe on which he dwells, amidst this scene of immensity and magnificence?—an atom in the infinity of space—a particle of vapor compared to the ocean—a being who in respect to the magnificence of creation and the grandeur of his Creator, is "as nothing, and is counted to him as less than nothing and vanity."

Yet, amidst all the magnificence of this vast system of universal nature, man is not forgotten by his Maker; his hand supports him, his wisdom guides him, and his overflowing goodness provides, in a thousand different modes, for his happiness and enjoyment. He shares of the Divine beneficence and care in common with all the bright intelligences that people the amplitudes of creation, and is as amply provided for as if the Almighty had no other world under his superintendence. Within the moral government of the Creator of the universe he may rest secure and confident that he is not overlooked amidst the immensity of being, for his presence pervades the infinity of space, and his knowledge extends to the minutest movements of all his creatures.—Under his paternal care, not only man, but the crawling worm, the fluttering insect, the little ant, and even the microscopic animalculum, find a home and provisions, as well as the highest order of his creatures; for "he openeth his hand and supplieth the wants of every living being."

Notwithstanding the size of the Milky Way, and the immense number of stars of which it is composed, it is now considered as nothing more than *one of the nebulæ*, or starry systems, which appear to be dispersed throughout the universe. It is supposed, and with some reason, that it is the nebula or assemblage of stars, in which our sun is placed. Its situation in this nebula is reckoned to be, not in the center of its thickness, but rather toward one of the sides, near the point where it diverges into two branches. According to this hypothesis, the Milky Way is to be considered as the projection of the nebula upon the concave surface of the sky, as seen from a point within it. "We gather this," says Sir W. Herschel, "from the appearance of the galaxy, which seems to encompass the whole heavens, as it certainly must do if the sun is within the same; for suppose a number of stars arranged between two parallel planes indefinitely extended every way, but at a given considerable distance from one another, and calling this a sidereal stratum, an eye placed somewhere within it will see all the stars in the direction of the planes of the stratum projected into a great circle, which will appear lucid on account of the accumulation of the stars, while the rest of the heavens at the sides will only seem to be scattered over with constellations, more or less crowded, according to the distance of the planes or number of stars contained in the thickness or sides of the stratum."

Thus if the solar system be supposed at *S*, in the middle of the nebula *a b c d e f*, with two branches, *a c*, *b c* (fig. 38), the nebula will be projected into a circle *A B C D*, the arches *A B C*, *A E C*, being the projection of the branches *a c*, *b c*, while the stars near the sides of the stratum will be seen scattered over the remaining part of the heavens among the spaces *F*, *L*, *H*, *K*, *G*. If the eye were placed somewhere without the stratum, at no very great distance, the appearance of the stars within it would assume the form of one of the lesser circles of the sphere, which would be more or less contracted according to the distance of the eye; and if this distance were exceedingly increased, the whole stratum might at last be drawn together into a lucid spot of any shape, according to the position, length and hight of the stratum.

In order to determine those points, Sir W. Herschel put in practice a method which he calls *gauging the heavens*, which consists in repeatedly counting the number of stars in the fields of view very near each other, by which he obtained a

---

once could never be counted. They were never estimated at less than fifty or sixty, and often reached or exceeded 150. He calculated that the number of stars visible through this telescope could not be less than 12,000,000.

mean of the number of stars in that part of the heavens. He then proceeds on the supposition that the stars are equally scattered, and from the number of stars in any part of the heavens he deduces the length of his visual ray, or the distance through which his telescope had penetrated, or, in other words, the distance of the remotest stars in that particular region of the heavens. To illustrate this, let us suppose the Milky Way a nebula, and that the sun is not placed in its center. Then, on the supposition that the stars are nearly equally scattered, it is evident that the part of the Milky Way where the stars are the most numerous extend farthest from the sun, and the parts where they are less numerous must extend to a less distance Proceeding on these grounds, Sir W. Herschel found the length of his visual ray for different parts of the heavens. In some cases he found it equal to 497 times the distance of Sirius, supposed to be the nearest star, as formerly stated. The following is a representation of a section of the nebula of the Milky Way, according to his delineation. This section is one which makes an angle of thirty-five degrees with our equator, crossing it in 124½ and 304½ degrees. A celestial globe adjusted to the latitude of fifty-five degrees north, and having *σ Ceti* near the meridian, will have the plane of this section pointed out by the horizon. If the solar system (fig. 39), be at *S*, the brightness of the Milky Way will be greatest in the directions *S a*, *S b*, *S*, *p*, where the stars that intervene are most numerous, or where the visual ray is longest. In the lateral directions *S n*, *S m*, the nebulosity will not appear from the small number of interposing stars, and the stars, though numerous, will appear more scattered. In the direction *S c*, on account of the opening between *a* and *b*, there will be an empty space contained between these two branches where the nebulosity is not observed, as is the case in the Milky Zone between *μ* Scorpio in the south and *γ* Cygni in the north, a length of about 102 degrees. The stars in the border, which are marked larger than the rest, are those pointed out by the gauges; the intermediate parts are filled up by smaller stars arranged in straight lines between the gauged ones. The circle around *S* represents an extent about forty times the distance of the nearest fixed stars, which may be considered as comprehending all those which are visible to the naked eye.

Fig. 38.

"From this figure," says Sir W. Herschel, "we may see that our nebula is a very extensive branching, compound congeries of *many millions of stars*, which most probably owes its origin to many remarkably large, as well as pretty closely scattered small stars that may have drawn together the rest." Again—"If it were possible to distinguish between the parts of an indefinitely extended whole, the nebula we inhabit might be said to be one that has fewer marks of antiquity than any of the rest. To explain this idea more clearly, we should recollect that the condensation of clusters of stars has been ascribed to a gradual approach; and whoever reflects on the number of ages that must have passed before some of the clusters that are to be found in my intended catalogue could be so far condensed as we find them at present, will not wonder if I ascribe a certain air of youth and vigor to very many regularly scattered regions of our sidereal stratum. There are, moreover, many places in it in which, if we may judge from some appearances, there is the greatest reason to believe that the stars are drawing toward secondary centers, and will in time separate into clusters so as to occasion many subdivisions. Our system, after numbers of ages, may very possibly become divided so as to give rise to a stratum of two or three hundred nebulæ; for it would not be difficult to point out so many beginning or gathering clusters in it. This throws considerable light upon that remarkable collection of many hundreds of nebulæ which are to be seen in what I have called the *nebulous stratum* in Coma Berenices. It appears from the branching and extended figure of our nebulæ, that there is room for the decomposed small nebulæ of a large reduced former great one to approach nearer to us in the sides than in any other parts." . . . . . "Some parts of our system seem indeed already to have sustained greater ravages of time than others; for instance, in the body of the Scorpion is an opening or hole, which is probably owing to this cause. It is at least four degrees broad, but its hight I have not yet ascertained. It is remarkable that the 80th nebula of the *Connoissance des Temps*, which is one of the richest and most compressed clusters of small stars I remember to have seen, is situated just on the west border of it, and would almost authorize a suspicion that the stars of which it is composed were collected from that place, and had left the vacancy.

Fig. 39.

The remarks in the above paragraph I present to the reader merely as the opinions of an illustrious astronomer and an indefatigable observer of celestial phenomena, without vouching for the accuracy or probability of such speculations and hypotheses. To determine the reality of such changes in bodies so numerous and so distant, would require an indefinite lapse of ages; yea, perhaps the revolutions of eternity are alone sufficient for determining the sublime movements and changes which happen among the immense assemblages of material existence which constitute the universe. There is a high degree of probability that everything within the material system is liable to change of one kind or other, and that there is no sun nor world, among all the myriads of globes which replenish the sidereal heavens, but what is *actually in motion*,—and moving, too, with a velocity which the inhabitants of such a world as ours can scarcely appreciate; and such motions, in the course of ages, may be productive of a vast diversity of scenery in different regions of the universe. And if so, it presents to view another instance of that *variety* which the Creator has introduced into his universal kingdom to gratify the unbounded desires of intelligent beings.

I shall conclude this chapter with the following description of the Milky Way, which Sir John Herschel has published since his residence in the southern hemisphere:—"The general aspect of the southern circumpolar region—including in that expression sixty or seventy degrees of south-polar distance—is in a high degree rich and magnificent, owing to the superior brilliancy and larger development of the Milky Way, which from the constellation of Orion to that of Antinous is a blaze of light, strangely interrupted, however, with almost starless patches, especially in Scorpio, near α Centauri, and the Cross; while to the north it fades away pale and dim, and is in comparison hardly traceable. I think it is impossible to view this splendid zone, with the astonishingly rich and evenly distributed fringe of stars of the third and fourth magnitudes—which form a broad skirt to its southern border, like a vast curtain—without an impression, amounting almost to a conviction, that the Milky Way is not a mere stratum, but an *annulus;* or at least that our system is placed within one of the poorer or almost vacant parts of its general mass, and that eccentrically, so as to be nearer to the parts about the Cross than to that diametrically opposed to it.

CHAPTER XI.

ON GROUPS AND CLUSTERS OF STARS.

On a cursory view of the heavens, the stars appear to be very irregularly scattered over the concave of the firmament. In some places a considerable interval appears between neighboring stars, while in others they appear so crowded that the eye can with difficulty perceive the spaces between them. Even to the unassisted eye, there are certain groups of this description which strike the attention of every observer, and lead to the conclusion that the stars of which they are composed have been brought together by some general law, and not by mere casual distribution. Of these, the group called the *Pleiades*, or Seven Stars, is the most obvious to common observers. This group is situated in the constellation Taurus, about 14° to the west of the star Aldebaran (*see* Plate I), and may be seen every clear evening from the end of August until the middle of April.* It is generally reckoned that only *six* stars can be distinctly counted in this group by common eyes, but that originally they consisted of *seven*, which every one could easily perceive, and it has therefore been conjectured that one of them has long since disappeared. To this circumstance Ovid who lived in the time of our Saviour, alludes in these lines:

> "Now rise the *Pleiades*, those nymphs so fair,
> Once seven numbered, now but six there are."†

In fabulous history it is said that the Pleiades the star Merope, one of the Atlantides, appears more dim and obscure than the rest, or is altogether extinguished, because, as the poets fancy, she married a mortal, while her sisters married some of the gods or their descendants. Dr. Long, however, declares that he himself had more than once seen seven stars in this group; and a learned astronomical friend assured him that he had seen eight stars among the Pleiades, where common eyes can discover but six; and Kepler says of his tutor Mæstlinus, that "he could reckon fourteen stars in the Pleiades without any glasses." This difference in the number seen by different persons in this group is obviously owing to the different degrees of acuteness of vision possessed by the respective individuals. However small the number perceived by the naked eye, the telescope shows them to be a pretty numerous assemblage. Dr. Hook, formerly professor of geometry in Gresham College, informs us that, directing his twelve-feet telescope (which could magnify only about seventy times) to the Pleiades, he did in that small compass count seventy-eight stars; and making use of longer and more perfect telescopes, he discovered a great many more of different magnitudes.

---

* A telescopic view of the Pleiades is exhibited in the Appendix.

† "Quæ septem dici, sex tamen esse solent."

The ingenious Mr. Mitchell, more than fifty years ago, started the idea of the stars being formed into groups or systems which are entirely detached from one another, and have no immediate connection. In reference to the Pleiades, he conducted his reasoning as follows:—"The Pleiades are composed of six remarkable stars, which are placed in the midst of a number of others that are all between the third and sixth magnitudes; and comparing this number six with the whole number visible in the heavens to the naked eye, he calculated, by the doctrine of chances, that among all this number, if they had been dispersed arbitrarily through the celestial vault, it was about five hundred millions to one that six of them should be placed together in so small a space. It is therefore so many chances to one that this distribution was the result of design, or that there is a reason or cause for such an assemblage."

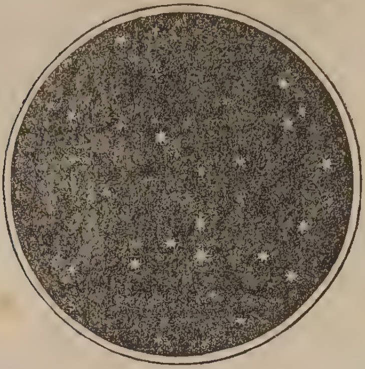
The constellation called *Coma Berenices* is another group, more diffused than the Pleiades, which consists chiefly of small stars which can scarcely be distinguished in the presence of the moon. This beautiful cluster lies about five degrees east of the equinoctial colure, and midway between the star *Cor Caroli* on the north-east, and Denebola, in the Lion's tail, on the south-west. If a straight line be drawn from *Benetnasch*—the star at the extremity of the tail of the Great Bear—through Cor Caroli, and produced to Denebola, it will pass through this cluster. It may also be distinguished as situated about twenty-six degrees west by north from the bright star *Arcturus*. The confused luster of this assemblage of small stars bears a certain resemblance to that of the Milky Way, and, beside the stars of which it is chiefly composed, it contains a number of nebulæ. Sir W. Herschel supposes that the stratum of nebulæ in this quarter runs out a very considerable way, and that it may even make the circuit of the heavens, though not in one of the great circles of the sphere. He also supposes that the situation of the stratum is nearly at right angles with the great sidereal stratum in which the sun is placed, that the Coma itself is one of the clusters in it, and that it is on account of its nearness that it appears to be so scattered. He apprehends that the direction of it toward the north lies probably, with some windings, through the Great Bear onward to Cassiopeia, thence through the girdle of Andromeda and the Northern Fish, proceeding toward Cetus; while toward the south it passes through the Virgin, probably on to the tail of Hydra and Centaurus.

Another group, somewhat similar, but less definite, is found in the constellation of Cancer; it is called *Præsepe*, or the Bee Hive, and is a nebulous cluster of very minute stars, not separately distinguishable by the naked eye. A telescope of very moderate power, however, easily resolves it into small stars. It is sufficiently luminous to be seen as a nebulous speck by the unassisted eye, and is somewhat like the nucleus of a comet, for which it has frequently been mistaken by ordinary observers. It is situated in a triangular position with regard to Castor and Procyon, or the Little Dog. A line drawn from Procyon in a north-easterly direction meets with Præsepe at the distance of twenty degrees. This line drawn in a north-westerly direction from Præsepe, meets Castor at the same distance. These lines form nearly a right angle, the angular point being in Præsepe. It may otherwise be discovered by means of two stars of the fourth magnitude lying one on either side of it at the distance of about two degrees. It may likewise be found by conceiving a line drawn through Castor and Pollux to the south-east, and continued about fifteen degrees, or three times the distance between Castor and Pollux. This cluster, Sir W. Herschel thinks, belongs to a certain nebulous stratum so placed as to lie nearest us. This stratum runs from ε Cancri toward the south, over the 67th nebula of the *Connoissance des Temps*, which is a very beautiful and much compressed cluster of stars, easily to be seen by any good telescope, and in which he has observed above 200 stars at once in the field of view of his great reflector, with a power of 157. This cluster appearing so plainly with any good common telescope, and being so near to the one which may be seen with the naked eye, denotes it to be probably the next in distance to that within the quartile formed by γ δ η θ. From the 67th nebula, the stratum of Cancer proceeds toward the head of Hydra.

I have seldom contemplated a more brilliant and beautiful view in the heavens than one of the fields of view of this cluster of stars. With a 3½ feet achromatic, and a power of 95, I have counted from fifty to seventy stars. Fifteen or twenty of the most brilliant of these presented beautiful configurations: one of them was an equilateral triangle; another, an isosceles; a third, nearly of the figure of a cone; a fourth, parallel lines, &c. In more than two instances, three brilliant equidistant stars appeared in a straight line, similar to the belt of Orion, while a considerable number of the remaining stars appeared extremely small. With a 6½ feet achromatic, whose object-glass is four inches diameter, and a power of 110, this view was rendered still more brilliant. Several fields of view, nearly of this description may be perceived in this cluster. Fig. 40 represents one of these views, in which some of the smaller stars are omitted. This view was taken with the 3½ feet telescope, having an erect eye-piece. The configurations appear somewhat different in their relations to each other when viewed with an inverting eye-piece.

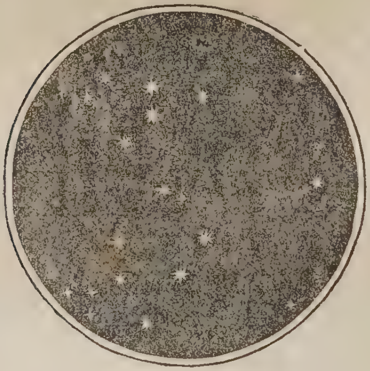
Another cluster is found in the sword-handle of *Perseus*, which is crowded with stars of a smaller size than in the clusters already noticed, and which requires a telescope of greater power to resolve them and show them separated from each other. Perseus is one of the northern circumpolar constellations, nearly opposite to the three stars in the tail of the Great Bear. A line drawn from these stars through the pole-star meets the sword and head of Perseus at nearly an equal distance on the opposite side. It is directly north of the Pleiades, between Andromeda and Auriga. The sword is in the neighborhood of Cassiopeia. A line drawn from *Algenib*, the brightest star in this constellation, to the middle of Cassiopeia, passes through the sword-handle where the cluster is situated, which is about midway between these two objects.

Fig. 40.



If the lowermost of the three small stars which form the *sword* of Orion be viewed with a good telescope, a beautiful configuration of stars will be perceived. Fig. 41 represents the principal stars comprehended in one field of view at this point, as taken with a six feet and a half telescope, with an inverting eye-piece, magnifying 110 times; it exhibits a distant resemblance of the whole constellation of Orion as seen by the naked eye. But in the neighborhood of certain parts of the Milky Way, particularly about the regions in the vicinity of the star *Altair* and in the constellation Cassiopeia, the stars, though smaller, are much more numerous. With a very moderate power on the above-mentioned telescope, I have had fields of view of from fifty to a hundred stars, some of them beautifully arranged, and such fields continued over a space of several degrees.

Fig. 41.



The above may be considered as specimens of groups of stars, which every one possessed of telescopes may easily examine for himself. They form very beautiful objects for exhibiting to young people and to amateurs in astronomy; and it cannot but strike the mind with wonder and admiration to behold, in one point of view, within a space little more than that of the *one-fifth* of the apparent size of the moon, nearly a hundred resplendent suns emitting their effulgence from regions immeasurably distant, and arranged in beautiful symmetry and order—a scene of creating power surpassing in grandeur ten thousand worlds such as ours, and in which our whole planetary system would appear only as the smallest twinkling star. Such telescopic views of the nocturnal heavens have a tendency to expand the capacity of the soul, to inspire it with magnificent conceptions, and to raise its affections above the low ambition and paltry concerns of this transitory scene to the distant and more magnificent scenes of the Divine empire. To the devout and contemplative philosopher the following lines of the poet may be applied:

> "Not to this evanescent speck of earth
> Poorly confined—the radiant tracks on high
> Are his exalted range; intent to gaze
> Creation through, and from that full complex
> Of never-ending wonders to conceive
> Of the sole Being right, who spoke the word,
> And Nature moved complete."
> THOMSON'S *Summer.*

Sir W. Herschel makes a distinction between *groups* and *clusters* of stars. A group is a collection of stars closely and almost equally compressed, and of any figure or outline. There is no particular condensation of the stars to indicate the existence of a central force, and the groups are sufficiently separated from neighboring stars to show that they form peculiar systems of their own. According to this definition, the congeries of stars I have pointed out above are to be considered as belonging to the class of *groups*. *Clusters* of stars differ from groups in their beautiful and artificial arrangement. Their form is generally round, and their condensation is such as to produce a mottled luster somewhat resembling a nucleus. The whole appearance of a cluster indicates the existence of a central force, residing either in a body or in the center of gravity of the whole system. The stars of which it is composed appear more and more accumulated toward the center.

Many such clusters are found in the heavens invisible to the naked eye, and whose existence as dim specks of light can only be recognized by the assistance of optical instruments. Telescopes of moderate power exhibit them only as small round or oval specks, somewhat resembling comets without tails; but when these objects are examined with telescopes of great power, "they are then," as Sir John Herschel remarks, "for the most part, perceived to consist entirely of stars crowded together so as to occupy almost a definite outline, and to run up to a blaze of light in the center, where their condensation is usually the greatest." "Many of them, indeed, are of an exactly round figure, and convey the complete idea of a globular space filled full of stars, insulated in the heavens, and constituting in itself a family or society apart from the rest, and subject to its own internal laws. It would be a vain task to attempt to count the stars in one of these *globular clusters*. They are not to be reckoned by hundreds; and on a rough calculation, grounded on the apparent intervals between them at the borders (where they are seen not projected on each other) and the angular diameter of the whole group, it would appear that many clusters of this description must contain at least ten or twenty thousand stars, compacted and wedged together in a round space, whose angular diameter does not exceed eight or ten minutes—that is to say, in an area not more than a tenth part of that covered by the moon." The stars composing such clusters appear to form a system of a peculiar and definite character. "Their round figure clearly indicates the existence of some general bond of union in the nature of an attractive force, and in many of them there is an evident acceleration in the rate of condensation as we approach the center, which is not referable to a merely uniform distribution of equidistant stars through a globular space, but marks an intrinsic *density* in their state of aggregation, greater at the center than at the surface of the mass."

Let the reader pause for a moment on the object now described, and consider the glimpse it affords us of the immensity of the universe, and of the innumerable globes of light with which it is replenished. A point in the firmament, scarcely perceptible to the unassisted eye, which a common telescope shows only as a small dim round speck, yet is found by powerful instruments to consist entirely of stars to the number of *ten or twenty thousand!* And at what a distance must such a cluster be when its stars appear to be blended and projected one upon another, hundreds of them appearing only like a lucid point! and yet the distance between any two of them is perhaps ten thousand times greater than that of Saturn from our globe. From such a region even light itself must take many thousands of years ere it can reach our world. In this almost invisible point, which not one out of fifty thousand, or even one out of a million of earth's inhabitants has yet perceived, what a scene of grandeur and beneficence may be displayed; and what a confluence of suns, and systems, and worlds and intelligences of various orders, may exist, displaying the power and wisdom and goodness of the great Father of all! Every circumstance connected with such an object shows that its distance must be immeasurably great, and consequently the luminaries of which it is composed immense in magnitude. But suns of such size and splendor cannot be supposed to be thrown together at random through the regions of infinity, without any ultimate design worthy of the Creator, or without relation to the enjoyments of intelligent existence; and therefore we may reasonably conclude that ten thousand times ten thousands, and myriads of myriads of exalted intelligences exist in that far distant region, compared with the number of which all the inhabitants of our globe are but "as the drop of a bucket, or as the small dust of the balance."

In short, in this dim and almost imperceptible speck we have concentrated a confluence of suns and worlds, at least ten times surpassing in size and splendor the sun, moon, and planets, and all the stars visible to the naked eye throughout all the spaces of our firmament! What then must be the number and magnitude of all the other clusters which the telescope has brought to view? what the number of those which lie beyond the limits of human vision in the unexplorable regions of immensity? and what must the UNIVERSE itself be, of which all those numerous starry systems are but an inconsiderable part? Here the human faculties are completely lost amidst the immensity of matter, magnitude, motion, and intelligent existence, and we can only exclaim, "Great and marvelous are thy works, Lord God Almighty!"

Figure 41 represents a view of one of the clusters alluded to above, as seen in the twenty-feet reflector at Slough. Sir J. Herschel, who has given a delineation of it in his "Treatise on Astronomy," says, "it represents, somewhat rudely, the thirteenth nebula of Messier's list, described by him as *nebuleuse sans etoiles.*" Its right ascension is 16h. 36′; and its north declination, 36° 46′; by which its place may easily be found on a celestial globe. It is situated on the constellation Hercules, between the stars η and ζ. These stars are of the third magnitude, and lie north and south of each other, at the distance of seven degrees and a third; they come to the meridian about the middle of July, at nine o'clock in the evening, but of course may be seen at many other periods of the year, particularly in the spring and autumn. The star η lies about twenty-two degrees nearly due west from the bright star *Vega* or α Lyræ. In the map of the stars on Plate II, it is marked with the letter *a*, and the star ζ below it with the letter *b*. The cluster is somewhat nearer to η, or the upper star, than to the other. It is just perceptible to the naked eye, and with a telescope of small power, such as a common "night and day telescope," it appears like a small round comet.

The following is a list of the places of six of the principal clusters of this description, which may be considered as specimens of these remarkable objects:

1. Right ascension, 15h. 10′; north declination, 2° 44′. This cluster lies about eight degrees south-west from *Unuk*, the principal star in the Serpent, and comes to the meridian, about the middle of June, at nine o'clock in the evening.

2. Right ascension, 13h. 34′; north declination, 39° 15′; between the tail of Chara and the thigh of Bootes, about twelve degrees north-west of Arcturus, nearly on a line between that star and *Cor Caroli*, but nearer Arcturus.

3. Right ascension, 13h. 5′; north declination, 19° 5′; in Coma Berenices, fourteen degrees west by south of Arcturus. A line drawn from Arcturus through η Bootes meets this cluster at somewhat more than double the distance of these two stars.

4. Right ascension, 17h. 29′; south declination, 3° 8′; between the stars γ and μ of Sepentarius, but nearer to the latter.

5. Right ascension, 21h. 25′; south declination, 1° 34′; in Aquarius, about 2 degrees north of η in the west shoulder, nearly in a line with ε *Pegasi* or *Enif*.

6. Right ascension, 21h. 22′; north declination, 11° 26′. This cluster lies north from No. 5, at the distance of thirteen degrees, and about three or four degrees north-west of the star *Enif*, or ε Pegasi.

Such are a few specimens of *compressed* clusters of stars. Sir W. Herschel has given a catalogue of more than a hundred of such clusters dispersed over different parts of the heavens, many of which require powerful telescopes to resolve them into stars. These clusters may be considered as so many distinct *firmaments*, distributed throughout the spaces of immensity, each of them comprising within itself an assemblage of stars far more numerous than what appears to the vulgar eye throughout the whole face of our nocturnal sky. To those intelligences that reside near the center of such clusters, the stars connected with their own cluster or system will be those which they will chiefly behold in their sky; and in those clusters which are of a globular form, the stars will appear nearly equally dispersed over the face of their firmament. In those starry assemblages which show a great compression about the center, an immense number of stars of the first magnitude will decorate their sky, and render it far more resplendent than that with which we are surrounded—another instance of that *variety* which distinguishes all the scenes of creation. Scarcely any other star will be visible except those which belong to their own system. If the magnificent system of stars with which our sun is connected be at all visible, it will only appear like a dim and inconsiderable speck in the remote regions of immensity, or as a small cluster or nebula, such as those we perceive with difficulty through our telescopes. Such are the grand, the diversified, and wonderful plans of the Creator throughout his vast and boundless universe.

CHAPTER XII.

ON THE DIFFERENT ORDERS OF THE NEBULÆ.

SECTION I.

GENERAL REMARKS ON THE SUBJECT OF NEBULÆ.

THE farther we proceed in our researches into the sidereal heavens, the scene of Creating Power and Wisdom becomes more expansive and magnificent. At every step of our progress the prospect enlarges far beyond what we had previously conceived; the multitude and variety of its objects are indefinitely increased; new suns and new firmaments open to view on every hand, overwhelming the mind with astonishment and wonder at the immensity of Creation, and leaving it no room to doubt that, after all its excursions, it has arrived only at "the frontiers of the Great Jehovah's kingdom." Wherever we turn our eyes amid those higher regions, infinity appears to stretch before us on either hand, and countless assemblages of the most resplendent objects are everywhere found diversifying the tracts of immensity. To investigate such objects in relation to their number, magnitude, motion, and the laws by which they are united and directed in their movements, completely baffles the mathematician's skill, and sets all his hitherto acquired powers of analysis at defiance, and demonstrates that we are still in the infancy of knowledge and of being. Here, all finite measures fail us in attempting to scan such amazing objects, and to penetrate into such unfathomable recesses; length, breadth, depth, and hight, and time and space, are lost. We are justly filled with admiration at the amazing grandeur of the Milky Way, where suns and worlds are counted by MILLIONS. When exploring its dimensions and sounding its profundities, we seem to have got a view of a universe far more expansive than what we had previously conceived to be the extent of the whole creation. But what shall we say if this vast assemblage of starry systems be found to be no more than *single nebula*, of which several thousands, perhaps even richer in stars, have already been discovered! and that it bears no more proportion to the whole of the sidereal heavens around us, than a small dusky speck which our telescopes enable us to descry! Yet such is the conclusion which we are led to deduce from the discoveries which have been lately made respecting the different orders of the nebulæ, of which I shall now proceed to give a brief description.

The word *nebula* literally signifies a *cloud*, or mist. This name is now used in astronomy to denote certain small spots, resembling whitish clouds, which are seen in the starry heavens by the telescope, and which present different kinds of appearances; either that of single stars enveloped in a nebulous vail, or of groups of small stars, or only the appearance of a shining or glittering cloud: which last are the nebulæ properly so called. The following are some general observations on the Nebulæ by Sir William Herschel. The success which accompanied the observations of this eminent astronomer in reference to the Milky Way, induced him to turn his telescope to the nebulous parts of the heavens, of which an accurate list had been published in the *Connoissance des Temps** for 1783 and 1784. Most of these yielded to a Newtonian reflector of 20 feet focal distance, and 12 inches aperture, which plainly discovered them to be composed of stars, or at least to contain stars, and to show every other indication of their consisting of them entirely.

"The nebulæ," says he, "are arranged into strata, and run on to a great length; and some of them I have been able to pursue, and to guess pretty well at their form and direction. It is probable enough that they may surround the whole starry sphere of the heavens, not unlike the Milky Way, which undoubtedly is nothing but a stratum of fixed stars. And as this latter immense starry bed is not of equal breadth or luster in every part, nor runs on in one straight direction, but is curved and even divided into two streams along a very considerable portion of it, we may likewise expect the greatest variety in the strata of the clusters of stars and nebula. One of these nebulous beds is so rich, that in passing through a section of it, in the time of only thirty-six minutes, I have detected no less than thirty-one nebulæ all distinctly visible upon a fine blue sky. Their situation and shape, as well as condition, seem to denote the greatest variety imaginable. In another stratum, or perhaps a different branch of the former, I have seen double and treble nebulæ variously arranged; large ones with small, seeming attendants; narrow but much extended lucid nebulæ or bright dashes; some of the shape of a fan, resembling an electric brush issuing from a lucid point; others of the cometic shape, with a seeming nucleus in the center, or like cloudy stars surrounded with a nebulous atmosphere. A different sort again contain a nebulosity of the milky kind, like that wonderful inexplicable phenomenon about θ Orionis; while others shine with a fainter mottled kind of light, which denotes their being resolvable into stars."

---

* *Connoissance des Temps*, or as it is sometimes written, *Connaissance des Tems*, literally signifies *the knowledge of time*. It is the title of an Almanac, or astronomical ephemeris, published at Paris, on nearly the same plan as the "Nautical Almanac," published at London. The following is the title of one published in the year 1825:—"Connaissaince des Tems, ou des Movemens Celestes, a l'Usage des Astronomes et des Navigateurs, pour l'an 1828. Publiee par le Bureau des Longitudes." It contains 216 pages.

"In my late observations on nebulæ," says Sir William on another occasion, "I have found that I generally detected them in certain directions rather than in others; that the spaces preceding them were generally quite deprived of their stars, so as often to afford many fields without a single star in it; that the nebulæ generally appeared some time after among stars of a certain considerable size, and but seldom among very small stars; and when I came to one nebulæ, I generally found several more in the neighborhood; that afterward a considerable time passed before I came to another parcel. These events being often repeated in different altitudes of my instrument, and some of them at considerable distances from each other, it occurred to me that the intermediate spaces between the sweeps might also contain nebulæ; and finding this to hold good more than once, I ventured to give notice to my assistant at the clock that 'I found myself on nebulous ground.'" From these observations of Herschel, it appears that the nebulæ are not dispersed indiscriminately through the heavens, but are found in certain regions and directions rather than in others, and that, as formerly stated, they probably make the circuit of the heavens, intersecting at a certain angle the Milky Way.

More than eighty years ago, it was suggested by the celebrated mathematician and astronomer, M. Lambert, in his "Letters on Cosmogony," that all the stars in the universe are collected into systems; that all the systems are in motion; that the individual stars or suns of each system move round a common center of gravity, which may possibly be a large opaque globe; and that all the systems of the universe, as one related system, revolve around some GRAND CENTER, common to the whole. "All those systems of worlds," says this astronomer, "resemble, though on a small scale, the solar system, inasmuch as in each the stars of which it is composed revolve round a common center, in the same manner as the planets and comets revolve round the sun. It is even probable that several individual systems concur in forming more general systems, and so on. Such, for example, as are comprehended in the Milky Way, will make component parts of a more enlarged system; and this way will belong to other milky ways, with which it will constitute a whole. If these last are invisible to us, it is by reason of their immense distance. It would not be at all astonishing, if milky ways, situated still farther from us in the depth of the heavens, should make no impression on the eye whatever." Again—"The sum of the milky ways, taken together, have their common center of revolution; but how far soever we may thus extend the scale we must necessarily stop at last; and where? At the center of centers, at the center of creation, which I should be inclined to term the capital of the universe, inasmuch as thence originates motion of every kind, and there stands the great wheel in which all the rest have their indentation. From thence the laws are issued which govern and uphold the universe, or, rather, there they resolve themselves into one law of all others the most simple. But who would be competent to measure the space and time which all the globes, all the worlds, all the worlds of worlds, employ in revolving round that immense body—the Throne of Nature and the Footstool of the Divinity! What painter, what poet, what imagination is sufficiently exalted to describe the beauty, the magnificence, the grandeur of this source of all that is beautiful, great, magnificent, and from which order and harmony flow in eternal streams through the whole bounds of the universe."

The discoveries made by Sir W. Herschel in reference to the nebulæ have in part realized some of the views suggested by Lambert in regard to the general arrangements of the systems of the universe. They afford convincing evidence that the stars are not dispersed as it were at random, in a kind of magnificent confusion, but are distributed systematically, in immense clusters, throughout the regions of boundless space.

There are various forms and classes of nebulæ which we shall notice in the sequel, but they may all be reduced to two great classes,—the *resolvable* and *irresolvable;* that is, those which may be resolved into clusters of stars by powerful telescopes, and those which no telescope hitherto constructed has yet been able to resolve into starry groups.

Prior to Sir W. Herschel's observations on the nebulæ, about a hundred of these objects had been descried in different parts of the heavens, of which an account had been given by Messier, as formerly stated. About 2000 more were afterward discovered by the unwearied exertions of our British astronomer, a description of which was inserted at different periods in the Philosophical Transactions. The places of these were afterward computed from his observations, and arranged into a catalogue, in the order of right ascension, by his sister, Miss Caroline Herschel; a lady singularly eminent for her astronomical knowledge, who assisted him in all his sidereal labors and discoveries, and was herself a discoverer of several interesting celestial phenomena, particularly comets. Her illustrious nephew, Sir John Herschel, read a paper before the Royal Society in November, 1833, in which he gives the places of 2500 nebulæ, or clusters of stars, of which 500 were detected by his own observations, the rest having been accurately determined by his father. Beside these, more than 500 nebulæ have been discovered in the southern hemisphere of the heavens, of which the Magellanic clouds are the most conspicuous and the most remarkable. They are three in number, two of them being near each other; the largest is at a considerable distance from the south pole, but the other two are only eleven degrees distant. To the naked eye, they appear like portions of the Milky Way.

These nebulæ have great variety of forms: some are comparatively bright, and others so obscure as to render it difficult to detect them in the field of the telescope, or to ascertain their shape. Some of them appear round, some oval, and others of a long elliptic shape; some exhibit an annular form, like luminous rings, and others like an ellipsis with a dark space in the center; but the greater number approximate to a roundish form. Of the 103 nebulæ inserted in Messier's list, eighteen were known at the time to consist of small stars; but Sir W. Herschel afterward found twenty-six more of them to consist purely of clusters of stars, eighteen of small stars accompanied with nebulosity, and the remainder not resolvable into stars by the highest powers of his telescopes. It is evident that these objects, however apparently small and obscure, must be bodies of *immense magnitude*, when we take into consideration the vast distance at which they must be placed from our globe. The following are Sir W. Herschel's views on this point:

"My opinion of their size is grounded on the following observations:—There are many round nebulæ of about five or six minutes in diameter, the stars of which I can see very distinctly; and on comparing them with the visual ray calculated from some of my long gauges, I suppose, by the appearances of the small stars in those gauges, that the centers of these round nebulæ may be 600 times the distance of Sirius from us." He then goes on to show that the stars in such nebulæ are probably twice as much condensed as those of our system, otherwise the center of it would not be less than 6000 times the distance of Sirius, and that it is possibly much underrated by supposing it only 600 times the distance of that star. "Some of these round nebulæ have others near them, perfectly similar in form, color, and the distribution of stars, but of only half the diameter; and the stars in them seem to be doubly crowded, and only at about half the distance from each other. They are indeed so small as not to be visible without the utmost attention. I suppose these miniature nebulæ to be at double the distance from the first. An instance equally remarkable and instructive is a case where, in the neighborhood of two such nebulæ as have been mentioned, I met with a third similar, resolvable, but much smaller and fainter nebula. The stars of it are no longer to be perceived; but a resemblance of color with the former two, and its diminished size and light, may well permit us to place it at full twice the distance of the second, or about four or five times the distance of the first; and yet the nebulosity is not of the milky kind, nor is it so much as difficultly resolvable or colorless. Now in a few of the extended nebulæ, the light changes gradually, so as from the resolvable to approach to the milky kind; which appears to me an indication that the milky light of nebulæ is owing to their much greater distance. A nebula, therefore, whose light is perfectly milky cannot well be supposed to be at less than six or eight thousand times the distance of Sirius; and though the numbers here assumed are not to be taken otherwise than as very coarse estimates, yet an extended nebula which in an oblique situation, where it is possibly foreshortened by one-half, two-thirds, or three-fourths of its length, subtends a degree or more in diameter, cannot be otherwise than of a *wonderful magnitude*, and may well OUTVIE OUR MILKY WAY IN GRANDEUR."

It appears to be a very natural conclusion, that the nebulæ which are perfectly similar in form, color, and the distribution of stars, but only half the diameter, and the stars doubly crowded, are about *double the distance from the first.* And if the distance of the larger nebulæ, whose stars are distinctly seen, be at least 600 times the distance of Sirius, as there is every reason to believe, then, the distance of those which are only half the diameter must be about 1200 times the distance of that star; that is at the very least, 24,000,000,000,000,000, or twenty-four thousand billions of miles. But the nebulæ whose light is "perfectly milky," or so far removed from us that the stars of which they are composed cannot be separately distinguished, may be justly considered as seven thousand times the distance of Sirius, or, in numbers, 168,000,000,000,000,000, or one hundred and sixty-eight thousand billions of miles!—a distance of which we can have no distinct conception. Light, notwithstanding its amazing velocity, would be nearly thirty thousand years ere it could fly from such nebulæ to the earth, and a cannon ball, with its utmost velocity, would require more than *thirty-eight thousand millions* of years before it could move over an equal space. Since the distance of these nebulæ is so immense, and since those which are amongst the largest and nearest are found by actual observation to be composed of countless numbers of stars, leaving us no room to doubt that the most distant are also immense systems of stars, how great must be *the magnitude*, and how inexpressible the grandeur, of the numerous luminaries of which they are composed!

I have stated above that more than three thousand nebulæ have already been discovered, and whose places in the heavens have been accurately determined, so that those who have access to powerful telescopes may have an opportunity of observing the greater part of them. From all the observations made by Sir W. Herschel, he is of opinion that our nebula, or the Milky Way, is *not* the most considerable in the universe; and he points out some very remarkable nebulæ which in his opinion cannot be less, but are probably *much larger*, than that of which our own sun and system form a part. Now, on these grounds let us consider what must be the extent and magnitude of only the *visible* universe. Supposing the number of stars composing the Milky way, to be ten millions, which is only half the number formerly assigned, (p. 59), and that each of the nebulæ at an average contains the same number; supposing further, that only two thousand of the three thousand nebulæ are resolvable into clusters of stars, and that the other thousands are masses of a shining fluid not yet condensed into distinct luminous globes; the number of stars, or *suns*, comprehended in that portion of the firmament which is within the reach of our telescopes would be 20,000,000,000, or *twenty thousand millions*, which is twenty millions of times the number of all the stars visible to the naked eye.

Great as the number is, and magnificent and overpowering as the ideas are which it suggests of the extent of creation, yet these vast assemblages of systems may be no more than as a single nebula to the whole visible firmament, or even as a grain of sand to the whole earth, compared with what lies beyond the range of human vision, and is hid fom mortal eye in the boundless and unexplored region of immensity! Beyond the boundaries of all that will ever be visible to the inhabitants of our globe, an infinite region exists, in which we have every reason to believe the Deity sits enthroned in all the grandeur of his overflowing goodness and omnipotence, presiding over innumerable systems far surpassing in magnificence what "eye hath yet seen" or the most brilliant intellect can conceive. For we ought never for a moment to surmise that the operations of Almighty Power are exhausted at the point where the efforts of genius and art can no longer afford us assistance in tracing the footsteps of the divinity through the mysterious regions of infinitude; nor should we ever suppose that man, placed on such a diminutive ball as the earth, and furnished with powers of so limited a nature as those with which he is now invested, will ever be able to grasp the dominions of Him who fills immensity with his presence, and "whose ways are past finding out."

SECTION II.

ON THE VARIOUS KINDS OF NEBULÆ.

I HAVE already alluded to the different shapes or forms of nebulæ. These objects, on account of their appearing with different degrees of luster, and assuming a great variety of shapes and modifications, have been arranged into different classes.

1. The first class is that of *clusters of stars*, in

which the separate stars are clearly distinguished by good telescopes. This class is again divided into *globular* clusters, or those which appear of a roundish form, and somewhat compressed toward the center; and *irregular* clusters or those which are neither circular nor elliptical, but of a somewhat indefinite or angular form. These last are generally less rich in stars, and less condensed toward the center, and are likewise less definite in their outline, so that their termination in many cases cannot be distinctly perceived. In some of them the stars are nearly all of the same size, in others extremely different; and "it is no uncommon thing," says Sir J. Herschel, "to find a very red star, much brighter than the rest, occupying a conspicuous situation in them." Sir W. Herschel regards these as globular clusters in a less advanced state of condensation, conceiving all such groups as approaching, by their mutual attraction, to the globular figure, and assembling themselves together from all the surrounding region, under laws of which we have no other proof than the observance of a gradation by which their characters shade into one another, so that it is impossible to say where one species ends and the other begins. Fig. 41, formerly referred to, represents one of the globular clusters in the constellation Hercules. Fig. 42 is a view of a curious but somewhat irregular group, seen in the southern hemisphere, as sketched by Mr. Dunlop, at Paramatta, New South Wales. It is the 30 Doradus, or Xipheas, and is rather a singular object, but evidently a large cluster of stars, presenting two or three very condensed strata, as if they were crowded to excess by an immense confluence of stars.

2. Another class that is termed *resolvable* nebulæ, or those which lead us to suppose that they consist of stars which would be separately distinguishable by an increase of light and magnifying power in the telescope. These may be considered as clusters too remote to be distinctly seen, the stars composing which are either too faint in their light or too small in size to make a definite impression upon the organs of vision. They are almost universally round or oval, which is supposed to be owing to their loose appendages and irregularities of form being extinguished by their distance, the general figure of the central or more condensed parts being only discernible. "It is under the appearance of objects of this character," says Sir J. Herschel, "that all the greater globular clusters exhibit themselves in telescopes of insufficient optical power to show them well; and the conclusion is obvious that those which the most powerful can barely render *resolvable*, would be completely *resolved* by a further increase of instrumental force.

3. Beside the above, there is an immense variety of nebulæ, *properly so called*, which no telescopes have hitherto been able to resolve into stars, and which is supposed to be a species of matter diffused throughout infinite space, in various portions and degrees of condensation and which may in the course of ages, be condensed into stars or starry systems. The following is a description of some of the more remarkable varieties of this class of nebulæ.

Fig. 43 represents a nebula of an elliptical or spindle-like form. It is visible to the naked eye in a clear night, when the moon is absent, and has sometimes been mistaken for a small comet. It appears like a dull, cloudy, undefined spot upon the concave of the firmament, and has sometimes been compared to the light of a small candle shining through horn. Its central parts appear brightest, but its light gradually fades toward each extremity. A few small stars appear adjacent to it, and even within its boundaries, but it appears pretty evident that they have no *immediate* connection with the nebula. Its form, as here delineated, may be seen with a telescope of moderate power, but no telescope hitherto constructed, even with the highest powers that could be applied, has yet been sufficient to resolve it into stars. In size, it is nearly half a degree long, and 12 or 15 minutes broad. Though the figure of this object appears oval or elliptical, it is not unlikely that it is in reality nearly of a globular figure, and that its oval appearance is owing to its position with regard to our eye. This nebula is situated in the girdle of Andromeda, within a degree or two of the star γ of that constellation. It is about 15° nearly west from *Almaach* and 8° north-by-west of *Merach*, with which stars it forms nearly a right-angled triangle It may be seen in a north westerly direction in the evenings of the months of January, February, and March, at a considerable elevation. It comes to the meridian about the middle of November, at nine o'clock in the evening. Its right ascension is 0h. 33'; and north declination, 40° 20'. This nebula may be considered as a representative, on a large scale, of a numerous class of nebulæ, which increases more or less in density toward the central point. The representation of it in the plate is somewhat longer and narrower than it appears through a telescope magnifying 140 times.

PLATE V.

MINIATURE MAP OF THE HEAVENS, ON MERCATOR'S PROJECTION, SHOWING THE COURSE OF THE MILKY WAY.

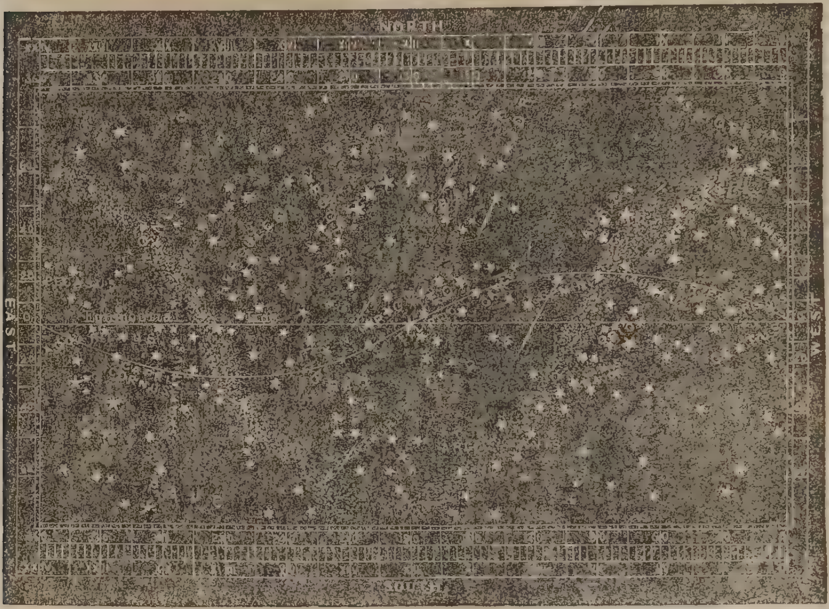


Fig. 44 represents a kind of elliptical nebula, with a vacancy of a lenticular form in the center. It is pretty evident that such nebulæ are in reality large rings, which appear of an oval or lenticular form in consequence of their lying obliquely to our line of vision. This is undoubtedly a large starry system, comprising perhaps millions of stars, at such a distance that their combined light appears only like a faint nebula. It probably is not much unlike the form of our Milky Way in which the sun is situated. Its right ascension is 2h. 12', and north decl. 41° 35'. It lies near γ Andromeda, or *Almaach*, about 4° to the eastward of that star, nearly in a line between it and *Algol*, in the head of Medusa, and about 19° east from the nebula represented in Fig. 43.

Fig. 45 is a representation of an *annular* nebula, which may be seen with a telescope of moderate power. It does not occupy so much space in the heavens as the preceding nebulæ, but it is well defined, and has the appearance of a flat, solid ring. It is not perfectly circular, but somewhat elliptical, the conjugate axis of the ellipse being to the transverse nearly to the proportion of 4 to 5. The opening occupies about half its diameter, and is not entirely dark, but filled up with a very faint hazy light, uniformly spread over it. Its light is not of a pure milky white, but is somewhat mottled in its appearance near the exterior edge. This curious phenomenon, like the preceding, is doubtless an immense stellar system, situated at an immeasurable distance in the profundity of space. It is situated in the constellation of Lyra, exactly half way between the stars β and γ, so that its position may be found by common observers without any difficulty. Its right ascension is 18h. 47'; and north declination 32° 49'. The following cut (fig. 46) represents some of the principal stars in the constellation of the Lyre. The largest star near the upper part is *Vega*, a bright star of the first magnitude; the next larger star, south-by-east of which is ζ; and the other star of the same magnitude to the south-east is γ; between which is the annular nebula, about 7½° from Vega.

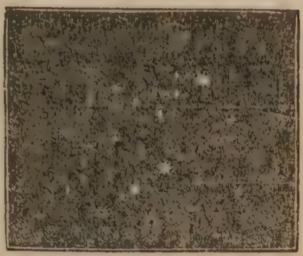
Fig. 46 represents an object somewhat similar to the above. It is situated between the constellations Anser and Cygnus, about 9½° south from the star γ Cygni, and 17° east from the phenomenon described above. Its right ascension is 20h. 9'; and north declination, 30° 3'. It comes to the meridian, about the 10th of September, at nine o'clock in the evening.

The opposite page contains representations of several other kinds of nebulæ, some of which are extremely curious and singular. Fig. 47 is a very singular and wonderful object It has the shape of a dumb-bell or hour-glass of bright matter, surrounded by a thin hazy atmosphere; the two connected hemispheres, and the space which connects them, are beautiful and pretty bright. The oval is completed by a space on each side, which is much more dim and hazy than the two hemispheres. The whole has an oval form, like that of an oblate spheroid. The southern hemisphere is somewhat denser than the northern, and there are one or two stars in it. It appears evidently to be a dense collection of stars, at an immeasurable distance from the region in which we reside, and leads us to form an idea of the endless diversities of shape and form among those countless assemblages of stars with which the universe is replenished. This nebula is situated in right ascension, 19h. 52′; north declination, 22° 16′; in the breast of Anser et Vulpecula, about midway between Albireo in the Swan, and the principal stars of the Dolphin, about three or four degrees north of Sagitta, a star of the fourth magnitude.

Fig. 48 is likewise a very remarkable object. It consists of a bright round nucleus, or central part, surrounded at a great distance by a nebulous ring. This ring appears split through nearly the greater part of its circumference, the two portions of which being separated at about an angle of 45°. This nebula lies near the remotest boundaries to which our telescopes can carry us. It has never been resolved into stars by the highest powers that have yet been applied; but there is little doubt that it is a grand scheme of sidereal systems, perhaps exceeding our Milky Way in number and magnificence. It is indeed supposed to bear a more striking resemblance to the system of stars in which the sun is placed than any other object which has yet been discovered in the heavens, as may be perceived by turning to figure 39, (p. 62), which represents Sir W. Herschel's scheme of the Milky Way; and hence Sir John Herschel describes it as "a brother system, bearing a real physical resemblance and strong analogy of structure to our own." This object, dim and distant as it may appear through our telescopes, and utterly invisible as it is to the unassisted eye, may be considered as a kind of universe in itself, ten thousand times more grand and extensive than the whole creation was supposed to be in the infancy of astronomy. Like the preceding nebula, it shows us what singular varieties of structure are to be found in the systems which compose the universe, and at the same time it exhibits a certain resemblance to another system of which we form a part; and perhaps something similar, though not precisely of the same form and arrangement, may be found in other parts of the sidereal heavens. This phenomenon is situated near the back of Asterion, about five degrees south-by-west of *Benetnasch*, the last star in the tail of the Great Bear; between which star and the nebula there is a small star of the fifth magnitude, nearer to the nebula than to Benetnasch. Its right ascension is 13h. 22′; and north declination, 46° 14′.

Fig. 46.[*]

North.



Figures 49, 50, 52, 53, 54, 55, 56, 57, and 58, represent some specimens of *nebulous stars*, or of nebulæ connected with very small stars.

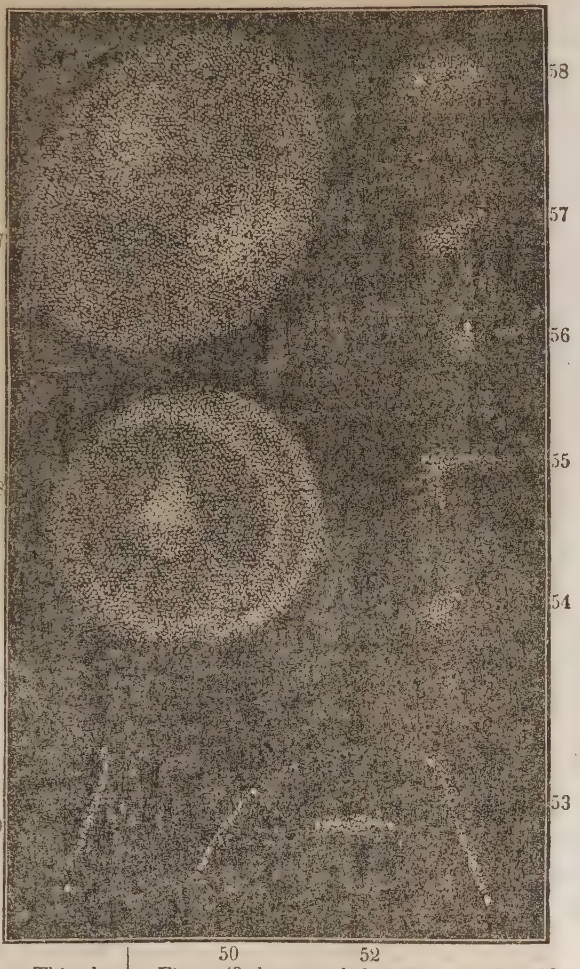


Figure 49 shows a nebulosity, or something like a nebulous stream, extending from one small star to another, as if there was a communication between them. The next three figures are representations of similar phenomena. In figure 52 the nebulous substance appears much broader than in the others, though this may possibly be owing to the nebula in its greatest extent being presented to our line of vision.

---

[*] It may not be improper here to remark, once for all, that the bearings or directions of the stars from one another, given here and in other parts of this volume, are strictly applicable only when the principal star, from which the bearings are stated, is *on or near the meridian*. When in other positions, they will appear to a common observer to have

Figures 54, 55, 56, are very small stars, with faint and small nebulæ attached to them in the shape of a puff. Fig. 57 is a small star, with a small, faint, fan-shaped nebulosity joined to it. Fig. 58 represents two considerable stars involved in a very faint nebulosity of three or four minutes in extent. What this nebulous substance in reality is, or what connection it may have with the stars which appear in its vicinity, it is difficult to conjecture. It is a species of nebulæ which does not appear to be resolvable into stars, and therefore may be regarded as a distinct luminous substance diffused throughout different regions of the universe, subserving some important designs in the physical economy of creation of which we are ignorant. Specimens of some of these phenomena will be found in the following situations:—1. Right ascension, 20h. 56′; north declination, 11° 24′; a little to the east of the cluster of stars called the Dolphin. 2. Right ascension, 8h. 46′; north declination, 54° 25′; about seven degrees north-west of the star *Theta* of the Great Bear. 3. Right ascension, 12h. 51′; north declination, 35° 47′; about four degrees south of the star *Cor Caroli*, the principal star in the Greyhounds. 4. Right ascension, 6h. 30′; north declination, 8° 53′; which is in the head of Monoceros, or the Unicorn, about eleven degrees east of Betelguese, in the right shoulder of Orion, and about seven degrees due south of Gemini, which is in the left foot of one of the twins.

Figures 59 to 65 represent a few specimens of objects which come under the denomination of *extensive diffusive nebulosities* These phenomena were very little noticed until lately, and can only be perceived by telescopes of large aperture, which collect a great quantity of light. In adverting to one of these objects, Sir W. Herschel describes it as follows:—"Extreme faint branching nebulosity; its whitishness is entirely of the milky kind, and it is brighter in three or four places than the rest; the stars of the Milky Way are scattered over it in the same manner as over the rest of the heavens. Its extent in the parallel is nearly one degree and a half, and in the meridional direction about fifty-two minutes." It appears that this diffused nebulosity is very extensive; for of fifty-two nebulæ of this description which had never been before observed, Herschel found them to occupy no less than 152 square degrees. A specimen of an extensive diffusive nebula of this description is represented in fig. 59.

Sir W. Herschel has presented us with fourteen specimens related to this class, of what he terms *nebulosities joined to nebulæ*, one of which is represented in fig. 60, where a bright nebulous speck is connected with a faint nebulosity, which seems to proceed from it as from a central point, increasing in breadth in proportion to the distance, until it terminates in a kind of irregular margin. Fig. 61 represents what is called a *milky nebula with condensation*. It appears to be a roundish nebula, condensed toward the central parts. It is natural to suppose, when we see a gradual increase of light, that there is a condensation of the substance which produces it in the space which appears brightest, or at least that the

---

different bearings; for example, the star *Vega* or Lyra, in the above figure, when about 50 or 60° above the western horizon, will appear at an equal altitude as the star *Beta*, south-west-by-south of it; and when about 30 or 40° above the eastern horizon, the two stars will appear, the one directly above or below the other. This difference in the apparent directions of the stars from each other is most observable in those which are near the pole; for example, the stars of the Great Bear appear in one part of their revolution *west* from the pole, and in another part of their course *east* of it. These and other circumstances require to be attended to, in order to find particular stars by their bearings from one or more principal stars.

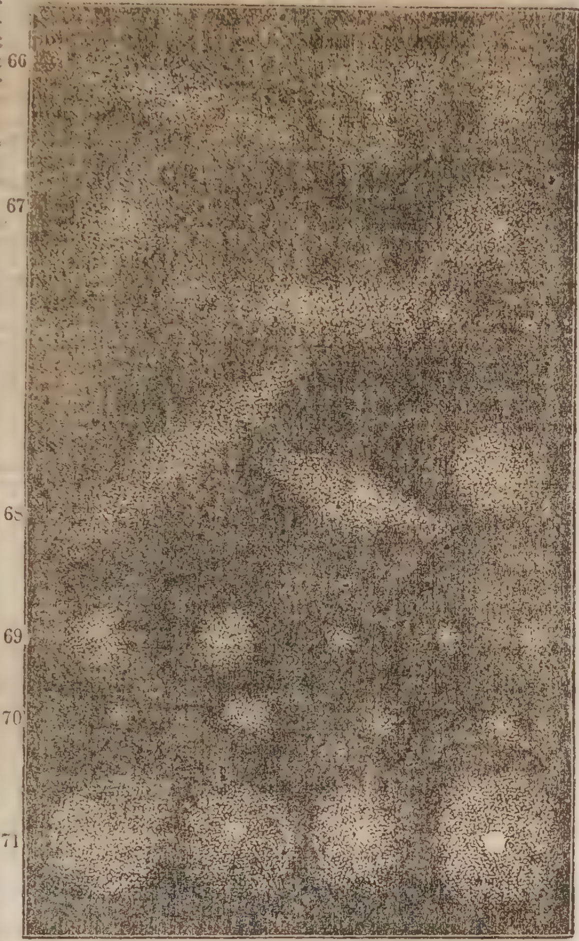
luminous substance is *deeper* in the brighter space. Some of the nebulosities of this class are not always extensively diffused, but are sometimes met with in detached collections, near to each other, but completely separate, as represented at *a*, *b*, *c*, fig. 62.

A diffused nebulosity of this kind may be seen about six or seven degrees due east from the star ***Zeta*** Cygni, near the back or tail of Anser. Its right ascension is 20h. 58′, and north declination 30° 6′. Another, whose right ascension is 20h. 49′, and north declination 31° 3′, is found about three or four degrees north-west of ***Zeta*** Cygni, and within two or three degrees of the preceding.

Figures 63, 64, and 65, are representations of nebulæ which are brighter in more than one place, which appearance is supposed to be owing to so many predominant seats of attraction, owing to a superior preponderance of the nebulous matter in those places, causing a division of it, from which will arise three or four distinct nebulæ.

Figures 66 to 71 are representations of nebulæ of various descriptions. The three upper figures, numbered 66, are nebulæ that are *suddenly much brighter in the middle*. A nucleus to which these nebulæ seem to approach is considered as indicating consolidation; and that, should we have reason to conclude that a solid body can be formed of condensed nebulous matter, the nature of which has been chiefly deduced from its shining quality, we may possibly be able to view it with respect to some other of its properties. The three figures, No. 67, represent *extended nebulæ and round nebulæ, that show the progress of condensation*. These nebulæ appear further condensed than the preceding, and appear surrounded with the rarest nebulous matter, which, not having as yet been consolidated with the rest, remains expanded about the nucleus in the shape of a very extended atmosphere. The three figures in the third row from the top of the plate, marked No. 68, and the first figure to the left hand of No. 69, represent nebulæ which are almost of a uniform light, and nebulæ that draw progressively toward a period of final condensation. "In the course of the gradual condensation of the nebulous matter," says Sir W. Herschel, "it may be expected that a time must come when it can no longer be compressed, and the only cause which we may suppose to put an end to the compression is, when the consolidated mass assumes hardness. From the size of the nebulæ, as we see them at present, we cannot form an idea of the original bulk of the nebulous matter they contain; but let us admit, for the sake of computation, that the nebulosity of a certain nebula, when it was in a state of diffusion, took up a space of ten minutes in every cubical direction of its expansion, then, as we now see it collected into a globular compass of less than one minute, it must of course be more than 1900 times denser than it was in its original state. This proportion of density is more than double that of water to air."

The small nebulæ represented in No. 70 are *stellar nebulæ*, which approach to the appearance of stars, and one or two of doubtful character. The four figures marked No. 71, represent separate views of the gradual condensation of the nebulous substance. In these we may evidently perceive a striking gradation in the light and brilliancy of the central parts. The figure on the left-hand side represents an object nearly in its original state of nebulosity; the next toward the right appears considerably condensed toward the central parts; the third figure represents a condensation still greater; and the one on the right-hand exhibits a condensation nearly complete, or a huge luminous body surrounded with a lucid atmosphere. Each of these is the representative of an extensive class of objects of this description.



SECTION III.

On planetary nebulæ.

This designation is given to a class of nebulæ which bear a very near resemblance to planetary discs when seen through telescopes. But, notwithstanding their planetary aspect, some small remaining haziness, by which they are more or less surrounded, evinces their nebulous origin. They are somewhat extraordinary objects, with round or slightly oval discs, in some instances quite sharply terminated, in others, a little hazy at the borders, and of a light exactly equable, or only a very little mottled, which in some of them approaches in vividness to the light of actual planets. The following are some of Sir W. Herschel's remarks on these bodies:—If we should suppose them to be single stars with large diameters, we shall find it difficult to account for their not being brighter, unless we should admit that the intrinsic light of some stars may be very much inferior to that of the generality, which, however, can hardly be imagined to extend to such a degree. We might suppose them to be comets about their aphelion, if the brightness as well as the magnitude of their diameters did not oppose this idea; so that, after all, we can hardly find any hypothesis so probable as that of their being nebulæ; but then they must consist of stars that are compressed and accumulated in the highest degree. At a subsequent period Sir William remarks, "When we reflect on the circumstances connected with these bodies, we may conceive that, perhaps, in progress of time these nebulæ which are already in a state of compression may be still farther compressed so as actually to become stars. It may be supposed that solid bodies such as we suppose the stars to be, from the analogy of their light with that of our sun when seen at the distance of the stars, can hardly be formed of a condensation of nebulous matter; but if the immensity of it required to fill a cubical space which will measure ten minutes, when seen at the distance of a star of the eighth or ninth magnitude, is well considered, and properly compared with the very small angle our sun would subtend at the same distance, no degree of rarity of the nebulous matter to which we have recourse can be any objection to the solidity required for the construction of a body of equal magnitude with our sun."

The nature of these nebulæ is involved in considerable darkness and mystery. As in the case of some of the other species of these phenomena, so in this, the mind feels unable to form any definite or satisfactory conceptions on the subject. The following remarks of Sir J. Herschel comprise most of what can be stated, in the meantime, on this subject:—"Whatever be their nature, they must be of enormous magnitude. One of them is to be found in the parallel of ν Aquarii, and about five minutes preceding that star. Its apparent diameter is about twenty seconds. Another, in the constellation Andromeda, presents a visible disc of twelve seconds perfectly defined and round. Granting these objects to be equally distant from us with the stars, their real dimensions must be such as would fill, on the lowest computation, *the whole orbit of Uranus*. It is no less evident that, if they be solid bodies of a solar nature, the intrinsic splendor of their surfaces must be almost infinitely inferior to that of the sun's. A circular portion of the sun's disc, subtending an angle of twenty seconds, would give a light equal to 100 *full moons*, while the objects in question are hardly, if at all, discernible with the naked eye. The uniformity of their discs, and their want of apparent central condensation, would certainly augur their light to be merely superficial, and in the nature of a hollow superficial shell; but whether filled with solid or gaseous matter, or altogether empty, it would be a waste of time to conjecture."

In this description there is nothing which strikes the mind with such astonishment as the *enormous magnitude* of these planetary nebulæ. A globular body which would fill the orbit of Uranus would contain 24,429,081,600,000,000,000,000,000,000, or more than twenty-four thousand *quartillions* of solid miles. The solid contents of the sun is about 357,000,000,000,000,000, or three hundred and fifty-seven thousand *billions* of cubical miles. If the former number be divided by the latter, the quotient will be 68,428,800,000, showing that the nebula in question would contain within its circumference sixty-eight thousand, four hundred and twenty eight millions, and eight hundred thousand globes as large as the SUN. A body of such bulk is more than thirty-four billions, two hundred thousand millions of times larger than all the primary planets and their satellites which belong to our system. What is the special destination of such huge masses of matter, or what important designs they subserve in the physical and moral arrangements of the Governor of the universe, it is beyond our power, in the meantime, to form even a probable conjecture. Future generations may perhaps be enabled to throw some light on this subject, though it is probable that the nature, properties, and ultimate designs of many such objects will only be fully disclosed throughout the revolutions of that interminable duration which succeeds the short span of human existence; but of this we may rest assured, that they are *not useless* masses of materials in the universe, but are subservient to purposes worthy of Him whose wisdom is infinite, and whose understanding is unsearchable.

The four figures toward the right-hand of the plate, marked No. 69, represent some specimens of planetary nebulæ. One of those bodies may be seen near the star ν Aquarii, as above stated. Its right ascension is nearly 20h. 52′, and its south declination about 12° 26′. It lies north by west of the star *Deneb Algedi*, at the distance of about ten degrees. Other nebulæ of this description may be found near the following stars:—3 *p* Sagittæ, 14 Andromeda, 63 *b* Crateris, 61 *g* Sagittæ, 10 Camelopardus, 36 Ursæ Majoris, 6 Navis, and 6 Draconis. About three minutes west from the star 16 *c* Cygni the following phenomenon is found:—A bright point a little extended, like two points close to each other. It is as bright as a star of the eighth or ninth magnitude, surrounded by a very bright milky nebulosity, suddenly terminated, having the appearance of a planetary nebula with a lucid center. The border is not well-defined; it is perfectly round, and about one minute and thirty seconds in diameter. This is a beautiful phenomenon, and of a middle species between the planetary nebulæ and nebulous stars.

Sir John Herschel, during his late residence at the Cape of Good Hope, is said to have discovered several new and singular objects in the southern hemisphere, some of them bearing a certain relation to the objects now described; among others, he is said to have detected a beautiful planetary nebula, which presents a perfectly sharp, well-defined disc of uniform brightness, exhibiting the exact appearance of a small planet with a satellite near its margin. The regular compactness and globular form of such objects seem to indicate that they are bodies *sui generis*, neither collections of distinct stars nor exactly of the same nature with the other masses of nebulous matter dispersed through the heavens. They seem to present a view of an immense system already completed, but of what nature it would be vain to conjecture. Another phenomenon of this kind is stated as being of an extraordinary nature, on account of the *blue* color which its light exhibits. He has likewise discovered a close double star involved in the center of a nebulous atmosphere, which is considered as a new and singular object.

SECTION IV.

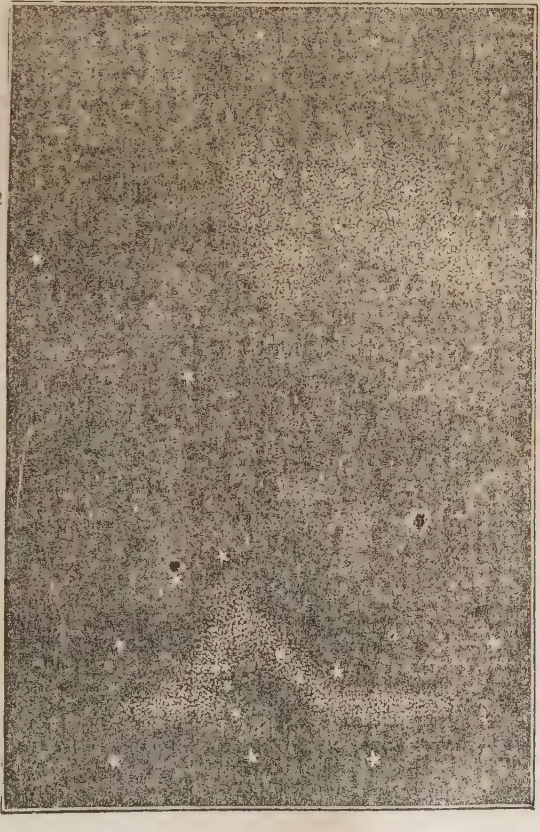
ON THE NEBULA IN ORION.

ONE of the largest and most remarkable nebula in the heavens is that which is found in the constellation of Orion. When a common observer looks at that constellation, the first object that arrests his attention is the three brilliant stars equidistant from each other in a straight line, which is called the *belt* of Orion. Immediately below these, hanging down as it were from the middle of the belt, three small stars at nearly equal distances are perceived, which are termed *the sword.* On directing the naked eye to the middle star of the three, the observer perceives something that has the appearance of a small star, but not well-defined; this is the great nebula of Orion; of which, however, he can form no definite conception until his eye be assisted by optical instruments. With a common one-foot pocket achromatic telescope the nebulosity may be plainly perceived; but the higher the magnifying power, and the larger the aperture of the object-glass, the more brilliant and distinct does this phenomenon appear, along with a number of small stars connected with it, which are quite invisible to the unassisted eye.

The first who discovered this phenomenon was the celebrated Huygens, who gave the following description of it in his *Systema Saturnium :*—"Astronomers place three stars close to each other in the sword of Orion; and when I viewed the middlemost with a telescope in the year 1656, there appeared, in the place of that one, twelve other stars; among these, three that almost touch each other, and four more beside appeared twinkling as through a cloud, so that the space about them seemed much brighter than the rest of the heavens, which appearing wholly blackish, by reason of the fair weather, was seen as through a certain opening, through which one had a free view into another region which was more enlightened. I have frequently observed the same appearance in the same place, without any alteration; so that it is likely that this wonder, whatever it may be in itself, has been there from all times; but I never took notice of anything like it among the rest of the fixed stars."

Fig. 72 exhibits a view of this phenomenon as seen by Dr. Long in 1741 with a seventeen-feet refracting telescope, which appears exactly the same shape as originally delineated by Huygens; but the apparent magnitudes of the stars connected with it are more accurately shown than in the engraved delineation of Huygens. Dr. Long says that the luminous space has sometimes appeared to him nearly of the same shape as the figure which is formed by the seven stars within it. Fig. 73 represents the same nebula, as seen by Sir W. Herschel in the year 1774 and in 1811. Its shape appears considerably different from the delineations of Huygens and Dr. Long; but the stars within and around it, which are common to both delineations, appear nearly in the same relative position. Sir John Herschel has given a representation of this nebula, as viewed through the twenty-feet reflector at Slough, which appears considerably different from the figures to which I have referred. I have frequently viewed this phenomenon with telescopes of differen sizes, particularly with a six feet and a half achromatic, having an aperture of four inches diameter, and which showed sidereal objects with great brilliancy and distinctness; but the shape of the object appeared more nearly resembling Dr. Long's representation (fig. 72) than any other delineation I have seen. A fourth star was distinctly seen in addition to the three represented by Dr. Long near the head of the opening, but smaller than the other three, and forming with them a small irregular square. The three other stars, instead of being *within* the one side of the nebula, as represented in both the figures, appeared quite beyond it, but nearly in a line with its margin. Whether this was owing to the inaccuracy of the delineation or to the actual change of the nebula I do not pretend to determine. The left-hand branch of the nebula likewise appeared considerably longer than here represented; but I cannot pretend to say what the appearance may be as seen through a twenty-feet reflecting telescope.

In forming a proper conception of this object, it is of some importance to ascertain the exact appearance it has presented at different periods,



72

73

and whether there be reason to conclude that it has been subject to changes. The following is Sir J. Herschel's description of this phenomenon:

"I know not how to describe it better than by comparing it with a curdling liquid, or a surface strewed over with flocks of wool, or to the breaking up of a mackerel sky, when the clouds of which it consists begin to assume a cirrous appearance. It is not very unlike the mottling of the sun's disc, only, if I may so express myself, the grain is much coarser and the intervals darker, and the flocculi, instead of being generally round, are drawn into little wisps. They present, however, an appearance of being composed of stars, and their aspect is altogether different from that of resolvable nebulæ. In the latter we fancy by glimpses that we see stars, or that could we strain our sight a little more we would see them; but the former suggests no idea of stars, but rather of something quite distinct from them."

The following are some of Sir W. Herschel's remarks on this nebula, and on stars with which it is connected:

"In the year 1774, the 4th of March, I observed the nebulous star which is the 43d of the *Connoissance des Temps*, and is not many minutes north of the great nebulæ; but at the same time I also took notice of two similar, but much smaller, nebulous stars, one on each side of the large one and at nearly equal distances from it.—(See fig. 73, &c.) In 1783, I examined the nebulous star, and found it to be faintly surrounded with a circular glory of whitish nebulosity, faintly joining it to the great nebulæ. About the latter end of that year I remarked that it was not equally surrounded, but most nebulous toward the south. In 1784, I began to entertain an opinion that the star was not connected with the nebulosity of the great nebulæ of Orion, but was one of those which are scattered over that part of the heavens. In 1801, 1806, and 1810, this opinion was fully confirmed by the gradual change which happened in that great nebula to which the nebulosity surrounding the star belongs; for the intensity of light about the nebulous star had by this time been considerably reduced by the attenuation of dissipation of the nebulous matter, and it seemed now to be pretty evident that the star is far behind the nebulous matter, and that consequently its light in passing through it is scattered and deflected so as to produce the appearance of a nebulous star."...."When I viewed this interesting object in December, 1810, I directed my attention particularly to the two nebulous stars by the sides of the large one, and found they were perfectly free from every nebulous appearance, which confirmed not only my former surmise of the great attenuation of the nebulosity, but also proved that their former nebulous appearance had been entirely the effect of the passage of their feeble light through the nebulous matter spread out before them.—The 19th of January, 1811, I had another critical examination of the same object, in a very clear view, through the forty-feet telescope; but notwithstanding the superior light of this instrument, I could not perceive any remains of nebulosity about the two small stars, which were perfectly clear, and in the same situation where about thirty-seven years before I had seen them involved in nebulosity. If, then, the light of these three stars is thus proved to have undergone a visible modification in its passage through the nebulous matter, it follows that its situation among the stars is less distant from us than the largest of the three, which I suppose to be of the eighth or ninth magnitude. The farthest distance, therefore, at which we can place the faintest part of the great nebula in Orion, to which the nebulosity surrounding the star belongs, cannot well exceed the region of the stars of the seventh or eighth magnitude."

From these observations it would appear that the nebulosities connected with the great nebula are subject to certain changes, and that its distance from our system is less than that of stars of the eighth magnitude, since a portion of the nebulous matter interposes between our sight and stars of this description. But this distance must be very great. If stars of the eighth magnitude are to be considered at an average as eight times farther distant than those of the first, then this nebula cannot be supposed to be less than 320,000,000,000,000, or three hundred and twenty billions of miles from the earth. If its diameter at this distance subtend an angle of ten minutes, which it nearly does, its *magnitude* must be utterly inconceivable. It has been calculated that it must exceed 2,000,000,000,000,000,000, or two trillions of times the dimensions of the *sun*, vast and incomprehensible as these dimensions are.

This nebula has never yet been resolved into stars by the highest powers of the telescope that have yet been applied; nor is there any reason to believe that it consists of a system of stars, as is the case with many other nebulæ which appear much smaller, and are evidently more distant. It is therefore, in all probability, a mass of self-luminous matter not yet formed into any system or systems, but of what nature it would be vain to conjecture. Whether it is more condensed than when it was first observed nearly two hundred years ago, as some have conjectured, or whether any portions of it have shifted their position, as seems to have been the opinion of Sir W. Herschel from the observations above stated, appears on the whole somewhat uncertain. On this point Sir J. Herschel makes the following remark:—"Several astronomers, on comparing this nebula with the figures of it handed down to us by its discoverer, Huygens, have concluded that its form has undergone a perceptible change; but when it is considered how difficult it is to represent such an object, duly, and how entirely its appearance will differ even in the same telescope, according to the clearness of the air, or other temporary causes, we shall readily admit that we have no evidence of change that can be relied on."

The phenomenon we have now been contemplating is calculated to suggest a train of reflections and inquiries.—What is the grand design in the system of nature of such an immense mass of luminosity—a mass of luminous matter to which the whole solar system is but only as a point—a mass at least twenty-nine millions of times larger than a globe which *would fill the orbit of Uranus?** Is it in a state of perfection completely answering the ultimate end of its creation, and will it remain forever in that state? Or, is it only a chaotic mass of materials progressing toward some glorious consummation in the future ages of eternity, when worlds and systems will be evolved from the changes and revolutions now going forward within its boundaries? Or, may we suppose that a luminosity of so vast extent serves the purpose of a thousand suns to ten thousands of opaque globes which revolve within its wide circumference? Considering the diversified methods of Divine operation, and the vast variety of modes by which worlds are arranged and enlightened, it is not impossible, nor even improbable, that numerous worlds may be in this way illuminated with a perpetual and uninterrupted day. As there appear to be worlds connected with one sun, with two, with three, and even more suns, so there may be thousands of worlds cheered and illuminated without such a sun as ours, and with an effulgence of light which is common to them all. But on these points we shall never be able to arrive at certainty so long as we sojourn in this sublunary sphere. Suffice it to say, that such an enormous mass of luminous matter was not created in vain, but serves a purpose in the divine arrangements corresponding to its magnitude and the nature of its luminosity, and to the wisdom and intelligence of Him whose power brought it into existence. It doubtless subserves some important purposes, even at the present moment, to worlds and beings within the range of its influence. Were we placed as near it as one-half the distance of the nearest star, great as that distance is, from such a point it would exhibit an effulgence approximating to that of the sun; and to beings at much nearer distances it would fill a large portion of the sky, and appear with a splendor inexpressible.—But the ultimate design of such an object, in all its bearings and relations, may perhaps remain to be evolved during the future ages of an interminable existence; and, like many other objects in the distant spaces of creation, it excites in the mind a longing desire to behold the splendid and mysterious scenes of the universe a little more unfolded.

---

*See page 74

SECTION V.

On the nebular hypothesis.

I have already stated that the nebulæ may be arranged into two classes, the *resolvable* and *irresolvable*. When Sir W. Herschel commenced his observations on the nebulous part of the heavens, and for several years afterward, he was disposed to consider the nebulæ in general to be no other than clusters of stars disguised by their very great distance; but a long experience and better acquaintance with the nature of nebulæ convinced him that such a principle ought not to be universally admitted, although a cluster of stars may undoubtedly assume a nebulous appearance when it is too remote for us to discern the stars of which it is composed. When he perceived that additional light had no effect in resolving certain nebulæ into stars, he was forced to the conclusion, that though milky nebulæ may contain stars, yet there are also nebulosities which are not composed of them, nor immediately connected with them.

Hence astronomers have been constrained to admit the existence of a certain species of fine luminous matter, distinct from stars, or planets, or any other materials existing around us, which is diffused in immense masses throughout the spaces of the universe. The large nebula in Orion, described above, is considered as one of the most striking evidences that such a substance is distributed throughout the sidereal regions; for the whole light and power of Herschel's forty-feet telescope, though four feet in aperture, was insufficient to resolve it into stars, although from certain circumstances it appears to be one of the nearest, as it is one of the brightest, of those nebulous masses. It has therefore become a subject of interesting inquiry, 'What are those huge masses of unformed matter we call the nebulæ? and what purposes do they serve in the economy of creation?"

It is an opinion now very generally entertained, that the self-luminous matter to which we refer is the chaotic materials out of which new suns or worlds may be formed, and that it is gradually concentrating itself by the effect of its own gravity, and of the circular motions of which it may be susceptible, into denser masses, so as ultimately to effect the arrangement and establishment of sidereal systems. It is argued that this opinion is highly probable, from the consideration that we find the nebulæ in almost *every stage of condensation.* Such nebulæ as are represented in Figures 59 and 62 are viewed as consisting of nebulous matter in its rudest and most chaotic state; and Figures 63, 64, 65, and also Figures 66, 67, 68, as similar matter in a state of progress toward condensation. The four figures marked 71 are considered as specimens of this gradual condensation, in which the progress may be traced from the left-hand figure to the right. It has even been maintained by some late writers on this subject that this, in all probability, is the mode in which the different systems of the universe were gradually brought into the state in which we now behold them, and that the sun and planets of the system to which we belong derived their origin from a similar cause; and it has likewise been attempted to connect the geological changes in the structure of our globe with the operation of a principle or law by which such a thin filmy substance as a nebula was condensed into such a heterogeneous mass of solidity as we find in the constitution of the terraqueous globe; and it has been insinuated that the zodiacal light is a portion of the original nebula of which the sun and planets were formed, and a presumptive evidence that the nebular hypothesis is true. According to these theorists, the sun is still to be considered as a nebulous star in a high state of condensation, and may exhibit such an appearance when viewed from a neighboring system.

Such conclusions, to say the least, are obviously premature. We know too little, in the meantime, of the nature of that nebulous matter which is dispersed through the heavens, or of the motions with which its particles may be indued, to be able to determine its susceptibility of being condensed and arranged into suns and planets. We have never yet seen the same nebula progressing from one stage of condensation to another, from a chaotic to a state of organization; nor is it likely we ever shall, even supposing the hypothesis to be well founded, as an indefinite number of years, or even of ages, must be requisite before such a revolution can be accomplished. Yet the observations of future astronomers on this department of the sidereal heavens may tend to throw some additional light on this mysterious subject.

It forms no conclusive argument, however against this hypothesis that it is difficult to conceive how a fluid of a nature so apparently rare can ever be condensed to the hardness of a planet or a sun; for if we suppose a nebulosity in its most diffused state to be twenty minutes in diameter, and to be compressed by central attraction and rotary motion until it become only one minute in diameter, the ratio of its density in the latter state, compared with that of the former, would be as eight thousand to one, since spheres are to each other as the cubes of their diameters Suppose its density in the first state were equal to that of atmospheric air; its density, when compressed in the proportion supposed, would be nine times heavier than water, which is nearly equal to the weight of silver, and twice the average density of our globe; but if such a process be going on in any of these bodies, numerous ages must elapse before such a consolidation can be effected, for no sensible change appears to have taken place during the period in which such bodies have come under our observation.

Nor do we conceive that this hypothesis is inconsistent with what we know of the attributes and operations of the Almighty; for all the movements and changes going on in our terrestrial system and throughout the universe are the effects of certain laws impressed upon matter by the hand of the Creator, by the uniform operation of which his wise and beneficent designs are accomplished. If, then, it forms a part of his designs that new suns and systems shall be formed to diversify the spaces of immensity, and if he has created huge masses of subtile luminous matter, and indued them with certain gravitating powers and rotary motions for this purpose, his almighty agency and infinite wisdom may be as clearly and magnificently displayed in this case as if a system of worlds, completely organized, were to start into existence in a moment. Perhaps the gradual evolution of his designs in such a case might afford matter of admiration and enjoyment to certain orders of superior beings who are privileged to take a near view of such stupendous operations. But supposing such physical processes going forward, we must necessarily admit that *a direct interference of the Deity is necessary before such worlds*, after being organized, *can be replenished with inhabitants;* for matter and motion, by whatever laws they may be directed, cannot be supposed to produce the organization of a plant or an animal, much less of a rational being, whose intellectual principle and faculties must be communicated by the immediate "inspiration of the Almighty." To suppose otherwise would be virtually to adopt a species of atheism.

All that we require on this point is some more direct and decisive proofs of the validity of the hypothesis we are now considering; and until such proofs be elicited we are not warranted to enter into particular speculations, and to speak with so much confidence on the subject as certain theorists have lately done. Sir John Herschel, who has paid more attention to this subject, and made more accurate observations on these nebulæ than almost any other individual, is far from being confident, and speaks with becoming hesitation and modesty in relation to this hypothesis. "If it be true," says he, "that a phosphorescent or self-luminous matter exists, disseminated through extensive regions of space in the manner of a cloud or fog — now assuming capricious shapes like actual clouds drifted by the wind, and now contracting itself like a cometic atmosphere around particular stars—what, we naturally ask, is the nature and destination of this nebulous matter? Is it absorbed by the stars in whose neighborhood it is found to furnish, by its condensation, their supply of light and heat? or is it progressively concentrating itself by the effect of its own gravity into masses, and so laying the foundation of new sidereal systems or of insulated stars? *It is easier to propound such questions than to offer any probable reply to them.* Meanwhile, appeal to fact, by the method of constant and diligent observation, is open to us; and as the double stars have yielded to this style of questioning, and disclosed a series of relations of the most intelligible and interesting description, we may reasonably hope that the assiduous study of the nebulæ will ere long lead to some clearer understanding of their intimate nature."

On the whole, the nebulæ, whether resolvable or irresolvable, open to view an inexhaustible field of contemplation and wonder. By far the greater part of the nebulæ are undoubtedly clusters of stars, some of them perhaps containing as many millions as our Milky Way, and occupying a space in the tracts of immensity which imagination can never fathom; but a considerable proportion of these bodies evidently appear to be masses of self-luminous substances, without any indication of being formed into organized systems; and how enormous must be the extent of most of those masses, and how vast the regions of space which they fill! If every one of those bodies be only one-half the size of the great nebula in Orion, what a prodigious mass of matter must they contain, and what an immense space must hundreds and thousands of them occupy! To limited minds such as ours, such spaces appear as approximating to *infinity*, and all our previous ideas of the amplitude of planetary systems sink into something approaching to inanity. Whatever purposes these immense masses of matter may serve under the administration of Infinite Wisdom, certain it is *they exist not in vain.* They accomplish designs worthy of the plans of Divine Intelligence, and have doubtless a relation, in one respect or another, to the enjoyments of intelligent beings; but the full development of the plans and agencies of the Deity in this, and in many other parts of the economy of the universe, must be considered as reserved for another and a future scene of existence.

SECTION VI.

List of some of the larger nebulæ.

For the sake of those who wish to inspect some of the nebulous bodies by means of telescopes, I have subjoined the following list from Messier's Catalogue, along with the more recent observations of Sir W. Herschel. The right ascensions and declinations are given in degrees and minutes, by which the places of these bodies may be very nearly found on a celestial globe. If it be judged expedient to reduce the degrees and minutes of right ascension to *time*, it may be done by the following rules:—Divide the number of degrees by 15, the quotient is hours; and the remainder reduced to minutes and divided by 15, gives the minutes, &c. of time: or, multiply the given number of degrees and minutes by 4, and divide the degrees in the product by 60, the quotient is hours, and the remainder minutes, &c. Thus, 320° 17′ is equal to 21 hours, 21 minutes, and 8 seconds of time.

In the following list, R. A. means right ascension; dec., declination; S., south; N., north; diam., diameter of the object, which is expressed in minutes of a degree.

1. R.A. 80° 0′ 33″; dec. N. 21° 45 27″; above the Bull's southern horn west of the star ζ: this consists of a whitish light, elongated like the flame of a taper: it exhibited a mottled nebulosity to Sir W. Herschel.
2. R. A. 320° 17′; dec. S. 1° 47′; diam. 4′; in the head of Aquarius, near the 24th star: it appears like the nucleus of a comet, surrounded with a large round nebula: Sir W. Hersche resolved it into stars.

3 R.A. 202° 51′ 19″; dec. N. 29° 32′ 57″; diam. 3′; between Arcturus and Cor Caroli: it is round, bright in the center, and fades away gradually: it exhibited a mottled nebulosity to Sir W. Herschel.

4. R.A. 242° 16′ 26″; dec. S. 25° 55′ 40″; diam. 2½′; near *Antares:* a mass of stars.

5 R.A. 226° 39′; dec. N. 2° 57′; diam. 3′; near 6 Serpent: a round nebula, resolved into stars by Sir W. Herschel.

6. R.A. 261° 10′ 39″; dec. S. 32° 10′ 34″; diam. 15′; between the bow of Sagittarius and the tail of Scorpio: a mass of small stars.

7. R.A. 264° 30′ 24″; dec. S. 34° 40′ 34″; diam. 30′: a mass of small stars near the preceding.

8. R.A. 267° 29′ 30″; dec. S. 24° 21′; diam. 30′; between the bow of Sagittarius and the right foot of Ophiuchus: an elongated mass of stars. Near this mass is the 9th of Sagittarius, which is encircled with a faint light.

9. R.A. 256° 20½′; dec. S. 18° 13′ 26″; diam. 3′; in the right leg of Ophiuchus: round and faint, but resolved by Sir W. Herschel into stars.

10. R.A. 251° 12′ 6″; dec. S. 30° 42′; diam. 4′; in the girdle near 30 Ophiuchus: a fine and round nebula, resolved into stars by Sir W. Herschel.

11 R.A. 279° 35′ 43″; dec. S. 6° 31′; diam. 4′; near K Antinous: a mass of many stars, mixed with a faint light.

12. R.A. 248° 43′; dec. S. 2° 30½′; diam. 3′; between the arm and left side of Ophiuchus: round and faint: near it is a star of the ninth magnitude: resolved into stars by Sir W. Herschel.

13. R.A. 248° 18′ 48″; dec. N. 36° 54′ 44″; diam. 6; in the girdle of Hercules, between two stars of the eighth magnitude: round, and bright in the middle, resolved into stars by Sir W. Herschel.

14. R.A. 261° 18½′; dec. S. 3° 5′ 45″; diam. 7′; in the drapery over the right arm of Ophiuchus: round and faint: near a star of the ninth magnitude: resolved into stars by Sir W. Herschel.

15. R.A. 319° 40′; dec. N. 10° 40′; diam. 3′; between the head of Pegasus and that of the Little Horse: round, and bright in the center, resolved into stars by Sir W. Herschel.

16 R.A. 271° 15′; dec. N. 13° 51′ 44″; diam. 8′; near the Serpent's tail; a mass of small stars, mixed with a faint light, resolved by Sir W. Herschel.

17. R.A. 271° 45′ 48″; dec. S. 16° 14′ 44″; diam. 5′; north of the bow of Sagittarius: a train of faint light, with stars.

18. R.A. 271° 34′; dec. S. 17° 13′; diam. 5′; above the preceding: a mass of small stars, surrounded with nebulosity.

19 R.A. 252° 1′ 45″; dec. S. 25° 54′ 46″; diam. 3′; between Scorpio and the right foot of Ophiuchus: round, and resolved into stars by Sir W. Herschel.

20. R.A. 267° 4′ 5″; dec. S. 22° 59′ 10″; between the bow of Sagittarius and the right foot of Ophiuchus: a mass of stars of the eighth and ninth magnitudes, surrounded with nebulosity.

21. R.A. 267° 31′ 35″; dec. S. 22° 31′ 25″; diam. 6′; near 11 Sagittarius: similar to the preceding.

22. R.A. 275° 28′ 39″; dec. S. 24° 6′ 11″; diam. 15′; near 25 Sagittarius: round, and resolved into stars by Sir W. Herschel.

23. R.A. 265° 42′ 50″; dec. S. 18° 45′, 55″; diam. 1° 30′; near 65 Ophiuchus: a mass of stars very near each other.

24. R.A. 270° 26′; dec. S. 18° 26′; near end of the bow of Sagittarius in the Milky Way. great nebulosity containing several stars, the light is divided into several parts.

25. R.A. 274° 25′; dec. S. 19° 5′; diam. 10′; near preceding, near 21 Sagittarius: a mass of small stars.

26. R.A. 278° 5′ 22″; dec. S. 9° 38′ 14″; diam. 2′; near n and o Antinous: a mass of small stars.

27. R.A. 297° 21′ 41″; dec. N. 22° 4′; diam. 4′; near 14 of the Fox: oval: it exhibited a mottled nebulosity to Sir W. Herschel.

28. R.A. 272° 29½′; dec. S. 24° 57′; diam. 2′; a degree from λ Sagittarius: round, and resolved into stars by Sir W. Herschel.

29. R.A. 303° 54½′; dec. N. 37° 12′; below γ Cygni: a mass of seven or eight small stars.

30. R.A. 321° 46′; dec. S. 24° 19′; diam. 2′; near 41 Capricorn: round, and resolved into stars by Sir. W. Herschel.

31. R.A. 7° 26½′; dec. N. 39° 9½′; diam. 40′; in Andromeda's girdle: it resembles two cones of light joined at their base, which is 15′ broad: resolved into stars by Sir W. Herschel.

32. R.A. 7° 27½′; dec. N. 38° 45½′; diam. 2′; below the preceding: round, without stars, and with a faint light.

33. R.A. 29° 9′; dec. N. 29° 32½′; diam. 15′; below the head of the North Fish and the Great Triangle: its light is uniform and whitish: it exhibited a mottled nebulosity to Sir W. Herschel.

34. R.A. 36° 51½′; dec. N. 41° 39½′; diam. 15′; between Medusa's head and the left foot of Andromeda: a mass of small stars.

35 R.A. 88° 40′; dec. N. 24° 33½′; diam. 20′; near μ and ν Castor: a mass of small stars near Castor's left foot.

36. R.A. 80° 11′ 42″; dec. N. 34° 8′ 6″; diam. 9′; near φ Bootes: a mass of small stars

37. R.A. 84° 15′; dec. N. 32° 12′; near the preceding: a mass of small stars, with a nebulosity, resolved into stars by Sir. W. Herschel.

38. R.A. 78° 10′; dec. N. 36° 12′; near σ Aurigæ: a square mass of stars.

39. R.A. 320° 57′; dec. N. 47° 25′; diam. 15′; near the Swan's tail: a mass of small stars.

40. R.A. 182° 45½′; dec. N. 59° 24′; diam. 1°; at the root of the Great Bear's tail: two stars, very near each other.

41. R.A. 98° 58′; dec. S. 20° 33′; below Sirius: a mass of small stars.

42. R.A. 80° 59′ 40″; dec. S. 5° 34′ 6″; diam. 6, between θ and c in Orion's sword: a beautiful nebula containing seven small stars.

43. R.A. 81° 3′; dec. S. 5° 26′ 37″; above the preceding: a star surrounded with nebulosity.

44. R.A. 126° 50½′; dec. S. 20° 31½′; between γ and δ Cancer: a mass of small stars.

45. R.A. 53° 27′ 4″; dec. N. 23° 22′ 41″; the Pleiades: a cluster of stars.

46. R.A. 112° 47′ 43″; dec. S. 14° 19′; between the Great Dog's head, and the hind feet of the Unicorn: a mass of stars with a little nebulosity.

47. R.A. 116° 4′; dec. S. 14° 50′; near the preceding: a mass of small stars.

48. R.A. 120° 36′; dec. S. 1° 16′ 42″; near the three stars at the root of Unicorn's tail: a mass of small stars.

49. R.A. 184° 26′ 58″; dec. N. 9° 16′ 9″; near ρ Virgo.

50. R.A. 102° 57½′; dec. S. 7° 57′ 42″; above θ

Great Dog: a mass of small stars below Unicorn's right thigh.

51. R.A. 200° 5′ 48″; dec. N, 48° 24′ 24″; below η Great Bear, near the ear of the Northern Greyhound: double: the two atmospheres, whose centers are 4′ 35″ distant, touch one another, and are bright in the middle; the one is fainter than the other: resolved into stars by Sir. W. Herschel.

52. R.A. 348° 39½′; dec. N. 60′ 22″; below *d* Cassiopeia: a mass of stars mixed with a nebulosity, according to Sir W. Herschel: this cluster appears like a solid ball, consisting of small stars, quite compressed into one blaze of light, with a great number of loose ones surrounding it.

53. R.A. 195° 30½′; dec. N. 19° 22′ 44″; near 42 Berenice's hair: round, and resolved into stars by Sir W. Herschel.

54. R.A. 280° 13′; dec. S. 30° 44′; diam. 6′; in Sagittarius: faint, and bright in the center.

55. R.A. 291° 30½′; dec. S. 31° 26½′; in Sagittarius; a white spot, resolved into stars by Sir W. Herschel.

56. R.A. 287°; dec. N. 29° 48′; near the Milky Way, faint, and resolved into stars by Sir W. Herschel.

57. R.A. 281° 20′; dec. N. 32° 46′; between γ and ζ Lyræ: round, and consisting of a mottled nebulosity.

58. R.A. 136° 37½′; dec. N. 13° 2′ 42″; in Virgo: very faint, without any star.

59. R.A. 187° 41′ 38″; dec. N. 12° 52½′; near the preceding: very faint, without any star.

60. R.A. 188° 7′; dec. N. 12° 46′; in Virgo: brighter than the two preceding.

61. R.A. 182° 41′; dec. N. 5° 12′; in Virgo: very faint.

62. R.A. 251° 48½′; dec. S. 29° 45½′; in Scorpio: like a comet, with a brilliant center surrounded with a faint light; resolved into stars by Sir W. Herschel.

63 R.A. 196° 5½′; dec. N. 43° 12½′; in the Canes Venatici: very faint.

64. R.A. 191° 27′ 38″; dec. N. 22° 52½′; in Berenice's hair: faint.

65 R.A. 166° 51′; dec. N. 14° 16′; in the Lion: faint, but resolved into stars by Sir. W. Herschel.

66 R.A. 167° 11′ 39″; dec. N. 14° 12′ 21″; very near the preceding: very faint, but resolved into stars by Sir W. Herschel.

67. R.A. 129° 7′; dec. N. 12° 36′ 38″; below the northern claw of the Crab: a mass of stars with nebulosity. It is a cluster pretty much compressed, in which Sir W. Herschel has observed 200 stars at once with a power of 157. (See p. 63.)

68 R.A. 186° 54½′; dec. S. 25° 30⅓′; diam. 2′; below the Crow, very faint.

69. R.A. 274° 11′ 46″; dec. S. 32° 31′ 45″; diam. 2′; below the left arm of Sagittarius: faint, like the nucleus of a small comet.

70. R.A. 277° 13′; dec. S. 33° 31′; diam. 2′; near the preceding, near four telescopic stars.

71. R.A. 295° 59′ 9″; dec. N. 18° 13′; diam. 3′ 30″; between γ and δ of the Arrow: very faint, and resolved into stars by Sir W. Herschel.

72. R.A. 310° 20′ 49″; dec. S. 13° 20′ 51″; diam. 2′; above the tail of Capricorn: faint, but resolved into stars by Sir W. Herschel.

73. R.A. 311° 43′; dec. S. 13° 28′ 40″; near the preceding; three or four small stars, containing a little nebulosity.

74. R.A. 21° 14′; dec. 15° 39 35″; near η in the string that connects the Fishes: very faint, but resolved into stars by Sir W. Herschel.

75. R.A. 298° 17′ 24″; dec. S. 22° 32′ 23″; between Sagittarius and the head of Capricorn: composed of small stars with nebulosity. The astronomer Mechain makes it only nebulous.

76. R.A. 22° 10′ 47″; dec. N. 50° 28′ 48″; diam. 2′; in Andromeda's right foot: composed of small stars with nebulosity, small and faint.

77. R.A. 37° 52½; dec. S. 57′ 43″; in the Whale: a mass of stars containing nebulosity.

78. R.A. 83° 53½; dec. S. 1′ 23″; diam. 3′; in Orion: a mass of stars with two bright nuclei, surrounded with a nebulosity.

79. R.A. 78° 49′; dec. S. 24° 43″; below the Hare: a fine nebula bright in the center, and a litle diffused, resolved into a mottled nebulosity by Sir W. Herschel.

80. R.A. 241°; dec. S. 22° 25′; diam. 2′; between y and δ Scorpio: round, and bright in the center, like a comet.

81. R.A. 144° 27′ 44″; dec. N. 70′ 7′ 24″; near the ear of the Great Bear: a little oval, bright in the center, and exhibiting a mottled nebulosity to Sir W. Herschel.

82. R.A. 144° 29′ 22″; dec. N. 70° 44′ 27″; near the preceding: faint and elongated, with a telescopic star at its extremity; it showed a mottled nebulosity to Sir W. Herschel.

83. R.A. 201° 8′; dec. S. 28° 42½′; near the head of the Centaur: very faint.

84. R.A. 183° 30⅓′; dec. N. 14° 7′; in Virgo: bright in the center, and surrounded with nebulosity.

85. R.A. 183° 35′ 21″; dec. N. 19° 24½; above and near Spica: very faint.

86. R.A. 183° 46′ 21″; dec. 14° 10′; in Virgo. the same as No. 84, and near it.

87. R.A. 184° 56′; dec. N. 13° 38′; in Virgo: as luminous as the preceding.

88. R.A. 185° 16′; dec. N. 15° 38′; in Virgo very faint, and like No. 58.

89. R.A. 186° 9′ 36″; dec. N. 13° 46′ 49″; near No. 87: very faint.

90. R.A. 186° 27′; dec. N. 14° 23′; in Virgo: very faint.

91. R.A. 186° 37′; dec. N. 14° 57′; above the preceding: fainter than the preceding.

92. R.A. 257° 38′; dec. N. 43° 22″; diam. 5′; between the knee and left leg of Hercules; a beautiful nebula, bright in the center, and surrounded with great nebulosity: resolved into stars by Sir W. Herschel.

93. R.A. 113° 48′ 35″; dec. S. 23° 19′ 45″; diam. 8′; between the Great Dog and Ship: a mass of small stars.

94. R.A. 190° 10′ 46″; dec. N. 42° 18′ 45″; diam. 2½′; above Cor Caroli: bright in the center, with a diffused nebulosity.

95. R.A. 158° 3′ 5″; dec. N. 12° 50′ 21″; in the Lion, above *l*: very faint.

96. R.A. 158° 46⅓′; dec. N. 12° 58′; near the preceding: fainter than the preceding.

97. R.A. 165° 18′ 40″; dec. N. 56° 13½′; diam 2′; near ζ Great bear: very faint: another near it, and another near γ.

98. R.A. 180° 50′ 49″; dec. N. 16° 8′ 15″; above the north wing of Virgo: very faint.

99. R.A. 181° 55′ 19″; dec. N. 15° 37′ 12″; on the north wing of Virgo: brighter than the preceding: between two stars of the seventh and eighth magnitude.

100. R.A. 182° 59′ 19″; dec. N. 16° 59′ 21″; in the ear of corn of Virgo; brighter than No. 98

101 R.A. 208° 52′; dec N. 55° 24′ 25″; diam. 7′; between the left hand of Bootes and the tail of the Great Bear; very faint: discovered by Mechain: mottled nebulosity, according to Sir W Herschel.

102. Between *Omicron* in Bootes and *Iota* of the Dragon, very faint: discovered by Mechain.

103. Between ι and δ Cassiopeia: a mass of stars.

CHAPTER XIII.

ON THE ABERRATION OF THE STARS, AND ON THEIR PROPER MOTIONS.

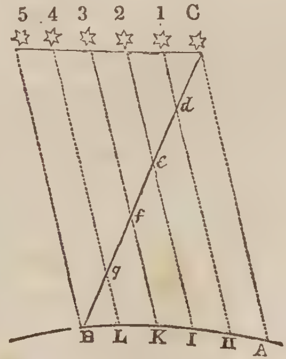
The aberration of the fixed stars is a small change of place in the heavens which they seem to undergo, and by which they appear to describe, in the course of a year, an ellipsis or circle, the greatest diameter of which is about forty seconds. This remarkable fact was discovered, near the middle of the last century, by the celebrated Dr. Bradley, formerly Regius Professor of Astronomy at Greenwich.

In Chapter IV, when describing the mode of finding the parallaxes of the fixed stars, I have given a brief detail of the circumstances which led to this discovery, and the observations from which the aberration of the stars was deduced. Before perusing the following illustrations of this subject, it may not be improper for the reader to reperuse what was there stated in reference to this point, particularly the illustration of this phenomenon, given in the description of Fig. 7 (p. 29, 30) It is there stated that Dr. Bradley and his friend Mr. Molyneux were very much perplexed at the result of their observations; since, instead of observing a motion indicating an annual parallax, they found a result directly opposite to what they expected. Many theories and conjectures were proposed to solve the appearances, but nothing satisfactory was elicited, until one day, when Dr. Bradley was enjoying the amusement of sailing about on the Thames, he observed that every time the boat tacked, the direction of the wind, estimated by the direction of the vane, seemed to change. This immediately suggested to him the cause of the phenomenon which had so much perplexed him, and he ultimately found it to be an optical illusion occasioned by a combination of the motion of light with the motion of his telescope while observing the polar stars—a discovery of no inconsiderable importance, and which will immortalize the name of this sagacious and indefatigable astronomer. He perceived that, if light is propagated in time, the apparent place of a fixed object will not be the same when the eye is at rest, as when it is moving in any other direction than that of the line passing through the eye and the object; and that when the eye is moving in different directions, the apparent place of the object will be different.

We see an object in consequence of the rays of light proceeding from it striking our eyes, and we see the place of the object *in the direction in which they proceed.* If light be in motion and the eye at rest, the object will appear in its real place, provided no refracting medium intervene; but if the eye be in motion, and this motion in a different direction from that of the rays of light, the object will not be seen in its true position. Let us suppose the earth, in its circuit round the sun, just arrived opposite to a fixed star, which sends off rays *perpendicularly* to the direction of the earth's motion. The eye of the spectator meets the ray, and, as he perceives not his own motion, he supposes the light to be moving in a different direction, as when we sail along a winding river, certain objects on the banks appear to pass us in different directions. The eye misses the perpendicular ray, but meets an oblique one, and thence receives the impression of the light in the direction which results from this compound motion—namely, in the diagonal of a parallelogram, the sides of which represent the real motion of light. The spectator sees the star in its true place only when he is approaching it or receding from it in a straight line. When moving in any other direction, the star appears a little in advance of its true position; and these apparent changes in the situation of the heavenly bodies, occasioned by the annual motion of the earth, are distinguished by the *aberration of light.* They are common, to a certain extent, to all the celestial orbs, and are only more perceptible and striking in the case of the fixed stars. In consequence of this aberration during the revolution of the earth round the sun, the stars appear, according as they are situated in the plane of the ecliptic, or in its poles, or somewhere between them, in the first case, to deviate in a straight line to the right or left of their true place; in the second, to describe a circle, or something nearly approximating to it; and in the third, an ellipse about that point which observation determines to be their real situation.

This subject requires a little degree of attention in order to a clear understanding of it. Perhaps the following illustrations may, in some measure, render it plain to the general reader. Suppose *A B*, in the following figure, to represent a part of the orbit of the earth, and *C B* a ray of light descending from a star upon the earth's orbit *A B*; if the eye be at rest at *B*, the object will appear in the direction *B C*; but if the eye be moving

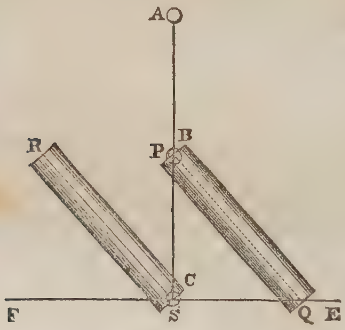
Fig. 74.



from A toward B, and light be propagated with a velocity that is to the velocity of the eye (or of the earth's motion) as CB to BA, that particle of it, by which the object will be discerned when the eye comes to B, will be at C when the eye is at A; the star, therefore, will appear in the direction AC; and as the earth moves through the equal parts of its orbit, AH, HI, IK, &c., the light coming from the star will move through the equal divisions Cd, de, ef, fg, gB, and the star will appear successively in the directions $H1$, $I2$, $K3$, $L4$, $B5$, which are parallel to AC; so that when the eye comes to B, the object will be seen in the direction of $B5$.

The following is an explanation of this phenomenon as given by Sir John Herschel. Suppose a shower of rain to fall perpendicularly in a dead calm; a person exposed to the shower who should stand quite still and upright would receive the drops on his hat, which would thus shelter him; but if he ran forward in any direction they would strike him in the face. The effect would be the same as if he remained still, and a wind should arise of the same velocity and drift them against him. Suppose a ball to fall from a point A (fig. 75) above a horizontal line EF, and that at B was placed to receive it the open mouth of an inclined hollow tube PQ; if the tube were held immovable, the ball would strike on its lower side; but if the tube were carried forward in the direction EF, with a velocity properly adjusted at every instant to that of the ball, *while preserving its inclination to the horizon*, so that when the ball in its natural descent reached C, the tube should have been carried into the position RS, it is evident that the ball would, throughout its whole descent, be found in the axis of the tube; and a spectator, referring to the tube the motion of the ball, and carried along with the former unconscious of its motion, would fancy that the ball had been moving in the inclined direction RS of the tube's axis. Our eyes and telescopes are such tubes. The earth is moving through space with a velocity of nineteen miles per second in an elliptic path round the sun, and is therefore changing the direction of its motion at every instant. Light travels with a velocity of 192,000 miles per second, which, although much greater than that of the earth, is yet not *infinitely so*. Time is occupied by it in traversing any space, and in that time the earth describes a space, which is to the former as 19 to 192,000, or as the tangent of $20''.5$ to radius. Suppose, now, APS to represent a ray of light from a star at A, and let the tube, PQ, be that of a telescope so inclined forward that the focus *formed* by its object-glass shall be *received* upon its cross-wire, it is evident from what has been said, that the inclination of the tube must be such as to make $PS : SQ$; velocity of light : velocity of the earth : : tangent $20\frac{1}{2}''$: 1; and therefore the angle SPQ, or PSR, by which the axis of the telescope must deviate from the true direction of the star, must be $20\frac{1}{2}''$.

Fig. 75.



The aberration of the stars has also been illustrated by the direction in which a gunner points his gun at a bird on the wing. Instead of leveling it exactly at the bird, he directs it a little before the bird in the path of its flight, and so much the more in proportion as the flight of the bird is more rapid compared with that of the shot. It may likewise be explained by supposing a person to be walking in a shower of rain with a narrow tube in his hand, in which case it is evident that the tube must have a certain inclination, so that a drop of rain which enters at the top may fall freely through it without touching its sides; which inclination must be greater or less according to the velocity of the drops with respect to the tube.

From the discovery of the aberration of the stars the following conclusions, among others, have been deduced,—1. That the small apparent motion which the fixed stars have about their real places, arises from the proportion which the velocity of the earth's motion in its orbit bears to that of light. This proportion is found to be as 1 to 10,310; or, in other words, light moves with a velocity ten thousand three hundred and ten times greater than that of the earth in its annual course round the sun.* 2. From this discovery it is proved that *the velocity of light is uniform* and the same, whether as emitted originally from the sun and stars, or reflected from the planets. The velocity of the earth in its orbit is about 68,000 miles an hour; consequently, the motion of light in the same time is 701,080,000, or a little more than seven hundred millions, which gives about eight minutes and eight seconds as the time it will take in passing from the sun to the earth.† This is about the same rate of the motion of light as first determined by Roemer from the eclipses of Jupiter's satellites; so that the two discoveries mutually harmonize and confirm each other, and prove to a demonstration the progressive motion of light, and that its rate of motion is the same whether as emanating from the sun, reflected from the satellites of Jupiter, or descending from the stars. 3. The aberration of light affects the apparent right ascensions and declinations of all the stars. Its effect on each particular star is to make it apparently describe a small ellipse in the heavens, having for its center the point in which the star would be seen if the earth were at rest. Hence, in all very nice calculations and determinations of the positions of the stars, allowance must be made for the effects produced by aberration. 4. The aberration of light *affords a sensible and direct proof of the motion of the earth* in its orbit round the sun. If the earth were not in motion, no such effect as that of the aberration of the stars could take place. If the earth were at rest, rays from a star would pass along the axis of a telescope directed to it; but were it set in motion with its present velocity, these rays would strike against the side of the tube, and it would be necessary to incline the telescope a little in order to see the star. The angle contained between the axis of the telescope and a line drawn to the true place of the star is just what we call its *aberration*, which could not take place if the earth were not in motion. That the earth is a planetary body moving through the depths of space along with the other planets of our system can be proved by numerous considerations; but the fact of the aberration of the stars exhibits this motion to our senses as clearly as if from a fixed point in the firmament we actually beheld it pursuing its course through the ethereal regions; so that the planetary nature of our globe, and the truth of the Copernican system, are no longer to be considered as mere hypotheses, but as facts susceptible of the strictest demonstration.

---

* This is the proportion of radius to the tangent of twenty seconds and a half, which is the greatest apparent displacement of the star caused by aberration, and the radius of the circle described by the star round its real place in the course of a year.

† This is found by multiplying 10,310 = the number of times that the velocity of light exceeds that of the earth, by 68,000 = the rate of the earth's motion in an hour; the product is 701,080,000. This product divided by 60 gives the rate of motion in a minute = 11,684,666. Divide 95,000,000, the distance of the sun from the earth, by this last number, and the quotient will give eight minutes and nearly eight seconds as the time light should take in passing from the sun to the earth.

ON THE PROPER MOTION OF THE STARS.

To the eye of a common observer, all the stars and constellations in the heavens appear to preserve the same relative distances from each other; and even astronomers, not more than two centuries ago, could perceive no separate motions or variations in the positions of these distant orbs. From this circumstance they were denominated *fixed stars*, to distinguish them from the *planets*, which were observed to shift their positions and to move through different parts of the heavens. After the telescope was invented and applied to astronomical instruments, astronomers began to suspect that some of the stars had a slight degree of proper motion or change in their relative position, but it was a considerable time before such motions could be distinctly ascertained. These motions first began to be observed by Dr. Halley, and afterward by Lemonnier and Cassini, and were completely confirmed by Tobias Mayer, who compared the places of eighty stars as determined by Roemer with his own observations, and found that the greater part of them had a proper motion. He likewise suggested that the change of place he had observed among these stars might arise from a progressive motion of the sun toward one quarter of the heavens. La Lande deduced a similar opinion from the rotary motion of the sun, by supposing that the same mechanical force which gave it a motion round its axis, would also displace its center; and give it a motion of translation in absolute space. Of the same opinion was Sir W. Herschel, and he attempted, by a comparison of the proper motions of all the stars that had been ascertained, to determine the point of the heavens toward which the motion of the sun was directed, which he supposed was that occupied by the star *Zeta* Herculis.

If the sun really have a motion in absolute space directed toward any particular quarter of the heavens, it is obvious that the stars in that quarter must appear to recede from each other, while those in the opposite region, which the sun is leaving behind, must seem gradually to approach, in the same manner as when we walk through a forest, the ranges of trees to which we advance are constantly widening in their apparent distance from each other, while the distance of those we leave behind is gradually contracting. It does not, however, appear, from the most recent observations, that the direction in which the sun or planetary system is moving is yet determined, although it is admitted that our system has a motion in space, and that the apparent proper motions of *some* of the stars *may* be the result of our being carried in a certain direction through absolute space by this motion. Such a motion, and even the direction of it, might be detected by such sidereal observations as those to which we allude, if we knew accurately the apparent proper motions of those bodies, and that they were independent of any *general motions* common to all the stars; but in the present stage of sidereal observation, it seems to be the general opinion of the most eminent astronomers, that no sufficient data are yet afforded for deducing definite conclusions on this subject.

The following table contains a few specimens of the annual proper motions of the stars in right ascension and declination, in seconds and decimals of a second, selected from the observations of Dr. Maskelyne. The first column contains the name of the star; the second, its magnitude; the third, its annual proper motion in right ascension; and the fourth, its motion in declination.

Names of the Stars.	Magnitude.	Annual Motion in R. A.	Annual Motion in Dec.
		Seconds.	Seconds.
Capella	1	+0.21	+0.44 N.
Sirius	1	—0.42	+1.04 S.
Castor	1	—0.15	+0.44 S.
Procyon	1.2	—0.80	+0.95 S.
Pollux	2	—0.74	0.00
ζ Leonis	1.2	—0.57	+0.07 S.
ζ Virginis	3	+0.74	+0.24 S.
Arcturus	1	—1.26	+1.72 S.
Altair	1.2	+0.48	—0.54 N.
α Lyræ	1	+0.23	—0.27 N.
Antares	1	0.00	—0.26 N.

In the above table, the sign + prefixed to the annual variation of right ascension, indicates that the variation is to be *added* to, and the sign — that it is to be *subtracted* from, the right ascension, to obtain the true place of the object at any given time.

It is found that not only among single, but even among *double* stars, such motions exist. While revolving round each other in the manner formerly described, they are at the same time carried forward through space with a progressive motion common to both, and without sensibly altering their distances from each other. One of the most remarkable of these is the double star 61 Cygni, formerly described, whose annual parallax and distance Professor Bessel appears to have lately determined.* The two stars of which it is composed are nearly equal in apparent size, and they have remained constantly at the same distance of 15 seconds for at least fifty-seven years past, or since their positions began to be accurately observed. The annual proper motion of these two stars is found to be, according to Bessel, 5″.123; which is the greatest annual proper motion of any of the stars which has yet been discovered; consequently, during the period now mentioned, they must have shifted their local situation in the heavens by a space equal to 4 minutes, 52 seconds; that is, a space equal to more than one-seventh of the apparent diameter of the moon. Such a change of place in bodies so immensely distant as 62,000,000,000,000 o miles indicates a prodigious rapidity of motion. "The relative motion of these stars and the sun," says Bessel, "must be considerably more than sixteen[*] semidiameters of the earth's orbit;" that is 1,552,000,000 of miles. They must therefore move at the rate of four millions two hundred and fifty-two thousand miles a day, and one hundred and seventy-seven thousand miles every hour; which is 68,000 miles an hour greater than the velocity of Mercury, which is the swiftest moving body in the planetary system. Here, then, we have a system of bodies of immense size moving with amazing velocity in different directions; for as these stars are doubtless suns, and consequently have a system of planets revolving round each, the planets must move round the sun to which they more immediately belong, and likewise round the other sun, or their common center of gravity, and at the same time they are carried forward to some distant region with the velocity now stated.

---

* See chap. iv, p. 31, &c.

Among single stars, that which is marked μ Cassiopeia, one of the smaller stars in that constellation, is marked as having the greatest proper motion of any yet ascertained. The amount of its annual motion is estimated at 3¾ seconds, which in the course of a century will amount to 6 minutes 15 seconds, a space in the heavens equal to one-fifth of the apparent diameter of the moon If this star be reckoned at the same distance from the earth as the double star 61 Cygni, the velocity of its motion every day will be 3,112,000 miles; every hour, 130,000; and every minute, 2,160. The annual proper motion of Arcturus, in declination, is 1″.72, which is nearly one-half the motion of μ Cassiopeia; and a great many others are found by observation to be constantly progressing through the heavens by annual intervals of different degrees in extent, but generally smaller than those stated above. These changes of position in the stars cannot be perceived by the naked eye, and are consequently imperceptible to common observers; and even with the most accurate astronomical instruments some of them cannot be determined until after a lapse of years. Such motions give us reason to conclude that all the bodies in the universe are in perpetual motion, and many of them acted upon by separate forces, which carry them in different directions; and although some of these motions appear little more than just perceptible at the immense distance at which we are placed from them, yet it is probable that even the slowest motion of any of the stars is not less than at the rate of several thousands of miles every hour, indicating the operation of forces incomprehensible by the human mind.

CHAPTER XIV.

ON THE DESTINATION OF THE STARS; OR, THE DESIGNS THEY ARE INTENDED TO SUBSERVE IN THE SYSTEM OF THE UNIVERSE.

For many ages during the infancy of astronomy, the stars were considered chiefly as an appendage to the world in which we dwell. The crystalline sphere in which they were supposed to be fixed was regarded as only the canopy of man's terrestrial habitation, and the orbs with which it is diversified as so many brilliant spangles to adorn it, and to diffuse a few glimmering rays to cheer the darkness of the night. This celestial arch, in which the sun and moon are also placed, was supposed to revolve around us every twenty-four hours, producing an alternate succession of light and of darkness, while the earth, as the center of the universe, was considered as remaining in a state of perpetual quiescence. Above the visible heavens, where the stars are placed, nothing was supposed to exist except the throne of the Almighty and the abodes of the blessed; and such are still the contracted views of the majority of the inhabitants of our globe respecting that immense and glorious firmament with which we are surrounded.

It is true indeed that the stars, in a certain subordinate sense, were intended for the benefit of man; for we actually derive many advantages from their apparent motions and influence. They present to our view a scene of beauty and magnificence which enchants the eye and gratifies the imagination, and tends to raise the soul above groveling pursuits and terrestrial vanities. They cheer the shades of midnight and enable us to prosecute our journeys after the sun has left our hemisphere; without the influence of whose light our winter evenings would be shrouded in impenetrable darkness, and not an object around us could be distinguished. In the absence of the moon all would be dark, as was chaos before light was formed to illuminate creation. Were the light of the starry orbs extinguished, instead of the grand and beautiful aspect now presented from above, the firmament would appear only like an immense blank, or a boundless desert, where nothing would be seen to stimulate human inquiry, or to display the attributes of the Creator. Those orbs are likewise of essential service to different departments of human life; they serve as guides to the traveler when journeying through vast and unfrequented deserts, and to the mariner when conducting his vessel from one country to another through the wide and pathless ocean. The Pole-star, on account of its apparently fixed position, has in every age been viewed with solicitous attention by the navigator; and before the invention of the compass it was his principal guide to direct his bark to the desired haven. In short, by means of the stars we have been enabled to determine the exact length of the day and of the year, the various subdivisions of time, the commencement and termination of the seasons, the circumference of the globe, the density of its materials, and the relative positions of places on every part of its surface; all which advantages it becomes man duly to appreciate, and with a grateful heart to adore the wisdom and goodness of Him "who made the sun to rule the day, and the moon and stars to rule the night," and who has rendered all his arrangements subservient to the happiness of his intelligent offspring.

But although the stars are of essential benefit to the inhabitants of our globe, yet we ought not for a moment to imagine that this was the chief and ultimate end for which they were brought into existence. We know that they are bodies of immense size, the least of them many thousands of times larger than our globe. But such a number of magnificent globes were not necessary, in order to shed a few glimmering rays upon the earth; since the creation of an additional moon would diffuse far more light over our world than that which descends to the earth from all the visible stars in the firmament. And we know that the Creator does nothing in vain. It is the characteristic of infinite wisdom to proportionate means to the end intended to be accomplished; but in this case there would be no proportion between the means and the end—between creating a thousand globes of light of incalculable magnitude, and shedding a few glimmering rays to alleviate the darkness of midnight; and therefore this cannot be supposed the chief end of their creation, without impeaching the wisdom and intelligence of Him "who stretched out the heavens by his understanding." Beside, whatever might be said in reference to the stars visible to the unassisted eye, it is impossible for a moment to conceive that those thousands, and ten thousands, and millions of stars, which are only visible through the most powerful telescopes, and whose light has never yet reached our globe, could have been created merely for the use of the inhabitants of this earth. Such a supposition must be forever discarded by every one who would entertain an honorable and consistent idea of the operations of infinite wisdom.

---

[*] About 16⅓ See p. 32.

What, then, it may be asked, is the chief and ultimate destination of those magnificent globes? We may answer in general terms, that it is a destination corresponding to the magnitude and grandeur, and the intrinsic splendor of those distant bodies. It is the characteristic of every wise artist and architect, that he selects the most proper means to accomplish the end intended, and proportionates every part of a machine or edifice to all the other parts, so as to produce a harmony and unity of design. A philosophical instrument-maker, for example, in constructing an orrery does not make wheels of a hundred yards in diameter for carrying balls of less than an inch in diameter round a circle of only six feet in circumference; nor does a watchmaker employ two hundred wheels and pinions in the construction of a timepiece, when less than a dozen may suffice; nor does an architect make the portico of an edifice five hundred times larger than the whole structure. Were any individual to act in this manner, he would at once be denounced as utterly destitute of wisdom, and viewed as a fool or a maniac. Now, we are to consider the Almighty, in all his arrangements throughout the universe, as acting on the same general principle which directs a wise and intelligent artist in all his plans and operations; for wisdom is an essential attribute of the Divinity, and all his works, when minutely inspected, must necessarily display this perfection to intelligent minds. To suppose otherwise, to imagine for a moment either that he has not proportioned one part of the universe to another, or that the greater part of it was created for no use at all, would be the hight of profanity and impiety, and would rob the eternal Majesty of Heaven of one of the most distinguishing attributes of his nature. Bearing this principle in mind, we are necessarily led to the conclusion—a conclusion as certain as any mathematical demonstration—namely, that the benefit of the inhabitants of our globe was *not* the chief or ultimate design for which the stars were created, but that the Deity had a higher and more expansive design to accomplish in their formation. We do not pretend to fathom *all* the subordinate designs the Creator may have had in his view in the creation of the stars, or of any other object; but as he has endowed us with rational faculties for the investigation of his works, it is evident that he intended we should be able to discover *some* of the main and leading designs which he intended to accomplish in the formation of the great bodies of the universe.

We therefore maintain that one of the grand and leading designs of the creation of the stars was, that they should serve as *suns* to give light to other worlds and systems with which they are more immediately connected. This proposition I have all along taken for granted in the preceding pages, and shall now adduce a few arguments to elucidate and support it.

1. *They all shine by their own native light.* This is the peculiar characteristic of a sun in distinction from the planetary globes, which all shine with *reflected* light, derived from the luminous center around which they revolve. The immense distance at which the nearest stars are placed from our globe is a clear proof that they shine, not with borrowed, but with inherent splendor; for reflected light from such a distance would be entirely dissipated ere it could reach our eyes. This likewise appears from actual observation, and from a comparison of the brilliancy of the fixed stars with that of the planets, in which there is found a striking difference. Mercury and Venus are the two planets which revolve in the immediate neighborhood of the sun, and consequently derive from him a greater portion of light than any of the other planets; yet it is found that the luster of the star *Sirius*, and even that of *Capella*, is much more brilliant than that of either Mercury or Venus; and it is demonstrably certain that both these stars are situated far beyond the orbit of Uranus; and therefore, if they derived their light from the sun, they behooved to be incomparably more obscure than any of the planets. The luster and brilliancy which the fixed stars exhibit when viewed with telescopes of large apertures and powers is exceedingly striking. Sir W. Herschel seldom looked at the larger stars through his forty-feet telescope, because their blaze was injurious to his sight. At one time, after sweeping a portion of the heavens with that instrument, he tells us that "the appearance of Sirius announced itself at a great distance like the dawn of the morning, and came on by degrees, increasing in brightness, until this brilliant star at last entered the field of the telescope with all the splendor of the rising sun, and forced me to take my eye from the beautiful sight." These and other circumstances clearly show that the stars are indued with native splendor, and are not dependent on any other luminaries for the brilliancy they display, and consequently are fitted to act as suns for the illumination of opaque globes with which they are more immediately connected.

2. *They are placed at an immense distance* from our earth and from one another, and consequently it is impossible that they could derive their luster from our sun; for the sun in his present situation could afford them no more light than a single star transmits to our globe; and to some of the more distant stars his rays would be altogether invisible. And if the sun cannot be supposed to enlighten any of those orbs, from the distance at which he is placed, there is no other body known

to us whence their light may be derived, if they do not shine with their own native splendor.

3. *They are bodies of immense magnitude.* We have already shown, both from mathematical considerations and popular illustrations, that the stars are unquestionably at a very great distance from our globe, a distance which is almost incomprehensible. (Chap. IV.) Their bulk must therefore be very great. If they were no larger than the globe on which we live, they would be altogether invisible, even although they shine with their own native light. Few of them can be considered as much less than our sun, and the greater number of them are in all probability much larger; they are therefore fitted by their enormous size, and their consequent attractive power, to be the centers of systems of planetary worlds, and to diffuse around them to an immense distance a splendid illumination. But it would be absurd to suppose that such a number of vast luminous globes, placed at such immense distances from each other, and from the earth, could have been created solely for the benefit of the inhabitants of our world; for it would argue a want of wisdom in not proportioning means to ends; since a single star of the one-thousandth part of its present bulk, placed within a million of miles of the earth, would afford us far more light than all the stars put together.

4. Were we removed to the distance only of the nearest stars, our sun would appear no larger than one of those twinkling orbs, and from some of them he would disappear altogether; at most, he would appear only as *one* of the small stars which deck the firmament, and probably one only of the fifth or sixth magnitude; consequently all the planets of our system would entirely disappear. Even Jupiter and Saturn, though each of them is a thousand times larger than the earth, would be quite invisible, by reason of their comparative smallness and their shining only by *reflected* light. The system to which we belong cannot therefore be supposed to have any *immediate* connection even with the nearest stars; and these stars must be considered as having appropriate purposes to fulfill in their own immediate sphere.

5. *The stars,* in point of number, size and splendor, *constitute almost the whole universe,* at least, so far as it has been unfolded to our view. The bodies which compose the planetary system contain a mass of solid matter about 2480 times larger than that of the earth, and the sun is about 500 times greater than the whole of them taken together. But this system, great as it appears in the eyes of mortals, is but as a diminutive ball, or even as a mere point, when compared with the myriads of stars which the firmament displays, and which the telescope has brought to view. These innumerable globes of light were created for *use*—to subserve important purposes in the plan of the Divine administration. They were not launched through the spaces of infinity at random, merely to display the energies of Omnipotence, and to light up the wilds of immensity with a useless splendor. Such a supposition would be derogatory to the attributes and character of the All-wise Creator, and would distort all the views we ought to entertain of a Being possessed of infinite perfection. Those immense bodies must therefore be conceived as intended chiefly to diffuse their light and splendor over worlds with which they are more immediately connected, and for the ultimate design of communicating happiness in various forms to the different orders of beings with which they may be replenished. What other subordinate ends they may accomplish in the grand scheme of the universe, beside the advantages we derive from them, is beyond our province to determine. It is not improbable, however, that every star or system, whether single, binary, or ternary, may have a subordinate end to serve to every other system, as forming parts of one whole under the government of Infinite Wisdom. As we derive advantages from these orbs, distant as they are, and as they diversify the ceiling of our earthly habitation with a splendid decoration, so they will likewise adorn the firmament of other systems, and display to the view of their inhabitants both the energies of Omnipotent Power and the manifold wisdom of God.

6. *We have some direct indications that the fixed stars are in reality suns.* It forms no argument against the idea of the stars being the centers of systems, that we have hitherto been unable to detect any of their revolving planets; for unless such planets be far beyond the magnitude of those belonging to our system, and unless their surfaces be fitted to reflect the rays of light with extraordinary brilliancy, we could not expect them to be visible at the remote distance at which we are placed, since the stars themselves appear only as shining points. But certain phenomena which have been observed, chiefly within the last century, give indication of the solar nature of the fixed stars. In the first place, there are phenomena which indicate that some of them at least, like our sun, have a rotation round their axes. In Chapter VII we have given a brief view of the phenomena of *variable* stars. One of these, named *Algol*, is found *regularly* to pass through a change of brightness from the second to the fourth magnitude, and again to its original brightness in two days and about twenty-one hours. The star β Lyræ passes through a periodic variation, from the third to the fifth magnitude, in six days and nine hours. A star in Hercules varies its luster periodically, in the course of sixty days and six hours. A star in Sobieski's shield changes from the fifth to the seventh or eighth magnitude, and returns to its greatest brightness, in a period of sixty-two days. These and many other stars give pretty evident indications of a rotation round their axes. Their periodic changes are *exact* and *regular;* and, in order to account for the phenomena, we have only to suppose that one of their hemispheres is either covered with large dark spots, or is encompassed with a medium which prevents it from emitting so much light to our eyes as the other, and that each hemisphere is presented to our view in alternate succession. Our sun, indeed, would not exhibit any sensible variation of luster at the distance of the stars, notwithstanding some large spots on his surface; but we have no reason to conclude that the stars, although they are all luminous bodies, are exactly alike in every part of their constitution, since variety appears to be a characteristic of all the arrangements in the universe. The darker hemisphere of the stars to which we allude may produce a change of illumination, which will form an agreeable vicissitude to the inhabitants of the worlds which roll around them, and which may produce an effect somewhat analagous to that which is produced by the alternate shining of a white and a yellow sun, as in the case of some of the double stars (see pp. 52, 53.)

Again, there are stars whose periods of variable luster are much longer than those now stated. Some of them pass through their periodic changes in 331 days, some in 494 days, and others not until after the lapse of eighteen years. Such changes, at least in some instances, may be accounted for by the intervention of opaque revolving bodies, or planets of a large size, passing directly between our eye and the stars, when revolving through that half of their orbits which lies next the earth. It is almost certain that either the one or the other of the circumstances now mentioned is the cause which produces the phenomena of variable stars, and in either case a strong presumption is afforded of the reality of other planetary systems. If *rotation* be the cause of the changes alluded to, the analogy between our sun and the stars is almost verified, for the most eminent philosophers have always considered that the rotation of an orb is necessarily connected both with motion in space, and with the existence of revolving planets. If such changes arise from the interposition of opaque globes, as is highly probable in some of the cases we have stated, then we have direct evidence that the stars are in reality the centers of systems, and that their planets are constructed on a scale of magnificence far surpassing that of our solar system. (See Ch. VII, pp. 43, 44.) It is highly probable that both the causes to which we have now adverted operate in producing the phenomena of variable stars. Those whose periodic variations are the shortest may be produced by rotation, and those in which years are requisite to accomplish all the changes, may arise from the intervention of very large opaque revolving bodies.

It has been surmised by some astronomers that certain very small stars which accompany larger ones probably shine by reflected light. Sir John Herschel, a few years ago, called the attention of astronomical observers to this point. The stars to which he has requested particular attention are such as the following:—ι Ursæ Majoris, γ Hydræ, κ Geminorum; α 2 Cancri, α 2 Capricorni, and several others. *Iota* Ursæ is a star of the third or fourth magnitude, in the fore foot of the Great Bear: right ascension, 8h. 46′ 54″; north declination, 47° 51′ 20″. *Gamma* Hydræ is a star of the fourth magnitude, about thirty-five degrees southeast from Regulus, and about twenty-nine degrees west by south from Spica Virginis: right ascension, 11h. 16′ 57″; south declination, 16° 42′. *Kappa* Geminorum is a star of the fourth magnitude, situated about three degrees and a half south of Pollux: right ascension, 7h. 33′ 38″; north declination, 24° 49′. The star α 2 Capricorni is of the third magnitude, about twenty-two degrees south by east of Altair, and about two degrees and a half north of ζ Capricorni, &c. It is to the very small and point-like stars which accompany these that the attention is to be directed; they are minute points of light which can only be perceived by telescopes of considerable power. Some of these are suspected as shining with reflected light; and if this point could be ascertained, it would form *a direct proof* of planets circulating around stars and enlightened by their beams. We have reason to hope, from the increase of astronomical observers, from the accuracy with which sidereal observations are now conducted, and from the improvements of which the telescope is still susceptible, that this interesting fact, will, ere long, be determined by ocular demonstration; and when such a discovery shall have been made, the telescope, which has already disclosed so many wonders, will then have performed one of its most sublime and mighty achievements.

In the meantime, we have no reason to entertain the least doubt that the stars are in reality *suns* and the distributors of light to other worlds any more than we ought to doubt of the motion of the earth, because we have never, from a fixed point in the firmament, beheld it wheeling its rapid course through the ethereal spaces around the sun. Since the stars cannot, with the least show of reason, be supposed to have been created chiefly for the use of our globe, it is as certain as moral demonstration can make it, that they were principally intended to fulfill a higher and a nobler purpose, and that this purpose has a respect to the accommodation and happiness of intelligent existence, either in the stars themselves or in worlds which revolve around them; for the Creator and Governor of the universe must be considered, in all his arrangements, as acting in perfect consistency with those perfections of his nature with which he is eternally and essentially invested. But to suppose the innumerable host of stars to be only so many vast insulated globes, hung up to irradiate the void spaces of infinitude, would be repugnant to all the conceptions which reason and revelation lead us to form of a Being of infinite perfection.

If then, the fixed stars are the centers of light and influence to surrounding worlds, how immense must that empire be over which the moral government of the Almighty extends!—how expansive the range, and how diversified the order of planetary systems!—how numerous beyond calculation the worlds which incessantly roll throughout the immensity of space! What countless legions of intellectual beings, of every rank and capacity must crowd the boundless dominions of the King eternal, immortal, and invisible!—and how glorious and incomprehensible must he be whose word caused this vast fabric to start into existence, and who superintends every moment the immensity of beings with which it is replenished! In attempting to grasp such scenes the human mind is bewildered and overwhelmed, and can only exclaim, "GREAT AND MARVELOUS ARE THY WORKS, LORD GOD ALMIGHTY."

"Seest thou these orbs that numerous roll above?
Those lamps that nightly greet thy visual powers
Are each a bright capacious sun like ours.
The telescopic tube will still descry
Myriads behind that 'scape the naked eye,
And farther on a new discovery trace
Through the deep regions of encompassed space.
If each bright star so many suns are found
With planetary systems circled round,
What vast infinitude of worlds may grace,
What beings people the stupendous space?
Whatever race possess the ethereal plain,
What orbs they people, or what ranks maintain?
Though the deep secret heaven conceals below,
One truth of universal scope we know;
Our nobler part, the same ethereal mind,
Relates our earth to all their reasoning kind,
One Deity, one sole creating cause,
Our active cares and joint devotion draws."

CHAPTER XV.

ON UNKNOWN CELESTIAL BODIES—ON METEORIC PHENOMENA--AND ON SHOOTING STARS.

We are not to imagine that we have yet discovered the greater part of the bodies which exist in those spaces whose range lies within the reach of our telescopes. All the discoveries which have hitherto been made in the heavens have been owing to the *light* emitted by very distant orbs having been concentrated on the eye by the magnifying and space-penetrating power of the telescope; but it is not improbable that there are numerous bodies within the circuit of the visible heavens which send forth no rays of light susceptible of being refracted or reflected to the eye by our finest instruments. Some of the largest bodies in the universe may either be opaque globes, or so slightly illuminated that no traces of their existence can ever be perceived from the region we now occupy. The greater part, if not the whole, of the orbs which have been described in the firmament, with the exception of the planets and comets of our system, are globes which shine with their own inherent luster, without which their existence would have been to us forever unknown. We are not warranted to call in question the existence of any class of bodies merely because our limited organs of perception and our situation in the universe prevent us from perceiving them. We have never yet beheld the planets which doubtless circulate around other suns, although there can be no question that such bodies really exist; and there may be opaque globes of a size incomparably larger than either planets or suns, which may serve as the centers of certain systems, or for some other important purposes to us unknown; for all that we have yet explored of the distant regions of creation is but the mere outskirts of that boundless empire which stretches out on every hand toward infinity. It is not unreasonable to believe that the number of magnificent bodies imperceptible to our organs of vision may far exceed all that we have hitherto discovered either by the naked eye or the telescope, even within the compass of that region which lies open to human inspection.

It has been remarked by La Place, that "a luminous star of the same density as the earth, and whose diameter should be two hundred and fifty times larger than that of the sun, would not, in consequence of its attraction, allow any of its rays to arrive at us." "A star which, without being of this magnitude, should yet considerably surpass the sun, would perceptibly weaken the velocity of its light, and thus augment the extent of its abberration." It is therefore *possible* that the largest *luminous* bodies in the universe, if their internal structure be composed of dense materials, would be invisible to us, in consequence of their great attractive power preventing their light from reaching the system to which we belong. In Chapter XII, I have given a brief view of the ideas entertained by Lambert respecting the arrangement of the universe into distinct systems of stars which have a more immediate connection with one another in consequence of the law of mutual gravitation, and whose views have been partly confirmed by the discoveries of Herschel. This illustrious mathematician and astronomer endeavors to prove, by an induction of facts and reasonings, that, in order to the stability of those systems, it is necessary, on the principles of universal gravitation, that there be a large central body, around which all the individuals which compose the system revolve. There is no necessity that such a central body should possess original or underived light. The fixed stars do not stand in need of it; and as for itself, if it require illumination, it will receive it from the suns that are more immediately adjacent. As to the *magnitude* of such a center, Lambert estimates that the central body of the system to which we belong must have a diameter at least equal to the whole circumference of the orbit of Saturn. "The magnitude of those bodies," he says, "ought not to alarm us, for, in the first place, we have nothing to do with their bulk, but with their density or quantity of matter by which the law of gravitation is regulated. We have no idea of the density of matter that is not porous; perhaps gold, the most dense of terrestrial substances, would be found a mere sponge compared with such a central body. Beside, nothing is great or small in immensity; and since on the wing of light we can traverse the vast regions of the heavens, matter and volumes ought no longer to excite our astonishment. Beginning with the satellites, even suns are but bodies of the first magnitude; the centers of the fixed stars, of the fourth; those of groups of systems, of the fifth, and so of the rest."

Lambert supposes that since such bodies must be of enormous bulk, and illuminated beside by one or more fixed stars, it might be possible to perceive the one which belongs to our own system, either in whole or in part, with the help of the telescope; that its apparent diameter may be very considerable; that, however weak its reflected light, it may not be enfeebled to such a degree as to be rendered imperceptible; that, being enlightened by one or more suns, it ought to present phases analogous to those of the moon; that such a central body ought to extend its influence even to the extremities of its system, and consequently ought to appear under a sensible diameter, or at least be visible by the telescope; and that as the attractive force of a body decreases as the square of the sine of its apparent semidiameter, so this apparent semidiameter cannot be invisible in any place to which its attractive force and its sphere of activity extend. Without sanctioning all the opinions which this ingenious mathematician has thrown out on this point, we may admit that the subject is worthy of special attention, and might be kept in view when we are exploring the heavens with our best telescopes. What if some of the planetary nebulæ be bodies of a nature similar to those to which we have now alluded?

If opaque globes of a prodigious size exist throughout the regions of the firmament, as there a reason to believe, they would afford us a clue for unraveling certain phenomena which have hitherto remained in some degree inexplicable. Stars have appeared all at once, and, after having shone for a year or more with a brilliant light, have gradually disappeared. Certain stars are found to pass through regular variations of luster, and for a certain period entirely disappear, but after a lapse of a certain number of months or days reappear, and resume their former brightness. On the supposition that opaque bodies exist nearly in the direction of such stars, some of these phenomena would admit of an easy explanation. Their appearing and disappearing might be nothing more than an occultation or an eclipse, caused by the interposition of the opaque globe between our eye and the star. This would, indeed, suppose *motion* to exist either in the opaque body, or in the star, or in the eye of the observer; and perhaps the annual motion of the earth, or the motion of the sun in absolute space, might contribute, in a certain degree, to produce the effect. Motion, of some kind or other, must necessarily be supposed, in order to account for the phenomena of variable stars, whatever hypothesis we may adopt for their explanation; but as nothing decisive can be stated on this subject, in the meantime I shall proceed to the consideration of some meteoric phenomena which are now supposed to have a connection with certain moving bodies in the heavens.

METEORIC PHENOMENA AND SHOOTING STARS.

In my volume entitled "Celestial Scenery," when describing the small planets Vesta, Juno, Ceres, and Pallas, I have given a detail of certain facts respecting the fall of large masses of solid matter from the higher regions of the atmosphere, usually denominated *meteoric stones*, which, there is every reason to believe, descend from regions at a considerable distance, and even beyond the sphere of the moon. Such phenomena seem to indicate the probability that certain opaque bodies, of different dimensions, are revolving through space in certain regions within the limits of our system. "Nor is this," says Mrs. Somerville, "an unwarranted presumption; many such do come within the sphere of the earth's attraction, are ignited, by the velocity with which they pass through the atmosphere, and are precipitated with great violence, upon the earth. The fall of meteoric stones is much more frequent than is generally believed. Hardly a year passes without some instances occurring; and if it be considered that only a small part of the earth is inhabited, it may be presumed that numbers fall in the ocean, or on the uninhabited part of the land, unseen by man. They are sometimes of great magnitude; the volume of several has exceeded that of a body of seventy miles in diameter. One which passed within twenty-five miles of us was estimated to weigh about 600,000 tons, and to move with a velocity of about twenty miles in a second, a fragment of it alone reached the earth. The obliquity of the descent of meteorites, the peculiar substances they are composed of, and the explosion accompanying their fall, show that they are foreign to our system."

But, without resuming the consideration of this particular phenomenon, there is another which of late years has excited a considerable degree of attention, and which may proceed from a cause somewhat similar, to which I shall chiefly direct the attention of the reader—namely, the phenomenon of *shooting or falling stars.* This phenomenon, though most frequently observed in tropical regions, is common in all parts of the earth, and has been seen in almost every season of the year. A shooting star seems to burst from a clear sky, and to dart across the heavens with a long train of light, which in a few seconds leaves no trace behind. Dr. Burney, of Gosport, for several years kept a record of such of these bodies as came under his own observation, and found that in the year 1819 there were 121, and in 1820 about 131; but a much greater number than these would doubtless be perceived could we detect all that make their appearance in the sky, the greater proportion, in all probability, being visible only during the hours usually allotted to sleep. Various opinions have been entertained respecting the cause of these appearances. Beccaria was of opinion they were occasioned by electricity, and brought forward the following facts as corroborative of his hypothesis:—About an hour after sunset, he and some friends that were with him observed a falling star directing its course directly toward them and apparently growing larger and larger, but just before it reached them it disappeared. On vanishing, their faces, hands, and clothes, with the earth and all the neighboring objects, became suddenly illuminated with a diffused and lambent light. During their surprise at this appearance, a servant informed them that he had seen a light shine suddenly in the garden, and especially upon the streams that he had been throwing to water it; when, sending up an electrical kite into the atmosphere, he likewise observed a quantity of electric matter about the kite, which assumed the appearance of a falling star. Whatever be the cause of shooting stars, it is pretty evident that they have their origin at a very considerable elevation above the earth. Brydone informs us that, from the top of Mount Etna, he noticed some of these meteors, "which still appeared to be as much elevated above us as when seen from the plain; so that in all probability those bodies move in regions much beyond the bounds which some philosophers have assigned to our atmosphere."

The most striking and remarkable form in which shooting stars have appeared is that of "meteoric showers," when thousands of those bodies have appeared to sweep along at once, and in continued succession for several hours, so that almost the whole visible canopy of the sky seemed to be in a blaze. As this phenomenon has recently excited considerable attention among philosophers, and as it is now generally considered as connected with some moving bodies in the heavens, I shall, in the first place, give a detail of some of the more remarkable circumstances with which it has been attended, as described by those who were eye-witnesses of the scene. One of the most remarkable displays of the phenomena to which we allude is that which was seen on the evening of the 12th and the morning of the 13th of November, 1833, in the United States of America. The following account of it is abridged from the *New York Commercial Advertiser* of November 13, 1833:

"The sky was remarkably clear on the night of this remarkable phenomenon. Some time before twelve o'clock, the meteors so frequently seen on summer evenings, called *shooting stars*, were observed to fall with unusual frequency and splendor. They continued from that hour to flash athwart the skies more and more, until they were eclipsed by the glories of the rising sun this morning. From four to six they were most numerous and refulgent. Within the scope that the eye could contain, more than twenty could be seen at a time shooting (save upward) in every direction. Not a cloud obscured the broad expanse, and millions of meteors sped their way across it on every point of the compass. Were it possible to enumerate them in the swiftness of their arrowy haste, we might venture to say that for the space of two hours, intervening between four and six, more than a thousand per minute might have been counted. Their coruscations were bright, gleamy, and incessant, and they fell thick as the flakes in the early snows of December. In one instance we distinctly heard the explosion of a meteor that shot across to the north-west, leaving a broad and luminous track; and witnessed another which left a path of light that was clearly discernible for more than ten minutes after the ball, if such it be, had exploded. Its length was gradually shortened, widening in the center, and apparently consisted of separate and distinct globules of light, drawn around a common center, glimmering less and less vividly until they finally faded in the distance. Compared with the splendor of this celestial exhibition, the most brilliant rockets and fireworks of art bore less relation than the twinkling of the most tiny star to the broad glare of the sun. The whole heavens seemed in motion, and never before has it fallen to our lot to observe a phenomenon so magnificent and sublime."

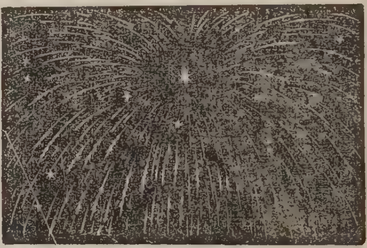
Various similar accounts of the same phenomena were given in the *Philadelphia*, *Hartford*, *Boston*, and other newspapers of the same date, of which the following are extracts:

"From a point in the heavens, about fifteen degrees south-easterly from our zenith, the meteors darted to the horizon in every point of the compass. Their paths were described in curve lines similar to those of the circles of longitude on an artificial globe. They were generally short in their course, resembling much an interrupted line, thus —— —— ——. They ceased to appear when within ten degrees of the horizon. I did not see a single meteor pass the meteoric pole I have described, nor one pass in a horizontal direction. Several of them afforded as much light as faint lightning. One in the north-east was heard to explode with a sound like that of the rush of the distant sky-rocket. Millions of these meteors must have been darted in this shower. The singularity of this meteoric shower consisted in the countless number of the celestial rockets, and more especially in their constant uniform divergence from near the zenith."

The following was an account sent by Professor Thomson, of Nashville, to Professor Olmsted, of New Haven, of the meteors which appeared November 13, 1833, as seen in the State of Mississippi:—"About an hour before daylight I was called to see the falling meteors; it was the most sublime and brilliant sight I had ever witnessed. The largest of the falling bodies appeared about the size of Jupiter or Venus when brightest. The sky presented the appearance of a shower of stars, which many thought were real stars and omens of dreadful events. I noticed the appearance of a *radiating point*, which I conceived to be the vanishing point of straight lines as seen in perspective. *This point appeared to be stationary.* The meteors fell to the earth at an angle of about seventy-five degrees with the horizon, moving from the east toward the west." The following is from a writer in the *Boston Christian Register:*—"My first attention was to determine the center or point from which the meteors started, which, from the place where I stood (lat. 42° 45′ N.), appeared in the Lion's heart, near Regulus. There is one thing that I have not seen noticed by any that have written, and which could not have been noticed by me had I not kept my eye on the center or point from whence the meteors all shot forth for a considerable time, and that was an appearance of a star less at first than the stars of the constellation by which it was surrounded, but it would increase until it was much larger than the stars, then totally disappear from ten to fifteen minutes, and then appear again; but the meteors shot forth in greater numbers in the interval between the appearances above-mentioned."*

It is worthy of particular notice, that the point from which the meteors seemed to emanate was observed, by those who fixed its position among the stars, to be in the constellation Leo; and, according to their concurrent testimony, this *radiant* point was stationary among the stars during the whole period of observation—that is, it did not move along with the earth in its diurnal revolution *eastward*, but accompanied the stars in their apparent progress *westward*, which proves the elevation of the meteors to be far beyond our atmosphere. The following cut represents the appearance of these meteors for several hours, as seen at Boston, New York, Philadelphia, and other places in the eastern parts of the United States. It is copied from one of the American periodicals published about the time when those phenomena appeared.

Fig. 76.



Meteoric phenomena nearly resembling what has been now described, have occurred at several former periods. One remarkable instance of what was called "showers of fire," occurred over eighty years ago in South America. At Quito, so many falling stars were seen above the volcano of Gayambo, that the inhabitants were led to imagine the mountain to be in flames. The people assembled in the plain of Exico, and a procession was about to set out in consequence from the convent of St. Francis, when they discovered the phenomenon to be occasioned by meteors which ran along the skies in all directions.

A more extensive and remarkable phenomenon of this kind occurred in the night of the 12th of November, 1779. Of this appearance, as it was seen at Cumana, an accurate account has been given by M. Humboldt and M. Bonpland. It occurred toward the morning, when thousands of meteors, eolides, fire-balls, or falling stars, as they were variously denominated, succeeded each other during four hours. Their direction was from north to south. They rose in the horizon at east-north-east, followed the direction of the meridian, and fell toward the south. There was little wind, and this from the east. No trace of clouds was seen. There was not a space in the firmament equal in extent to three diameters of the moon which was not filled with burning stars. They were of different sizes; they left luminous traces of from five to ten degrees in length. The appearance of these traces continued seven or eight seconds. Many of the stars had a distinct nucleus as large as the apparent disc of Jupiter. The largest were from 1° to 1° 13′ in diameter. Their light was white, and they seemed to burst as by explosion. They were seen by all the inhabitants of Cumana, the oldest of whom asserted that the great earthquakes of 1766 were preceded by similar phenomena.

---

* This astonishing exhibition covered a very considerable part of the earth's surface. It has been traced from the longitude of 61° in the Atlantic Ocean to 100° in Central Mexico, and from the North American lakes to the West Indies.

It is a circumstance worthy of particular notice, that these meteoric showers have taken place chiefly on the 12th and 13th of November, and hence they are now distinguished by the name of the *November Meteors.* Captain Hammond gives the following account of shooting stars seen at Mocha, on the Red Sea, November 13th, 1832, the day and month on which they have most generally been seen:—"From one o'clock, A. M., until after daylight, there was a very unusual phenomenon in the heavens. It appeared like meteors bursting in every direction. The sky at the time was clear, the stars and moon bright, with streaks of light and thin white clouds interspersed in the sky. On landing in the morning, I inquired of the Arabs if they had noticed the above. They said they had been observing it most of the night. I asked them if ever the like had appeared before? The oldest of them replied that it had not."

On the morning of the 12th of November, 1799, a remarkable phenomenon of this kind was seen by Mr. Ellicot, near Cape Florida, which he thus describes:—"The phenomenon was grand and awful; the whole heavens appeared as if illuminated with sky-rockets, which disappeared only with the light of the sun after daybreak. The meteors, which at any one instant of time appeared as numerous as the stars, flew in all possible directions, except *from* the earth, *toward* which they all inclined more or less, and some of them descended perpendicularly over the vessel we were in, so that we were in constant dread of their falling on us." The same appearances were observed *on the same night* at Santa Fé, Cumana, Quito, and Peru, in South America, as far north as Labrador and Greenland, and as far east as Weimar in Germany; thus having been visible over an extent on the globe of 64° in latitude, and 94° of longitude. Meteoric showers were also seen on the morning of the 13th of November, 1831, in the Ohio country, and along the coast of Spain.

Flights of shooting stars, more or less numerous, have been seen in different places, both in Europe and America, at the same period—namely, the 13th of November, in the years 1834, 1835, 1836, and 1837, so that they are now considered as a regular periodical phenomenon. In a letter I received, in 1837, from Elijah H. Burritt, Esq., A. M., a scientific gentleman in the state of Connecticut, and a correspondent of Professor Olmsted, he has the following notice on the subject: "With respect to the shooting stars, I believe, Professor Olmsted is now very strong in the belief that they are exactly *periodical* and *annual.* The recurrence of this singular phenomenon on the morning of the 13th of November, 1836, and very nearly at the same hour,—the radiation of the meteors from the same point of the heavens, differing only one half a degree (as did those of 1834), namely 145° right ascension in the face of Leo, and all the attending phenomena being the same, though upon a scale less magnificent,—settle the question as to its being a regular and annual phenomenon. According to his notion, the zodiacal light is an attribute of the same cause, or an emanation from the same radiant. Accordingly, my friend Dr. Olmsted was fortunate enough to see just so much of the zodiacal light last May as to enable him to identify it with the phenomena of November, 1834, except that it was in the other node."

One of the most remarkable circumstances attending this display, in 1833, was, that the meteors all seemed to emanate from one and the same point, a little south-east of the zenith. Following the arch of the sky, they ran along with immense velocity, describing in some instances an arc of 30° or 40° in a few seconds. On an attentive inspection, it was seen that the meteors exhibited *three* distinct varieties; the *first* consisting of *phosphoric lines,* apparently described by a point; the *second,* of large *fire-balls* that at intervals darted along the sky, leaving luminous trains which occasionally remained in view for a number of minutes, and in some cases for half an hour or more; the *third,* of undefined *luminous bodies,* which remained nearly stationary in the heavens for a considerable time. Those of the first variety were the most numerous, and resembled a shower of fiery snow driven with inconceivable velocity. The second kind appeared more like falling stars,—a spectacle which was contemplated by certain beholders with great amazement and terror. They were sometimes of enormous size. One of them seen in North Carolina appeared larger than the full moon rising, and its light rendered even small objects visible. The same ball, or a similar one, seen at New Haven, passed off in a north-west direction and exploded a little northward of the star Capella, leaving a train of peculiar beauty. The line of direction was at first nearly straight, but it soon began to contract in length, to dilate in breadth, and to assume the figure of a serpent scrolling itself up until it appeared like a luminous cloud of vapor floating gracefully in the air, where it remained in full view for several minutes. Of the third variety, the following are examples:—At Poland, State of Ohio, a luminous body was distinctly visible in the north-east for more than an hour. It was very brilliant, in the form of a *pruning hook,* and apparently twenty feet long and eighteen inches broad. It gradually settled toward the horizon until it disappeared. At Niagara Falls, a large luminous body, shaped like a *square table,* was seen near the zenith, remaining for some time almost stationary, emitting large streams of light.

The recurrence of this wonderful phenomenon at the same season of the year soon attracted the attention of the philosophers of Europe, and they resolved to watch more particularly the aspect of the nocturnal heavens in the month of November. The celebrated M. Arago made arrangements to procure simultaneous observations from the different parts of France, for the night between the 12th and 13th of November, 1836. The following is the substance of the report which was published of these observations. The places at which observations were made, and the number of meteors counted, were as follows:

Paris, at the observatory	170
Dieppe, 100 miles north-west of Paris	36
Arras, 100 miles north of Paris	27
Strasburg, 250 miles east of Paris	85
Von Altemare, 260 miles south-east of Paris	75
Angou, 180 miles south-west of Paris	49
Rochefort, 260 miles south-south-west of Paris	23
Havre, 120 miles west of Paris	300

Beside these positive observations, information was received of similar phenomena having been observed at other places. In the neighborhood of Tours, for example, the peasants declared they had seen a rain of fire during the night; and in the valley of the Rhone, near Culloy, three asteroids succeeded each other with such rapidity that the people, seeing them through a fog, supposed them to be flashes of lightning, or a repetition of the brilliant aurora of the 18th of October. As in the great meteoric shower of 1833, so at this time, the greater part of the falling stars which were particularly observed, seemed to issue from a point in the constellation of Leo. Of those noticed at Bercy, fifty seven traversed lines which, if continued, would have ended in that constellation; and of eighty-five observed at Strasburg, fifty-seven had similar courses. M. Arago purposes an inquiry, whether, from their number, this shower of falling stars may or may not be considered unusual; and he gives the following comparisons: At Paris, on the preceding night, none were seen, during an hour; from three to five were seen in the same space of time on the night after the shower, and from two to three on the second night. On the preceding night, at Bercy, not one was seen in two hours. At Von Altemare, on the 6th of November, none were seen during two hours' watching; on the 7th, there were four in four hours; on the 8th, none in three hours; on the 9th, one in six hours; and on the 14th, two in six hours.

I have been somewhat particular in stating the more remarkable circumstances connected with this phenomenon, as there is every reason to believe that it is produced by an unknown celestial body at a considerable distance from the earth; and I shall now proceed to give a brief view of the opinions which certain philosophers entertain, and the deductions they have been led to make in reference to this subject.

In the "American Journal of Science" for April, 1834, Dr. Olmsted, professor of mathematics and natural philosophy in Yale College, New Haven, has entered into an elaborate investigation of this subject in a communication which occupies about forty-two pages. The whole of this paper is well worthy of the attentive perusal of the philosophic inquirer, but the limits to which I am necessarily confined in this chapter will permit me to state only the *general results* of the professor's investigations; all of which appear to be deduced from the phenomena with great acuteness and ingenuity of reasoning. These results are:

1. That the meteors of November 13 *had their origin beyond the limits of our atmosphere.* For the source of the meteors did not partake of the earth's motion, which was demonstrable from a variety of circumstances, some of which have been alluded to above.

2. That *the hight of the place whence the meteors emanated,* above the surface of the earth *was about* 2238 *miles.* This was ascertained from a comparison of different observations made in different places, and from trigonometrical calculations founded upon them.

3. *The meteors fell toward the earth being attracted to it by the force of gravity.* It seemed unnecessary to assign any other cause, since gravity is adequate to produce the effect.

4. *They fell toward the earth in straight lines, and in directions which, within considerable distances, were nearly parallel with each other.* The courses are inferred to have been straight lines, because no others could have appeared to spectators in different situations to have described arcs of great circles.

5. *They entered the earth's atmosphere with velocity equal to about four miles per second,* o more than ten times greater than the maximum velocity of a cannon ball, and about nineteen times that of sound. This was inferred from the laws of falling bodies.

6. *The meteors consisted of combustible matter and took fire and were consumed in traversing the atmosphere.* They were seen glowing with intense light and heat, increasing in size and splendor as they approached the earth. They were seen extinguished in a manner in all respects resembling a combustible body like a sky-rocket; and in the case of the larger, a cloud of luminous vapor was seen as the product of combustion. That they took fire *in the atmosphere* is inferred from the fact that they were not luminous in their original situation in space, otherwise the body from which they emanated would have been visible.

7. *Some of the larger meteors must have been bodies of great size.* Some of them appeared larger than the full moon rising. Such a body seen at 110 miles distance behooved to have been one mile in diameter; at fifty-five miles, one half mile; at 22 miles, one-fifth of a mile; at 5½ miles, one twentieth of a mile, or 264 feet.

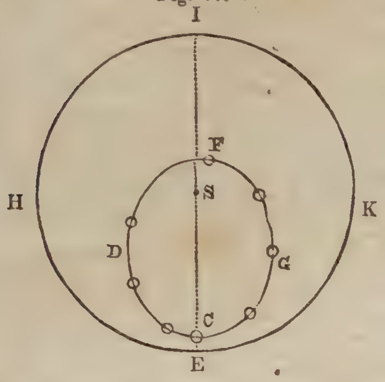
8. *The meteors were constituted of light and transparent materials.* They were of light materials, otherwise their momentum would have been sufficient to enable them to make their way through the atmosphere to the surface of the earth. They were transparent bodies, otherwise we cannot conceive how they could have existed together in their original state without being visible by reflected light.

9. The next, and one of the principal subjects of inquiry was, *What relations did the body which afforded the meteoric shower sustain to the earth?*—Was it of the nature of a satellite that revolves round the earth as its center of motion? Was it a collection of nebulous matter which the earth encountered in its annual motion? or was it a comet which chanced at this time to be pursuing its path along with the earth around their common center of motion? It could not have been a satellite, because it remained so long stationary with respect to the earth; nor was it a *nebula,* either stationary or wandering lawless through space. Such a collection of matter could not remain *stationary* within the solar system; and had it been in motion in any other direction than that in which the earth was moving, it would soon have been separated from the earth, since during the eight hours while the meteoric shower lasted, the earth moved in its orbit through the space of 540,000 miles. The conclusion to which Professor Olmsted arrives, after a due consideration of all the circumstances, is the following:

That the meteors of November 13*th consisted of portions of the extreme parts of a nebulous body, which revolves around the sun in an orbit interior to that of the earth, but little inclined to the plane of the ecliptic, having its aphelion near to the earth's path, and having a periodic time of* 182 *days nearly.*

This conclusion, the professor thinks, will account for the following, among other circumstances:—Why the phenomenon remained so long stationary with respect to the earth; why it was seen in that particular part of the heavens; and why it returns at stated periods, having appeared at Mocha, in Arabia, just one year preceding, and in a manner very similar to the present, as described by Humboldt and by Ellicot thirty-our years before. It will likewise account for an auroral light, resembling daybreak, which was seen in the east several hours before the dawn of day, and it is also supposed it may account for the different appearances of the *zodiacal light*. The professor is of opinion that the body alluded to is somewhat analagous to that of a comet. Fig. 77 represents the supposed orbit of this body in relation to that of the earth. *E H I K* represents the orbit of the earth; *S*, the position of the sun; and *C D F G*, the supposed orbit of the body which was the source of the meteoric phenomena. At the time these phenomena were seen, the body is supposed to have been at *C* when the earth was at *E*.

Fig. 77.



Arago appears to entertain an opinion on this subject not very different from that of Dr. Olmsted. He supposes that there may be myriads of bodies, composed probably of *nebulous* matter similar to the tails of comets, circulating round the sun in a zone or ring that crosses the earth's orbit at that part where it is about the 12th November, and that some of them, drawn from their course by the earth's attraction, fall toward it, and taking fire when they enter the atmosphere, in consequence of their prodigiously rapid motion, present the luminous phenomena of falling stars. The body or bodies from which these meteors proceed, he considers as unquestionably in rapid motion, performing a revolution round the sun in some plane different from that of the earth's orbit; and that the apparent course of the meteors will be compounded of this proper motion and of the earth's motion in its orbit at the time. It follows, that the point from which they seem to come will be that toward which the earth is moving at the time, namely, the constellation *Leo ;* for the line or tangent of the earth's annual motion at the 13th and 14th November points exactly to that constellation.*

Thus it appears that celestial bodies are revolving around us of which we formerly had no knowledge or conception. A new planetary system, within the limits of the old, is beginning to be revealed to us, the number of the bodies belonging to which may be much greater than we are yet aware of, and their particular properties and motions may at no distant period be detected and explained. This is one proof, among others, that bodies of a considerable size may exist in the heavens, and be prosecuting their courses in various directions, though they have never been detected by our telescopes. The subject is peculiarly interesting to philosophers and astronomers. The facts which have already been observed afford a *sensible proof* of the attractive power of the earth over bodies at a distance in the heavens; and it is to be hoped that the future observations and investigations of scientific men, in relation to such phenomena, will throw some further light on the nature and properties of bodies which have hitherto been involved in darkness and mystery.—What the destination of such bodies may be, or the ends they serve in the economy of nature, we are as yet entirely ignorant of. It appears pretty evident that they are bodies of no great density, otherwise their effect on the earth might have been more terrific and disastrous. Had their quantity of matter been considerable, when accompanied with so prodigious a velocity as they evidently had, their momentum would have been such as to have dashed them with violence upon the earth, where the most appalling effects might have been produced, in the demolition of human habitations, and the destruction of thousands of their inhabitants. But it does not appear that any of them made their way through the atmosphere *to the surface of the earth*, which was doubtless owing to the comparatively light materials of which they were composed. This circumstance, along with many others, evidently shows that we may be surrounded with numerous bodies and substances impalpable to the organs of vision, any one of which might be sufficient to deprive us of our comforts, and even prove destructive to our existence, were it not under the direction and control of Infinite Wisdom and Benevolence.

---

* A gentleman in South Carolina thus describes the effect of the phenomenon of 1833 upon his negroes: "I was suddenly awakened by the most distressing cries that ever fell on my ears. Shrieks of horror and cries of mercy I could hear from most of the negroes on three plantations, amounting in all to about six or eight hundred. While earnestly listening for the cause, I heard a faint voice near the door calling my name. I arose, and taking my sword, stood at the door. At this moment I heard the same voice still beseeching me to rise, and saying, 'Oh, my God! the world is on fire!' I then opened the door, and it is difficult to say which excited me most—the awfulness of the scene, or the distressed cries of the negroes. Upward of one hundred lay prostrate on the ground; some speechless, and some uttering the bitterest cries, but most with their hands raised, imploring God to save the world and them. The scene was truly awful; for never did rain fall much thicker than the meteors fell toward the earth, east, west, north and south, it was the same!"

CHAPTER XVI.

ARGUMENTS ILLUSTRATIVE OF THE DOCTRINE OF A PLURALITY OF WORLDS.

Having in the preceding pages exhibited a condensed view of the principal facts in relation to the Sidereal Heavens, I shall now inquire into some of the designs which the Almighty Creator appears to have had in view in replenishing his universe with such an immense number and variety of magnificent orbs. In Chapter IX, of "Celestial Scenery," I entered on a consideration of this subject, and illustrated at some length a few leading arguments, which tend to prove that *matter* was created chiefly in subserviency to *mind*, and that the main object of the creation of the planets, as proved from all the decorations and special arrangements connected with them, was to afford habitations for numerous orders of sensitive and intellectual beings. Without resuming the consideration of any of the arguments there stated, I shall in this chapter offer a few additional arguments corroborative of the same position, which, taken in connection with the former, will, I trust, amount to a moral demonstration that all the great globes in the universe are in some respect or another connected with intelligent existence.

I. The first class of arguments I shall illustrate is the following:—That *the doctrine of a plurality of worlds is more worthy of the perfections of the Infinite Creator, and gives us a more glorious and magnificent idea of his character and operations than to suppose his benevolent regards confined to the globe on which we dwell.*

1. The doctrine of a plurality of worlds is more accordant with the idea of the *infinity* of the Divine Mind than any other position. It is admitted by all rational theists and theologians that the Divine nature fills the immensity of space, and we consequently adore the Creator as an infinite and incomprehensible being. But we can have no ideas approximating to what infinity really is, unless by the prospects opened to us of the indefinite extension of material existence. Beyond the limits we may assign to the material world, our ideas, if we have any ideas at all, run into confusion, and approximate to inanity. It does not comport with the idea of a Being of infinite perfection that his works should be confined to one point of infinite space, or that one comparatively small race of intelligent beings should be the sole object of the moral government of Him whose presence fills the regions of immensity. It is more corresponding to the conceptions we ought to form of such a Being that the immensity of his works should correspond, in some degree, to the immensity of his nature; and, so far as our knowledge and observation extend, this is in reality the case. Beyond the range of natural vision, the telescope enables us to descry numerous objects of amazing magnitude; and, in proportion to the excellence of the instrument and the powers applied, objects still more remote in the spaces of immensity are unfolded to our view, leaving us no room to doubt that countless globes and masses of matter lie concealed in the still remoter regions of infinity, far beyond the utmost stretch of mortal vision. But huge masses of matter, however numerous and widely extended, if devoid of intelligent beings, could never comport with the idea of happiness being coextensive with the range of the Creator's dominions. Such an idea would completely obscure the luster of all his other attributes, and prevent them from being known and appreciated wherever his Omnipotence is displayed. To consider creation, therefore, in all its departments, as extending throughout regions of space illimitable to mortal view, and filled with intelligent existence, is nothing more than what comports with the idea of Him who inhabiteth immensity, and whose perfections are boundless and past finding out.

2. The idea of the indefinite extension of the universe and a plurality of worlds is most accordant with the *eternity* of the Divine Mind. When we go back in imagination to ages and centuries of duration more numerous than the drops of ocean or the sands on the sea-shore, we find the Deity existing in all the plenitude of his incommunicable attributes; for "He inhabiteth eternity," as well as immensity. There is nothing repugnant either to reason or revelation to suppose that, innumerable ages before our globe was arranged into its present state, many regions of infinite space were replenished with material existence; for the Scriptures nowhere assert that the *materials* out of which our globe was arranged were brought from nothing into existence *at the period* when Moses commences his narrative of the processes which preceded the formation of man. Nor have we any reason to believe that the operations of Creating Power have ceased since the structure of our world was completed, but have some evidences of the contrary; for example, in the case of *new stars* which have made their appearance at different periods since the time of the Mosaic creation, and even within the limits of the last century. It does not appear corresponding to the idea of an *Eternal* Being, whose existence can never terminate, and whose perfections are the same at all periods of duration, that everything should stand still in the universe, and that nothing new should arise into existence during the lapse of infinite duration, which would in effect be the case if the work of creation were absolutely finished, or if man were the principal intelligence connected with the material system.

Whether the happiness of the Divinity may be increased by the contemplation of his purposes and plans being brought into effect, we cannot positively declare; though it does not appear contrary to reason or the Dictates of Scripture to suppose that even the felicity of the Deity may, in a certain limited and modified sense, be susceptible of augmentation.* But whatever opinion may be formed on this point, from the constitution of *finite* minds, and the principles and desires implanted in them, it appears necessary to *their* progressive enjoyment that new scenes and manifestations of Divine perfection should be continually opening to their view; and if the universe be indefinitely extended, as it appears to be, and if new worlds are continually springing up under the creating hand of the Omnipotent, then we behold a prospect of progressive knowledge and enjoyment suited to the desires and aspirations of intelligent minds, which can never terminate throughout all the future periods of eternity. It is indeed *absurd* to suppose that a Being without beginning and without end should have his attention solely or chiefly directed to one point of his universe, and to one class of intelligences, "to whom," in point of number and of rank, "they are counted as nothing and less than nothing, and vanity."

---

*It is declared in Psalm cxlvii, 11: "The Lord taketh pleasure in them that fear him, in those that hope in his mercy;" and in relation to Messiah it is said, "Jehovah is

In respect to a Being, then, who fills the infinity of space with his presence, and who is possessed of eternal duration, it is nothing more than what is consistent with these attributes, and what we should naturally expect, that his empire should stretch over the regions of immensity, and that it should be filled with innumerable intelligences, capable of appreciating his power and goodness, and of paying a tribute of gratitude and adoration. The two attributes to which we have adverted could never be thoroughly displayed to finite minds, unless creation were extended through the illimitable tracks of space, and new creations gradually unfolding themselves to view. Were creation as limited as many suppose, were it confined chiefly to the world in which we dwell, and the beings connected with it, we might in the course of a few ages be said in some measure to comprehend the Creator, having explored all the displays he has made of his power, wisdom, and goodness; for we know nothing more of the Deity than the *manifestations* he has made of himself in his works and his moral dispensations. Everything in relation to man and his habitation might be known after the investigations of a very limited number of ages, and nothing further would remain to stimulate the exercise of the rational faculties throughout all the succeeding periods of infinite duration. But we may rest assured that the Divine Being is absolutely incomprehensible, and that no created intelligence will ever be able to sound the depth of his perfections, or to trace the full extent of his operations.

3. It is more accordant with the *wisdom* of the Deity that the universe should be inhabited by intelligent minds, than that it should remain in a state of perpetual desolation and solitude.

Could it be proved that the planets of the solar system, and all the other magnificent globes which are dispersed throughout creation, are only rude masses of matter, without life and intelligence, it would confound all our ideas of the intelligence of the Divine mind. Wisdom is universally acknowledged to be one of the eternal and essential attributes of the Divinity. But how could the glory of this attribute be traced from the contemplation of a mass of mere inanimate matter, however vast and splendid in its general aspect, when no end or design of its creation is perceived? Where should we be enabled to perceive the nice adaptation of means to ends? the harmonious operation of principles and causes producing grand and beneficent effects? the accomplishment of glorious and useful designs by admirable arrangements? We could only behold a vast and stupendous assemblage of means *without an end;* or, at least, without an end corresponding to their magnitude and grandeur. We should behold merely a display of boundless and uncontrollable *power* acting at random, and producing no effect which could excite the love and admiration of holy intelligences. For what could they behold to excite such emotions, although they were permitted to make the tour of the universe? Scenes of emptiness and desolation, of silence and solitude, where no sound is heard, where no animated being enlivens the boundless prospect, where no interchange of sentiment or affection can take place, and where no praises from adoring worshipers ever ascend to the Ruler of the skies. A rational being traversing scenes of this description would feel as little enjoyment as a bewildered traveler, amid storms and tempests, wandering over a vast howling wilderness, where human feet had never trod, and where the sweet accents of the human voice are never heard to cheer the surrounding solitude.

But when we view the magnificent globes which are scattered throughout immensity as replenished with numerous orders of intelligent beings, we behold an *end* worthy of the grandeur of the means which have been employed, worthy of the omnipotent power which has been exerted, and corresponding to the perfections of him who is "the only wise God," who is "wonderful in counsel, and excellent in working." We behold a display of Divine wisdom and munificence which is calculated to arrest the attention and draw forth the admiration of all rational beings, and to excite the most ardent desires of beholding the distant scenes of the universe more completely unfolded—a display calculated to gratify intelligences of the highest order, and of the most capacious powers to excite them to the most sublime investigations, and to inspire them with emotions of love, reverence, and adoration of Him who created all worlds, and for whose pleasure they are and were created.

4. The idea of the universe being replenished with sensitive and intellectual existence is accordant with every rational view we can take of the *goodness* or *benevolence* of the Deity

The goodness of God is that attribute of his nature by which he delights to communicate happiness to all the ranks of his sentient and intelligent offspring. Like every other attribute of the Divine mind, it is strictly boundless or infinite, coextensive with the eternal greatness of that mind, and commensurate with infinite knowledge, wisdom, and omnipotence. The benevolence of the Deity may be said to constitute his whole moral character, and to reflect a radiance on all his other perfections. To his *love* of happiness, as it now exists among every order of his creatures, and to his *desire* of producing it in all his future arrangements, no possible limits can be affixed. Hence, in the sacred records, the Divine Being is summarily described by this perfection alone, "*God is love.*" It is not merely asserted

---

well pleased for his righteousness' sake." In reference to the material works of creation it is said, Psalm civ, 31, "The glory of the Lord shall endure forever; *the Lord shall* REJOICE *in all his works.*" The expression, "The glory of the Lord," denotes the display of the Divine perfections made in the works of creation, as is evident from the subject of the psalm in which it occurs, which celebrates the power, wisdom, and providence of God, in relation to the objects of the visible world. In reference to these objects it is said, "The Lord shall *rejoice* in them, which seems to imply, speaking after the manner of men, a degree of pleasure or satisfaction in beholding his wise and benevolent plans, and his eternal purposes, brought into effect and fulfilling the ends intended.

that God is benevolent, but that he is *benevolence* itself. Benevolence is the essence of his being and character—a summary of everything that can render him amiable and adorable in the eyes of all his intelligent creatures. This benevolence is permanent and immutable, and must be *forever active* in distributing blessings wherever percipient beings exist. As it consists in the love of happiness, and the desire of communicating it wherever there is scope for its exercise; as it is the boundless energy of the infinite Mind in unceasingly doing good, it must be displayed, in a greater or less degree, wherever matter exists, and wherever wisdom and omnipotence have been exerted throughout the universe. We know that it is incessantly displayed throughout all the departments of our terrestrial system, in the ample provision made for the wants of every species of animated existence, in "giving" the various tribes of men "rain from heaven and fruitful seasons, and filling their hearts with food and gladness;" and, in a wonderful diversity of modes, distributing enjoyment among percipient beings. It is celebrated in the highest strains by the inspired writers as one of the most glorious and distinguishing characteristics of Jehovah. "The Lord is good to all; his tender mercies are *over all* his works." "He is merciful, and gracious, and *abundant* in goodness." "His bounty is great above the heavens," and "he exercises loving kindness throughout the earth." "O give thanks to the Lord, for he is good, for his mercy endureth forever."

But however great and inexhaustible the source of happiness in the Divine mind, the *exercise* of goodness *necessarily supposes the existence of sensitive or rational beings*, toward whom benevolence may be displayed. Where no such beings are to be found, this attribute cannot be exercised or traced in its operation. Mountains and plains, rocks of marble and diamonds, or valleys adorned with all manner of precious stones, however rich and splendid, cannot feel the effects of Divine beneficence. If, therefore, the numerous globes throughout the universe were destitute of inhabitants, there would be no extensive display of this essential perfection of the Divine nature; and to those few intelligences who might be permitted to view the desolate wastes of the universe, or to receive information respecting them, it would appear as if the Divine goodness had either been exhausted or had ceased its operations, and been withdrawn from the scene of creation, as if "the Lord had forgotten to be gracious, and in anger shut up his tender mercies." We have reason, however, to believe, both from scripture and from reason, that it is the great end of all the operations of Deity that a theater may be prepared, on which the emanations of his goodness may be communicated to innumerable orders of beings throughout his vast creation. There is no other conceivable end for which the fabric of universal nature was reared than that it should serve as a scene of enjoyment to innumerable beings susceptible of feeling the effects of the Creator's bounty, and that therein they might behold a magnificent display of the grandeur of his eternal attributes; but if by far the greater part of creation were uninhabited, such an end would be frustrated. However expansive the scene of the universe may be—however numerous and magnificent the worlds and systems which exist within its boundless range, the glories of Omnipotence would remain forever vailed and unknown, except to a small race of beings who occupy only a point in the immensity of space, and who cannot possibly be acquainted with the ten-thousandth part of the scenes which lie in the remoter spaces of creation.

If, therefore, we would not rob the Divinity of the most distinguishing attribute of his nature, we must admit that wherever creation extends, his goodness and beneficence are displayed, and, consequently, that intelligent beings of various orders must exist throughout all its amplitudes. Wherever power and wisdom are displayed, it ought to be considered as a necessary consequence that there also goodness is exercised, as the one is subsidiary to the other, and stands related as means to an end, or as cause to effect. It would be a most glaring piece of inconsistency to suppose that the Divine benevolence is confined to one or two worlds or orders of beings, when millions of expansive systems diversify the fields of immensity; more especially when we consider that the goodness of the Deity is of so *communicative* a nature that all the interval between a polypus and a man is filled with thousands of species of animated beings, of every conceivable form, and structure, and capacity, in order that happiness of every degree may be diffused among every possible order of sentient existence. Every element of nature, every department of our terrestrial system, forms an appropriate abode for living beings. The air, the waters, and the earth teem with animated existence of every size and form, and in such vast multitudes as to exceed all human calculation; and if the displays of Divine goodness be thus exuberant in our sublunary world, it would be absurd in the highest degree to suppose for a moment that the millions of vast globes, which roll in the distant regions of creation are devoid of inhabitants, since the communication of happiness appears to be one great end of all the operations of infinite wisdom and omnipotence.

Thus it appears that the doctrine of a plurality of worlds is not only accordant with every rational view we ought to entertain of the eternity and immensity, the wisdom and goodness, of the Divine Being, but that the opposite opinion would be repugnant to every consistent and scriptural view we can take of the character of the Supreme, and would obscure the glory of every divine perfection. This view, therefore, of the universe, considered as replenished with innumerable intelligences, is calculated *to exhibit a more glorious and magnificent idea of the character and operations of the Deity* than to suppose his benevolent regards confined to the globe on which we dwell. Instead of having only one comparatively small world and race of beings under his sway, we here contemplate him as the supreme ruler of ten thousand times ten thousands of mighty worlds, and conducting them all, with unerring skill, in their vast career. We behold him exercising his moral administration over a vast *universe of minds*, more numerous than the faculties of men or of angelic beings are adequate to compute, supporting and directing all the amazing powers of thought, wisdom, intelligence, affection, and moral action throughout every part of his eternal empire, displaying the depths of his wisdom and intelligence, the rectitude of his character, and the grandeur of his omnipotence to countless orders of intellectual existence, presenting before them prospects of magnificence and grandeur boundless as immensity, distributing among them all the riches of his beneficence, and inspiring them with the hope that the grandeur of his kingdom and the glory of his perfections will continue to be displayed with increasing splendor throughout all the periods of an endless duration. Such a Being is calculated to draw forth the highest degree of love and admiration from all his intelligent offspring, to inspire them with glowing ardor in his service, and to excite them to incessant adoration; whereas, did the universe consist merely of a boundless mass of matter without animation, thought, or intelligence, a vail of darkness and mystery would be thrown over all the perfections and purposes of the Divinity; creation would appear a vast, mysterious, and inexplicable system; and no hope would ever be entertained of tracing the designs for which it was brought into existence.

II. Another general argument for the plurality of worlds, and for an extensive population of the universe, may be founded on the following proposition:—that *wherever any one perfection of Deity is exerted, there also* ALL *his attributes are in operation*, and must be displayed, in a greater or less degree, to certain orders of intelligences. This is a most important consideration, which ought to be taken into account in all our views of the Divine character, and in all our investigations of the Divine administration—a consideration which is too frequently overlooked in the views and reasonings both of philosophers and theologians.

The Divine Being is ONE undivided essence; he is not compounded of *separable* parts or qualities, insulated from each other. We ought not, therefore, to conceive of his attributes as so many independent powers or properties, any one of which may be exerted without the concurrence or coöperation of the other. From the limited views we too frequently take of the Divinity, and from the imperfection of our present faculties, we are apt to fall into this mistake; but since all the perfections we attribute to the Eternal Mind are attributes of one indivisible and uncompounded Being, we ought never to imagine that *power* in any instance operates without *goodness*, or *wisdom* without *rectitude*, or that it can ever happen that any one of those perfections can be displayed without the harmonious operation of the whole. In whatever regions of the universe, therefore, God is seen to operate by his power, we may rest assured that there also he displays himself in the plenitude of all his other perfections; that intelligence, wisdom, benevolence, veracity, and rectitude follow in the train of omnipotence, displaying in undivided luster and harmony the glories of his character. It is GOD, invested with all his eternal and immutable, his natural and moral attributes, and not any single perfection, that acts, arranges, and governs throughout the whole amplitude of creation; and as such, his moral grandeur, as well as the physical effect of his power, must be displayed in every department of the material universe. From the influence of habit, and in consequence of the limited faculties of our nature, we are accustomed to say, that in one object *power* is displayed, and in another that *wisdom* is manifested; because, that in the one the attribute of power appears to us most prominent, and in the other, wisdom is more strikingly apparent. A lofty range of mountains, rearing their summits above the clouds, and stretching along for several hundreds of miles, strikes the mind with an idea of *power* in Him who formed them; but the fine mechanism, accomplishing certain useful purposes in the body of an emmet or a gnat, or the delicate construction of the eye of a dragon-fly, arrests our attention more particularly as an evidence of *wisdom*, although in each of these cases both power and wisdom are displayed. In no act or operation whatever of the Divine Being can it be said, that in that act he is *only* wise, or only powerful, or only benevolent; for in every operation, and in every part of his procedure, he acts in the *plenitude* of all his essential attributes, although the full display of all his perfections may not, in every instance, be open to our inspection.

If, then, the positions now stated be admitted (and I see not how they can be called in question), it necessarily follows that all the vast globes dispersed throughout the universe are either inhabited or contribute, as our sun does, to the comfort and enjoyment of percipient existence; for if wisdom and goodness uniformly and of necessity accompany the agency of power, and if these attributes can be exercised only in relation to sentient or intelligent beings, such beings must exist wherever such perfections are exercised. To suppose the contrary would involve a palpable absurdity, and present a distorted and inconsistent view of the adorable character of Jehovah.

In our survey of the sidereal heavens, and the remoter provinces of the Divine empire, we behold little more than an overwhelming display of almighty power. Our remoteness from those magnificent scenes prevents us from tracing the minute contrivances of Divine Wisdom in relation to any particular system, or the displays of Divine Beneficence toward its inhabitants. But our incapacity in perceiving the effects of wisdom and goodness forms no arguments against the actual exercise of these perfections. If it be admitted that infinite wisdom and benevolence are the necessary accompaniments of almighty power, we may rest assured that those perfections are in full and constant exercise wherever creating power has been exerted, although, from our present situation in the universe, their operation be concealed from our view. In every instance where Omnipotence has put forth its energies, it may be considered as a stage or theater on which the Divine wisdom and benevolence may be displayed. And as wisdom and goodness can only have a reference to percipient and intelligent beings, wherever those perfections are exercised, such beings must necessarily be conceived to exist; otherwise, we in effect destroy the *simplicity* of the Divine nature, we divide the Divine essence into so many independent attributes, and virtually declare that in the work of creation the Deity does *not* act in the full exercise of his indivisible and eternal perfections.

The above considerations, if duly weighed and understood, appear to me to embody an argument for the doctrine of an indefinite plurality of worlds, which may be considered as amounting to a moral demonstration.

III. There is *an absurdity involved in the contrary supposition*—namely, that the distant regions of creation are devoid of inhabitants.

1. There are two modes of reasoning which have been employed to prove the truth of a proposition: the *direct* method, by bringing forward arguments, or following out a train of reasoning bearing expressly on the position to be supported; or the *indirect* method, by showing the absurdity of maintaining the opposite position. Mathematicians term this latter species of reasoning the *reductio ad absurdum*, and sometimes employ it instead of the direct method, by showing that the contrary of the position laid down is impossible, or involves an absurdity; and this method of proof is considered as valid, and as strictly demonstrative as the other; for the opposite of truth must be falsehood. If, therefore, any proposition, whether mathematical or moral, can be shown to involve an absurdity, or to be inconsistent with a well-known and acknowledged truth, or directly contrary to it, we may safely conclude that such a proposition must be *false*.

To feel the force of such an argument in the present case, let us suppose for a moment that the planetary and stellar orbs are destitute of inhabitants. What would be the consequences? All those vast bodies must then be considered as regions of eternal silence, solitude, and desolation. The sun illuminates the surfaces of such huge globes as Jupiter and Saturn, but there are no visual organs to perceive the luster he throws around, no percipient beings to feel the influence of his heat and other benign agencies. Time is measured, with exquisite precision by days, and months, and years, but all to no purpose; for no rational beings enjoy the advantage of such measures of the lapse of time, and the Deity—to whom "one day is as a thousand years, and a thousand years as one day"—stands in no need of such movements to mark the periods of duration. Day and night, spring and summer, succeed each other, but they have no relation to the wants or enjoyments of sensitive or intellectual natures. The melody of the groves, the bleating of flocks, the lowing of herds, the harmonious accents of human voices, or the music of angelic choirs, never for a moment disturb the profound and awful silence which forever prevails; not a single murmur meets the ear, unless howling winds, amidst dreary deserts and rugged rocks, should render the scene still more hideous and doleful. Some of those mighty globes are encircled with splendid rings and a retinue of moons, which adorn the canopy of the sky, and present a scene of grandeur far more diversified and sublime than human eyes have yet beheld, but no intelligent agents exist in those regions to admire and enjoy the wondrous spectacle and to adore the great Creator. In short, all is one wide scene of dreariness, desolation, horror, and silence, which would fill a spectator from this world with terror and dismay.

Were an inhabitant of the earth to be transported to Jupiter or Saturn, he might behold resplendent scenes in the canopy of the firmament; but how great would be his disappointment to find nothing but boundless deserts and desolate wastes, without one sentient being to cheer the horrors of the scene, and not a rational intelligence to communicate a single sentiment or to join him in the contemplation of the objects above and around him; and were he to range throughout an indefinite lapse of ages from one globe to another, and from one corner of the universe to another, and find the same gloomy solitudes and desolations, he could find no stimulus to excite him to admiration or rapture, or to elevate his soul in adoration of the Creator. Even the most resplendent scenes, adorned with all the riches and beauties which the most lively imagination can depict,—mountains of diamonds and plains diversified with all the beauties of the vegetable creation,—could impart no real pleasure while unenlivened with the principle of animation and the energies of *mind*. What a gloomy and horrible picture would such a scene present of the frame of universal nature, and what a vail of darkness and mystery would it throw over the perfections of the Eternal! for it is the scenes connected with life, animation, mental activity, and moral sentiment, glowing affection, social intercourse, and the mutual sympathies of intellectual beings, that can alone inspire the soul with rapturous emotions, throw a charm over any part of creation, and exhibit the Almighty Creator as amiable and adorable. It is chiefly from the relation in which the material world stands to sensitive and intellectual existence that its beauty and order are recognized and admired by contemplative minds, and that the wisdom and beneficence of the Deity are traced in all their minute and multifarious bearings. In our world, as it now stands, the arrangement of mountains and vales, the various properties of the watery element, and its transmutation into vapors, clouds, and dew, the admirable mechanism of the atmosphere, the fertility of the earth, and the beautiful coloring which is spread over the face of nature,—which are productive of so many beneficial effects, and so evidently display the wisdom of Deity,—would all appear as so many means without an end, as contrivances *without use*, if the earth were destitute of inhabitants. And if all the other departments of creation were likewise devoid of animation and intelligence, scarcely a trace would be left throughout boundless space of the wisdom and benevolence of the Eternal Mind.

2. In the next place, such a position as that which I am now opposing would be inconsistent with that principle of *variety* which appears so conspicuous throughout the whole range of the Divine operations, and with *that progressive expansion of intellectual views* which appears necessary to the perpetual enjoyment of immortal beings.

In order to permanent enjoyment it is necessary, from the very constitution of the mind, that one scene of happiness should succeed another,—that the soul should look forward to the future, to something *new* or more grand and expansive than it has yet beheld or enjoyed. It can never rest in present objects and attainments, but is always on the wing for something higher and more exquisite than it has yet grasped or enjoyed. What is the reason, in most cases, why *imprisonment* produces so doleful an effect upon the mind, but because its views and its actions are confined to a narrow circle? And if in such a situation newspapers, books, paper, pens and ink, be withheld, so as still further to circumscribe the mental view, its want of enjoyment and its misery are still more increased. Why would a literary man feel unhappiness had he no access to books, journals, and the periodicals of the day, nor any other means of information respecting passing events, but because he would thus be confined to his present range of view, and prevented from enlarging it? And why should the man who devours the periodical journal to-day feel as craving desires to-morrow to peruse similar records of intelligence, to mark the progress of passing events, but from the same vehement desire to expand his present intellectual views? Were such desires to remain ungratified, and the prospect of further information entirely shut up, a certain degree of misery would necessarily be felt by every rational mind. In another world, something similar would happen in the case of all intellectual beings, were no new scenes and prospects ever unfolded to view.

Divines have generally admitted that the eternal world, in the case of the righteous, will be a state of perpetual and uninterrupted enjoyment. Such enjoyment, however, could never be realized, unless new scenes and objects, worthy of the admiration of exalted intelligences, were progressively displayed. But the contemplation of rude masses of matter, however vast in point of size and extent, and however magnificent in point of splendor, were they entirely unconnected with mind and moral action, would produce no high degree of enjoyment to beings possessed of capacious powers of intellect; for in such objects they could trace no evidences of skill or design, nor would they perceive any overflowings of Divine goodness to inspire them with gratitude and praise. We are warranted from Revelation to expect that in the future world the *knowledge* of good men will be indefinitely increased, in respect to their more enlarged conceptions of the Divine Being, and of his works and ways; that, among other subjects, they shall become more acquainted with the distant regions of creation, the destination of those great globes which we now behold at an impassable distance, the history of their inhabitants, the various stages of improvement through which they have passed, the most remarkable events which have happened among them since their creation, the relations which the different worlds bear to each other, the various orders of intellectual beings and their distinctive characteristics and endowments, with many other particulars which would afford an ample field of investigation and contemplation which could scarcely ever be exhausted, and a source of progressive and permanent delight. But all such prospects of knowledge and enjoyment would be forever shut out, were the universe a collection of mere matter unconnected with mind or intelligence, and the distant view of an immortal existence would present little else than a scene of monotony or a boundless blank.

In the future world, although the circumstances in which the mind will exist, will be different from its present local associations, yet its faculties, desires, and affections, will not be *essentially* changed. It will continue the same identical being, only transported to another region, and connected with other objects and associations.—It will have the same or similar aspirations after happiness, the same desires after new objects and discoveries, and the expansion of its intellectual views, and the same delight in beholding one scene of creating grandeur after another unfolding itself to view, as it feels, in a certain degree, in the present state. Such desires after progressive improvement in knowledge and happiness are implanted by the Creator, and form an essential part of the constitution of the human soul, and therefore can never be eradicated so long as it is sustained in existence. But it is evident, from what has been already stated, that such desires could never be gratified, and that its expectations of higher degrees of intellectual expansion and enjoyment would be frustrated, were the scene of Omnipotence nothing more than an indefinite extension of matter without life or intelligence; for in such a case there would be little scope for the exercise and expansion of its powers throughout an immortal existence.

3. The supposition that matter throughout the universe is not connected with mind would present a distorted view of the character of the Almighty, and throw a vail over the most glorious perfections of his nature. It would virtually deprive the Creator of the attribute of *wisdom;* since no display of it would be perceived in the most magnificent works of his hands. It would, in effect, rob him of his *goodness;* since, throughout the mightiest and most extensive portion of his works, no enjoyment is communicated to beings endowed with either sensitive or rational natures, which are alone capable of being recipients of his bounty; consequently, no tribute of gratitude and thanksgiving would be offered, and no praises or adorations would ascend to the throne of the "King eternal, immortal, and invisible," from the greatest portion of his boundless dominions It would prevent us from beholding any extensive display of the *rectitude* of his character and the equity of his government in the moral administration of the universe. Now, wisdom, goodness, and rectitude, can only be exercised in reference to intelligent natures, and cannot possibly be displayed where such beings have no existence.

The denial therefore of the position, that the great universe is peopled with inhabitants, would lead us to contemplate a Being whose power has brought into existence a magnificent assemblage of means without an end; who has prepared glorious habitations fitted for the enjoyment of rational natures, but has never peopled them; who is the alone source of happiness, and yet refuses to communicate of his goodness where there is full scope for its exercise; and who is the Supreme Lawgiver and the spring of moral order, and yet affords no display of his moral attributes throughout the immensity of his works: for this earth, and all the beings that have ever been connected with it, are but as a drop to the ocean compared with the immensity of the material universe. Can it therefore be a theater of sufficient expansion for the display of the character and attributes of that being who has existed from eternity past, and will exist to eternity to come, and whose presence fills the amplitudes of boundless space?

If, then, such absurd consequences necessarily follow from maintaining the position, that there is no plurality of worlds, *that position cannot possibly be true.* It undermines truths of the first importance, which lie at the foundation of all consistent views of the character of the Deity, and which are acknowledged to be such by all rational theists and Christian divines. And, since what is directly opposed to truth must be error, and *vice versa*, it follows that the doctrine we are supporting must be considered as susceptible of moral demonstration; for it may be laid down as an axiom, that it is essential to the character of Deity that he act consistently in all parts of his dominions, that he display in every instance *all his perfections* in harmony, and that wherever his omnipotence has been exerted, there likewise he must display his wisdom, benevolence, and rectitude.—Whatever opinion therefore directly tends to undermine or oppose such views of the Divine character and perfections must be absolutely untenable, and the opposite opinion must be indisputably true.

In my work on "Celestial Scenery" I entered on the consideration of several arguments which tend to prove the doctrine of a plurality of worlds, and that the planets of the solar system in particular are the abodes of intellectual beings. This position was illustrated at some length from the following considerations: that there are bodies in the planetary system of such *magnitudes* as to afford ample scope for myriads of inhabitants; that there is *a general similarity* among all the bodies of the system, which affords a presumptive evidence that they are intended to subserve the same ultimate designs; that, connected with the planets, there are certain *special arrangements* which indicate their adaptation to the enjoyment of sensitive and intellectual beings; that the scenery of the heavens, *as viewed from the surfaces of the larger planets and their satellites*, forms a presumptive proof of the same position; and that the fact *that every part of nature in our world is destined to the support of animated beings*, affords a powerful argument in support of this doctrine. These arguments and considerations, when viewed in all their bearings, and in connection with the wisdom and goodness of the Divine Being, might be considered, without any further discussions, as quite sufficient to substantiate the position, that the planets and satellites of our system, as well as other departments of the universe, are the abodes of sensitive and intelligent beings.

In the preceding pages I have offered a few additional considerations bearing on the same point, which, I trust, will tend to corroborate the arguments and reasoning formerly adduced.—I have shown that the doctrine of a plurality of worlds is more worthy of the perfections of the Infinite Creator, and gives us a more magnificent idea of his character and works, than to suppose his benevolent regards confined to our comparatively diminutive world; that it is more accordant with the *infinity* and *eternity* of the Divine Being, and with his *wisdom* and *benevolence* than the opposite position; that wherever any one perfection of Deity is exerted, there also *all* his attributes are in operation; and consequently, wherever Omnipotence is seen to operate, there likewise, wisdom, benevolence, rectitude, and every other Divine perfection, must be displayed, and can only be displayed in reference to intelligent beings; that there is *an absurdity involved* in the contrary supposition; that this supposition would represent the universe as an immense desert, unworthy of the contemplation of intelligent minds; that it would prevent the progressive expansion of intellectual views in a future state, and present a distorted view of the character and attributes of the Almighty Creator. All these arguments and considerations, when viewed in a proper light, tend to yield a mutual support to each other, they hang together in perfect harmony, and they are in full consistency with the most amiable and sublime conceptions we can form of the Divinity; and therefore ought to carry irresistible conviction to the mind of every unbiased and intelligent inquirer. To my own mind, they amount to *a moral demonstration;* so that I am as fully convinced of the truth of the position we have been maintaining, as if I were transported to the regions of distant worlds, and permitted to mingle in association with their inhabitants

CHAPTER XVII.

A PLURALITY OF WORLDS PROVED FROM DIVINE REVELATION

It is somewhat difficult to persuade the greater part of mankind that there are any habitable worlds beside our own, or that rational beings, somewhat analogous to man, may inhabit the planets of our own or of other systems. Even the greater part of Christians, and some who are possessed of a considerable degree of intelligence, can scarcely be persuaded that there are more worlds than one, or that the Divine government extends beyond the Christian Church and the nations of the earth; and they attempt to vindicate their opinion by asserting that the Scriptures never make the least allusion to any world except that in which we dwell. Although this were in reality the case, it would form no argument against the doctrine of a plurality of worlds; for the revelations contained in the Scriptures are chiefly of a *moral* nature, their great object being to counteract the depravity of man, and to afford information respecting the plans, and perfections, and moral government of the Divine Being, which the unassisted light of nature was unable to explore. They were not intended to teach us the principles of physical science, or the particular knowledge of any other subject which the human faculties were of themselves adequate to acquire; but to direct us, in all our surveys of the works of God, to look upward to him as the Supreme Agent, to trace his attributes in all his operations, and to offer him a tribute of grateful adoration.—The Scriptures, therefore, would be fully sufficient to answer all the purposes of a revelation to man, although they made no allusion to other worlds, or to other intelligences within the range of the Divine government.

Since the system of nature, the system of revelation, and the rational faculties of man, had their origin from the same Almighty Being, we should naturally expect that they should perfectly harmonize in their grand lineaments, and in the truths they are calculated respectively to unfold; or, at least, that there should be no glaring contradiction between the intimations given by the one and by the other. If the investigations of reason in regard to the material universe necessarily lead to the conclusion that numerous worlds exist throughout immensity, and if the Scriptures contain a communication from God, we should never expect to find in that revelation any proposition asserting that there is only one world and one race of intelligent beings in the universe, and it is needless to say that no such proposition is to be found in the Bible. On the contrary, though the Scriptures never directly or explicitly treat of this subject, the doctrine of a plurality of worlds *is embodied in many passages of the sacred writings;* and the language of the inspired penman is in all cases perfectly consistent with the idea of myriads of worlds existing throughout the universe. To illustrate this position, in a few instances, is the object of this chapter; and as the passages of Scripture in which this sentiment is embodied are more numerous than is generally apprehended, I shall select only a few of them as the subject of comment and illustration.

The first passage on which I shall offer a few remarks is Psalm viii, 3, 4: "When I consider thy heavens, the work of thy fingers, the moon and the stars, which thou hast ordained; what is man, that thou art mindful of him! or the son of man, that thou visitest him!"

When composing this hymn of praise to God, the Psalmist evidently appears to have been contemplating, with intelligence and pious emotion, the glories of the nocturnal sky—the moon walking in brightness along the canopy of heaven, and the stars and planets diffusing their luster from more distant regions. Viewing those resplendent orbs, his thoughts seem to have taken a flight into the regions of immensity, and by the guidance of his rational powers, and aided by the spirit of inspiration, he takes an expansive view of the multitude, the magnitude, and the grandeur of those magnificent orbs which roll in the distant tracks of creation. Overwhelmed with his views of the immensity of the universe, and of the perfections and grandeur of its Creator, he breaks out into this striking exclamation, "Lord! what is *man*, that thou art mindful of him! or the son of man, that thou visitest him!" Surveying with his intellectual eye the boundless extent of God's universal empire, he shrinks, as it were, into nothing, and seems almost afraid lest he should be forgotten or overlooked amid the immensity of beings over which the Divine government extends. Now, there could be no emphasis or propriety in this exclamation, if the inhabitants of this globe were the only rational beings that peopled the material universe; for, if man is the principal inhabitant of creation, it could be no matter of wonder and astonishment that God should be "mindful of him," and exercise toward him a special regard and superintending care. Such a minute attention and affectionate regard is nothing more than what we should have naturally expected. But, if the immensity of space be diversified with ten thousand times ten thousand worlds, replenished with rational inhabitants, as science and right reason demonstrate; if the race of Adam appear no more in proportion to the beings that people the amplitudes of creation, than as a drop to the ocean, then the Divine condescension appears truly wonderful and astonishing,—that, from the hights of his glory in the heavens, the Most High should look down with an eye of complacency on the puny inhabitants of earth, and regard them with a Father's attention and care. This is evidently the leading idea which the pious exclamation of the Psalmist is intended to convey; and therefore, if this globe were the only or the principal abode of rational beings, such language would be mere hyperbole, or something approaching to bombast, which would be inconsistent with the veracity and solemnity of an inspired writer.

It appears, then, that the passage under consideration is not only consistent with the doctrine of a plurality of worlds, but necessarily embodies in it the idea of the Divine empire being indefinitely extended, and comprising within its range numerous orders of exalted intelligences. It likewise teaches us, that while the Almighty has diversified the fields of immensity with innumerable worlds; that while he sits enthroned on the magnificence of his works in the distant regions of his creation, and governs the affairs of unnumbered orders of intellectual existence, *he also exercises the minutest superintendence over every world he has created*, however diminutive in comparison of the whole. His eye rests on the humblest and the minutest of its objects, and his Spirit watches over it as vigilantly as if it formed the sole object of his physical and moral administration; so that neither man nor the smallest microscopic animalculæ are overlooked amid the multifarious objects of the Divine government. This is an attribute *peculiar to the Most High*, which flows from the immensity of his nature and the boundless knowledge he has of all his works, and which gives us a more glorious and sublime idea of his character than if his regards were confined to one department of his empire, or to one order of his creatures; and in nothing is the Divine Being so immensely separated from man, or from any other rank of intelligent existence, as in the display he gives of this wonderful and incommunicable attribute. By overlooking this peculiar characteristic of the Divinity, and attempting to compare his procedure with the limited conceptions of our own minds, we are apt to indulge in very contracted and erroneous views respecting his nature and universal government, as well as in regard to the revelations of his word and the dispensations of his providence.

The next passage I shall notice is Isaiah xl, 15, 17. "Behold, the nations are as a drop of a bucket, and are counted as the small dust of the balance." "All nations before Hɪᴍ are as nothing, and they are counted to him less than nothing and vanity."

In the chapter from which these words are taken, the prophet announces deliverance from the captivity of Babylon, and the approach of that period when "the glory of Jehovah shall be revealed, and when all flesh shall see it together."—In order to obviate every difficulty that might seem to stand in the way of the accomplishment of such a glorious event, the prophet describes, in the most sublime language, the perfections and character of him by whose agency this astonishing change in the world was to be introduced. He is declared to be that Almighty Being "who measures the ocean in the hollow of his hand, who meteth out the heavens with the span, who comprehendeth the dust of the earth in a measure, and weigheth the mountains in scales, and the hills in a balance." The prophet likewise denounces the folly and wickedness of idolatry, by exhibiting the character and operations of him whom no material images, however splendid, can ever represent or adumbrate. "He sitteth on the circle of the sky which surrounds the earth, and the inhabitants thereof are as grasshoppers; he stretcheth out the heavens as a curtain; he bringeth forth their host by number; he calleth them all by their names, by the greatness of his might; for that he is strong in power, and there is no searching of his understanding." Among these sublime descriptions are contained the passages I have quoted,—"Behold, the nations are as the drop of a bucket." "All nations before him are as nothing," &c. Such declarations could scarcely be made with propriety, if all the rolling orbs of heaven were destitute of inhabitants; for then it would not be true that "all nations are as the small dust of the balance," and that they are "counted to Jehovah as less than nothing and vanity." They who deny the doctrine of a plurality of worlds assume the position, "that man holds the principal station in the material universe;" but were this the case, then the nations of the earth, and "their multitude and glory," behooved to be considered as the greater portion, or as one of the greater departments of the Divine empire; and if so, it would be approaching to extravagance and bombast for any one to declare that they are only like a drop compared with the ocean, like a few particles of dust compared with a mighty island, or, in comparison with other departments, that "they are as nothing, and less than nothing and vanity."

We are here to consider the comparisons and contrasts drawn in those passages as referring, not to Jehovah, abstractedly considered, but to the *manifestations* he has given of his power, wisdom, and grandeur, in the scenes of the universe. Hence we are directed in the chapter from which our quotations are taken, to "lift up our eyes on high," and contemplate "the firmament of his power;" to "behold the hosts" of resplendent globes which he has dispersed throughout the regions of space "by the greatness of his strength," and to consider that the vast extent of the celestial spaces have been "meted out with a span." When the inspired writers demand from their hearers a sentiment of reverence and admiration, they do not present to them metaphysical reasonings or abstract views in reference to the perfections of Jehovah, but describe those exhibitions of his power and grandeur which are calculated to strike the senses and imagination, and to excite the emotion intended. Thus, when the prophet Jeremiah wished to impress his hearers with a reverential sense of the greatness of God, he describes him by the *effects* of his power and wisdom as displayed in his operations. "Who would not fear thee, O King of nations! He hath made the earth by his power, he hath established the world by his wisdom, and hath stretched out the heavens by his discretion. When he uttereth his voice, there is a noise of waters in the heavens, and he causeth the vapors to ascend from the ends of the earth; he maketh lightnings with rain, and bringeth the wind out of his treasures."

In like manner, in the passages under consideration, we are to consider the contrast here stated as drawn, not between all nations and Jehovah as an abstract Being, whose perfections are infinite; for in this respect no comparison can be made, but as drawn between this earth with all its inhabitants, and the innumerable globes which are scattered throughout the regions of immensity. And the most enlightened astronomer, after his boldest excursions into the illimitable tracks of creation, could devise no language to express his emotions, and the contrast that subsists between this globe and the immensity of the heavens, more appropriate and energetic than the passage before us. This world, with "all that it inherits," is here represented as a single drop of water to the mighty ocean, or as a few particles of dust to the most spacious continents, when compared with the grandeur and immensity of nature; yea, to complete the contrast, it is "counted as nothing and less than nothing and vanity." When we survey the vast globes which compose the planetary system; when we wing our flight in imagination to the starry regions, and leave the sun and all his attendants behind us, until they dwindle to an undistinguishable point; when we prosecute our course through thousands of nebulæ, every one of them containing unnumbered suns and systems; and when the mind is bewildered and overpowered at the immensity of the prospect, we cannot but perceive that the language of the prophet is the most impressive, and the fittest that could have been selected; that it is most emphatic, and literally true. But if this earth were the principal part of God's universe, there could be no propriety in such language, and it could be considered as allied only to extravagance and pompous declamation—a characteristic which ought never to be applied to the writers of the sacred records.

We ought likewise to consider that the contrast is not stated between the earth considered merely as a *material system*, and the amplitudes of the firmament, but between *the nations of the earth* and the innumerable order of beings which people the universe, plainly implying, in my apprehension, that unnumbered myriads of intelligences occupy the celestial worlds, in comparison of which all who now dwell upon the earth, or who have occupied its surface since time began, are only as a drop to the ocean. The passage before us may therefore be considered as almost a direct intimation of a plurality of worlds; and, if it could be proved that no other worlds existed, I should scarcely consider the strong language here used as the dictate of inspiration; but when we consider what appear to be the true references of the prophet's language, and the magnificent ideas it suggests, it conveys the most glorious and sublime conceptions of the grandeur of "the high and lofty One who inhabiteth eternity," and whose presence fills the immensity of creation.

The next passage I shall adduce in support of the position under consideration, is Nehemiah ix, 6: "Thou, even thou, art Lord alone; thou hast made heaven, the HEAVEN OF HEAVENS, with all their host, the earth, and all things that are therein, the seas, and all that is therein, and thou preservest them all; and the HOST OF HEAVEN worshipeth thee."

Here the Most High is represented, not by a metaphysical exhibition of his infinity, eternity, and omnipotence, abstractedly considered, but by the *manifestations* he has made of himself in his wonderful operations, both in heaven and on earth; and this is the general, I may say universal, mode in which the sacred writers exhibit the character and perfections of the Deity. "Thou hast made heaven, the heaven of heavens, with all their hosts." By "heaven" is here to be understood the visible firmament, with all the stars and planets perceptible by the human eye, which is the sense in which the term heaven is generally taken when God is represented as its Creator. The "heaven of heavens" is an expression which is worthy of particular attention, and evidently includes in it an idea far more extensive and sublime than what most readers generally attach to it. It evidently intimates that, far beyond the visible starry heavens which we behold, there are unnumbered firmaments, composed of other stars and systems stretching out toward infinity on either hand, and which mortals in their present state will never be able to descry. We have already attained some glimpses of such firmaments. More than a hundred millions of stars, in addition to those distinguishable by the naked eye, are within the reach of the telescope, if all the regions of the sky were by this instrument thoroughly explored. We behold several hundreds, and even thousands of *nebulæ* in different spaces of the heavens, each of them consisting of thousands of stars, which would form a firmament as glorious and expansive as that which appears to a common observer in the midnight sky; so that were we removed from one of those nebulæ to another, we should behold at every stage a new firmament, composed of stars or other luminaries altogether different from what we had seen before, or from what we perceive in the firmament which is visible from our globe.—Those facts, which have been brought to light by the discoveries of modern astronomy, while they display the infinite power and grandeur of the Divinity, serve likewise to illustrate many of the declarations of his word, and particularly such expressions as that before us,—"the heaven of heavens," the boundless empire of the "King eternal and invisible," in which he reigns over unnumbered intelligences. The same emphatical expression is used in the prayer of Solomon at the dedication of the temple: "But will God in very deed dwell on earth? Behold, the heaven and heaven of heavens cannot contain thee!" implying that far beyond the range of the material universe, vast and extensive as it is, the great Jehovah resides in the glory of his invisible attributes, filling immensity with his presence.

By "*the host of heaven*" is doubtless to be understood the inhabitants of those numerous worlds and vast regions here designated by the most emphatic expression which could be selected, "the heaven of heavens;" intimating that the same Almighty Being who launched into existence those innumerable globes also replenished them with countless orders of intelligent existence, capable of enjoying his bounty, and offering to him a tribute of adoration. Hence it is here declared, "the host of heaven *worshipeth* thee;" evidently implying, if there is any rational idea to be elicited from the passage, that the bodies which compose "the heaven of heavens" are occupied with inhabitants; that these inhabitants are endowed with capacious powers of intellect; that their numbers correspond with the amplitude of the regions which they occupy; that most, if not all of them, are invested with the attribute of moral perfection, and are consequently in a state of happiness; that they employ their faculties in contemplating the perfections and operations of their Creator; and that they magnify and adore him in the loftiest strains, as the center and source of all their felicity: all which appears to be implied in the passage, "the host of heaven worshipeth thee." For no being can with propriety be said to worship Jehovah, unless such as are endowed with moral and intellectual powers, capable of appreciating his perfections, as displayed in the universe, and of perceiving that he is worthy of all homage and adoration. In accordance with such views the Psalmist, when his soul was inspired with the higher strains of devotion, in a sublime apostrophe, calls upon the whole intelligent universe to adore the name of Jehovah:—"Praise ye Jehovah from the heavens; praise him ye heaven of heavens,"—or, ye *inhabitants* of those higher regions,—"praise him, all ye his angels; praise him, all ye his hosts. Let them praise the name of the Lord, for his name alone is exalted, and his glory is above the earth and heaven." If therefore there were no other worlds than that on which we dwell, such magnificent expressions would lose all their sublimity, would be almost without meaning, and might be regarded rather as the turgid exclamations of an enthusiast than as the sober dictates of inspiration. But when we take into view the immensity of the universe, and the numerous worlds and beings it contains, such expressions, though among the strongest which human language can furnish, fall far short of communicating the lofty ideas they are intended to represent.

Such passages as the following may likewise be considered as embodying views of the same description:—Psalm ciii, 19,—"The Lord hath prepared his THRONE in the heavens; and his kingdom ruleth over all."

This, along with a number of similar passages interspersed throughout the Scriptures, evidently implies that *the heavens* form the principal part of the Divine empire, compared with which, this earth is but as a point, and "all its inhabitants reputed as nothing." They are represented as the chief and appropriate residence of Jehovah, where he displays the glory of his perfections to unnumbered intelligences. Hence he is declared to have "*established his throne* in the heavens," intimating, that it is in those higher and more expansive regions that the principal arrangements of his government have been made, that the beneficence and rectitude of his character are manifested, and that the grandeur of his moral administration is most extensively displayed. But it is evident, that where there are no intellectual beings, there can be no moral government; and therefore, if the Almighty has a government in the heavens, these heavens must be peopled with beings endowed with moral and intellectual faculties, capable of being the subjects of a moral administration. To suppose a government without subjects, is evidently preposterous and absurd. It is added, "His kingdom ruleth over all." Wherever these expansive heavens extend, and however numerous and august the worlds and systems which lie within their range, they are all under the superintendence and sway of the Divine government, which extends its care and moral energies over the remotest regions of the universe. But as there can be no kingdom without rational and moral subjects, therefore, wherever the kingdom of Jehovah extends throughout the illimitable spaces of immensity, there must be myriads of beings endowed with rational and moral natures. Similar remarks might be made upon such declarations as the following: "The Lord, he is *God* in the heaven above," intimating his rule or dominion over the worlds on high: "Behold the heaven and the heaven of heavens is the Lord thy God's," intimating, likewise, that he presides in high authority over all the beings they contain; "Thine, O Lord, is the greatness, and the glory, and the majesty; for all in heaven and in earth is thine. Thine is the kingdom, O Lord, and thou art exalted above all;" "Heaven is my *throne* and the earth is my footstool;" "His kingdom is an everlasting kingdom;" "His dominion is an everlasting dominion;" and "He doeth according to his will *in the army of heaven*, and among the inhabitants of the earth." All these, and similar passages, imply *rule* and *dominion* over the inhabitants of the heavens; and consequently intimate that the celestial worlds are occupied by the subjects of the Divine government. It is not improbable that the expression which so frequently occurs in Scripture, "*The Lord of hosts*," or the Lord of armies, has a particular reference to the universal dominion of Jehovah over the countless myriads which people the distant regions of creation.

Psalm cxlv, 9: "The Lord is good to all; and his tender mercies *are over all his works*."

The goodness of God, in innumerable modes and instances, is displayed, not only toward man, but to all the diversified orders of animated existence in this lower world. But it is not confined to this terrestrial sphere, but is diffused wherever his wisdom and omnipotence have prepared habitations for sensitive and intellectual beings. Hence it is here declared, that "his tender mercies," or the emanations of his goodness and beneficence are diffused "*over all his works*;" implying that throughout the whole range of the material system, however far it may extend, the beneficence of the Deity is displayed to numerous ranks of his sensitive and intelligent offspring; for unless such beings exist throughout all places of his vast dominions, there could be no scope for the exercise of his benevolence, and of course, it could not be said, with propriety, to extend "over *all* his works." In the same point of view we may consider an analogous expression in Psalm cviii, and other places of Scripture,—"Thy mercy is great above the heavens;" or, as Mr. Locke translates it, "Great is thy BOUNTY *above the heavens*;" an expression which leads us to conclude, that far beyond these visible heavens which the unassisted eye beholds, and even beyond the reach of all the orbs which the telescope has enabled us to descry, the Divine goodness shines in rich manifestations, diffusing felicity and ecstatic joy among unnumbered legions of happy existence; for "bounty" or "goodness," can have a relation only to such beings.

In the following passage of Psalm cxiv, 10–13, it is declared, "All thy works shall praise thee, O Lord, and thy saints shall bless thee.—They shall speak of the glory of thy kingdom, and talk of thy power; to make known to the sons of men his mighty acts, and the glorious majesty of his kingdom. Thy kingdom is an everlasting kingdom," &c.

This passage may be considered as embodying a prediction that in the future ages of the church men of piety will acquire more elevated and comprehensive views of the extent and the grandeur of the universal kingdom of Jehovah, and will display a more enlightened zeal than in ages past, in exhibiting to their fellow-men the august operations of Omnipotence, and the magnificence of that empire over which the Most High presides.—"They shall speak of the glory of Jehovah's kingdom, and talk of his *power.*" If this kingdom were chiefly confined to the evanescent speck of earth on which we live, it would scarcely be worthy of the epithets which are here bestowed upon it. It is a kingdom of GLORY; it is a kingdom in which are displayed *mighty acts* or operations; it is a kingdom of *glorious majesty;* it is a kingdom in which are displayed "power," and "*greatness which is unsearchable;*" it is a "kingdom of all ages," and its administration will be carried forward throughout all the revolutions of eternity—"thy kingdom is an *everlasting* kingdom." Were its government conducted chiefly in reference to earth and its inhabitants, such descriptions of its grandeur could scarcely be expected from inspired writers, nor would such a limited kingdom correspond to the majesty of an infinite, omnipotent, and eternal Being, who has the range of immensity as the theater of his operations. But when we contemplate the universal kingdom of Jehovah extending throughout the unlimited regions of space; when we behold it filled with worlds of immense magnitude, and with systems of worlds in such a multitude and variety that no man can number them, we perceive at once that such a kingdom warrants the application of such lofty epithets and expressions as are here used; that it is indeed a kingdom displaying omnipotent "power," and "greatness unsearchable;" that it is connected with "mighty operations;" that it is invested with "glorious majesty;" and that it is worthy of everlasting duration. But as the idea of a kingdom necessarily includes *subjects,* and as the multitude of subjects constitute the chief glory of an empire, so we must necessarily admit that all the provinces of this celestial kingdom are replenished with inhabitants, or in other words, *subjects* of the Divine government; without which it could have no "glory" nor "majesty," nor could it with propriety be entitled to the designation of a "kingdom."

Such passages as the following may likewise be considered as corroborating the preceding positions: Psalm cxiii, 4–6, "Who is like unto the Lord our God, who dwelleth on high? The Lord is high above all nations, and *his glory above the heavens.* He humbleth himself to behold *the things that are in heaven* and in the earth." "Thy goodness is great above the heavens, and thy truth reacheth to the skies. Thou are exalted, O God, *above the heavens,*" &c.

These passages, and others of a similar import, embody the general idea that the omnipotence and grandeur of the Divinity are displayed in regions far beyond that firmament which is visible from our globe by common observers, yea, beyond the utmost limits to which telescopic discoveries have conducted us; for "his glory is *above,*" or beyond "these heavens." And if nothing but empty space existed beyond these limits, or mere matter without mind, it could scarcely be said that the Divine *glory* is displayed beyond these heavens. It is further stated that the glory of the Almighty is so expansive, and that his universal kingdom extends through regions so immeasurably distant that he may be said, speaking after the manner of men, "to *humble himself* when he beholds *the objects in the heavens*" which lie within our observation. This declaration contains not only a sublime representation of the magnificence of the Divine nature and operations, but appears to me to embody in it a demonstration of what we formerly asserted as highly probable—namely, that that portion of the universe which lies within the range of telescopic vision, and which contains so many millions of splendid suns and systems, is but a *small part* of the universal kingdom of Jehovah, compared with what lies beyond the utmost boundaries of human vision; for he is here represented as *humbling* himself when he looks down from the remoter glories of his empire on all that is visible to the view of mortals. To the same purpose is the pious exclamation of the Psalmist in the 8th Psalm: "O Lord, our Lord, how excellent is thy name in all the earth! *who hast set thy glory above the heavens!*" And if the glory of the Divinity be manifested in regions far beyond the visible firmament, we may rest assured that it consists in displaying his perfections, and communicating happiness to innumerable orders of rational beings, who are the subjects of his moral government.

I shall only further offer a few cursory remarks on the following passages:—Psalm xix, 1, "The heavens declare the glory of God," &c. The word *glory* in this and similar passages, when applied to the Divinity, denotes the display of his wisdom, goodness, omnipotence, and other attributes. The heavens, with all the host of rolling orbs which they contain, are here declared to manifest the "glory," or the infinite perfections, of Him who formed them. The number and magnitude of the opaque and luminous globes contained within the vast expansion of these heavens, and their astonishingly rapid motions, evidently proclaim his *omnipotence;* but if those bodies accomplished no end corresponding to the extent and grandeur of the means employed; if they were all so many expansive deserts, without any relation to intellectual existence, they could afford no evidences of wisdom and beneficence, and consequently could not be said, with any show of reason, to "declare the glory of God." In the visions recorded in the Book of Revelation, the celestial inhabitants are represented as falling down before the throne of the Eternal in acts of adoration, and proclaiming, "Thou art worthy, O Lord, to receive glory, and honor, and power; for thou hast created all things." And in another scene they are introduced as celebrating with rapture the Divine operations: "Great and marvelous are thy works, Lord God Almighty."—"Blessing, and glory, and wisdom, and thanksgiving, and honor, and power, be unto our God for ever and ever." Similar remarks to the above might be made in reference to these ascriptions of praise and adoration. If creation were a kind of chaos, or wilderness void of inhabitants, and if wisdom, design and goodness were not displayed in the Divine arrangements, there would be little to excite the *admiration* and devotional rapture of superior intelligences; and they could not be said with propriety to ascribe *wisdom,* and glory, and thanksgiving to God, while they beheld no display of some of these attributes in the mightiest of his works. But we are told in various passages of Scripture that the Most High "established the world," or the universe, "by his wisdom, and stretched out the heavens by his understanding." In Psalm cxlvii, 4, it is declared—"He telleth the number of the stars; he calleth them all by their names." It is evident that we are not to consider this declaration as expressive merely of an arithmetical idea or something similar to the practice of an astronomer, who distinguishes the stars by certain letters, characters or appellations; but as expressive of the intimate knowledge which the Almighty has of all those mighty orbs wherever dispersed throughout the regions of infinitude, and likewise his perfect acquaintance with all the intellectual beings, and the special arrangements connected with every one of them—a circumstance which conveys a most sublime idea of the omniscience and omnipresence of the Deity. Hence, in the words immediately following, the mind of the Psalmist, overpowered with this idea, bursts forth in this exclamation, "great is our Jehovah, and of great power; his understanding is infinite."

In the Epistle to the Hebrews, chapter i, 2, and xi, 3, a plurality of worlds is declared: "Through faith we understand that *the worlds* were framed by the word of God, and that the things which are seen were not made of things that do appear." The Greek word αιων, in this passage, is sometimes used to denote *an age* or *dispensation*, but is also frequently used to designate the material world; in which sense it must be taken in the passage before us, as is evident from its connection, and from the subject on which the apostle is treating. It is to the visible or material world that our attention is here directed as having been produced from an invisible cause. The term αιωνας being used in the plural number, evidently intimates that there are more worlds than one, and that there may be thousands or millions; but, independently of this direct intimation of a plurality of worlds, the passages formerly quoted, when viewed in a proper light, and considered in all their references and bearings, may be considered as conclusive proofs of the same position, and as intimating to us, not simply a plurality of worlds, but extending our views of their number and magnificence as far as science has yet conducted us, and even beyond the range of astronomical discovery; for we are told that the Divine perfections are displayed "above," or beyond, the utmost range of "the visible heavens."

Many other passages beside the above might have been pointed out as bearing on the same subject, but the remarks already made on the passages which have been selected may serve as a key to illustrate many others, as they happen to occur to the intelligent student of the Scriptures. We read, for example, of the Almighty "operating, by his moral government and arrangements," "among the army," or armies, "of heaven," as well as "among the inhabitants of the earth;" and that the whole population of our world "is reputed as nothing in his sight." We find in different portions of the psalms, the inhabitants of the heavens, and "the heaven of heavens"—the "angels who excel in strength"—"all his hosts," or legions of intelligences, "in all places of his dominions, who do his pleasure, hearkening to the voice of his word,"—we find all these ranks of beings called upon to join in one united chorus of praise and thanksgiving to "Him whose name alone is exalted, and whose glory is above the earth and heaven." We read in the Book of Job, among many other descriptions of the grandeur of the Deity, that "by his spirit he garnished the heavens;" and that the astonishing displays of his omnipotence they contain "are but parts of his ways," and that "the thunder of his power none can understand." All of which representations, and many others, may be considered as embodying the idea, not only of a plurality, but of myriads of worlds existing in the universe.

There is one general remark which may be applied to all that we have stated in this chapter, and that is—*It is not necessary to suppose that the inspired writers had revealed to them all the wonders of modern astronomy.* They appear, in some instances, to have been ignorant of the precise meaning and the extensive references of the language they used. The prophets are said to have "inquired and searched diligently what manner of time the spirit of Christ which was in them did signify, when it testified beforehand the sufferings of Christ and the glory that should follow;" intimating that they were partly unacquainted with the precise references of the predictions they uttered. They were only the *amanuenses* of the Divine Spirit, and were directed to such language as was accordant with the Divine economy and with the facts existing in the universe, although they themselves might not be aware of the grandeur of those objects to which their expressions referred; and the correspondence of their language with the phenomena of the heavens and the earth, and the discoveries of modern times, constitutes one evidence among others of the truth of Divine Revelation.

CHAPTER XVIII.

ON THE PHYSICAL AND MORAL STATE OF THE BEINGS THAT MAY INHABIT OTHER WORLDS.

On the enunciation of this topic, some readers will probably, be apt to surmise, that the author is attempting to go beyond the range of subjects within which the human understanding should be confined. We have never seen the inhabitants of other worlds; we have been favored with no *special* revelations respecting them; we have not even caught a glimpse of the peculiar scenery of the globes in which they reside, excepting a few portions of their celestial phenomena; and while we are chained down by the law of gravitation to this sublunary sphere, we cannot fly on the wings of a seraph to visit any of the distant orbs of the firmament. It is true, that on such a subject we cannot attempt to descend into particulars. But there are certain general and admitted principles on which we may reason, and there are certain phenomena and indications of design exhibited in the structure of the universe from which certain general conclusions may be deduced; beyond such generalities I do not intend to proceed, nor to indulge in vain conjecture.

There are many things of which we have acquired a certain degree of knowledge, and yet have never seen. We do not see the air we breathe, nor most of the gaseous fluids; we do not see the principle of life, or the rational spirit which animates our bodies; we cannot possibly see the Divine Being, although his presence pervades all space. But, in regard to all these objects, we have acquired a certain degree of information; and therefore, although we have never seen any of the inhabitants of other planets, and never will so long as we remain in our present abode, yet we may form some general conceptions respecting them, both as to their physical and moral state. All that I propose on this point may be comprehended under the following general remarks:

1. The planets, wherever they exist, in our own or in other systems, are inhabited by *sentient beings*. The formation of *material* fabrics, such as all the planetary bodies are, necessarily indicate that beings connected with *material* vehicles and organs of sensation were intended to inhabit them. The arrangements for the diffusion of light, heat, and the influence of the power of attraction, and other material agencies, evidently show that such agents were intended to act on beings formed with organical parts and functions, capable of being the recipients of impressions from them. All such beings, therefore, must be considered as furnished with bodies constructed with organical parts *analogous* to what we find in man or other animated beings on our globe; but the size and form of such bodies, the parts of which they are composed, the functions they respectively perform, their symmetry and decoration, and their powers of locomotion, may be very different from those which obtain in our sublunary world; and it is not unlikely, from a consideration of the *variety* which exists in the universe, that there is a certain difference, in these and other respects, in every planet and world that exists throughout immensity.

2. The principal inhabitants of the planets and other worlds are not merely sensitive beings, but are likewise endowed with *intellectual faculties*. This may be inferred from the scenery connected with their habitations. Connected with the planet Jupiter, we behold four splendid moons, larger than ours, performing their revolutions around it *in regular periods of time*, without the least deviation from their courses. The general aspect of these moons, their diversified phases and rapid changes, along with their frequent eclipses, must produce a sublime and variegated appearance in the nocturnal sky of that planet; while, from the surface of the moons themselves, the still more splendid appearance of Jupiter and the phases of the other moons will present a nocturnal scene of peculiar sublimity and magnificence. Connected with the planet Saturn, we find scenes still more august and diversified; beside seven large moons, two resplendent rings of vast extent surround the body of this planet, producing the most sublime and diversified phenomena, both to the planet itself and to all its satellites, adorning the firmaments of those bodies with a splendor and magnificence of which we can form but a faint conception.* Were we permitted minutely to inspect the surfaces of these planets, we should doubtless find many beautiful arrangements in the scenery of nature with which they are adorned, probably far surpassing in picturesque variety and grandeur what appears on the surface of our globe. When we inspect the surface of the moon through a good telescope, we behold a beautiful diversity of extensive plains, of lofty mountains, in every variety of size and form—of plains and valleys surrounded with circular ramparts of hills—of mountains towering far above, and vales and caverns sinking far below the general level of the lunar surface, with many other varieties; and we have only to suppose the general surface of that orb adorned with vegetable productions somewhat analogous to those of our globe, in order to present a scene of picturesque beauty and magnificence.

Now, it appears a natural, if not a *necessary* conclusion, that such grand and beautiful scenes could only be intended for the contemplation and enjoyment of beings endowed with rational natures, since mere sentient beings, such as the lower animals in our world, are insensible either to the beauties of the vegetable kingdom or the glories of the spangled firmament. If our globe had been created merely for the support of such beings, it is not probable that it would have been adorned with all the beautiful arrangements which now exist, and the splendid and diversified scenes with which it is furnished. The lion, the tiger, and the hyena find every accommodation they desire in dens, deserts, thickets, and forests; and they appear to feel no peculiar enjoyment in flowery fields, expansive lakes, beautiful landscapes, or the sublimities of a starry firmament. If, then, there were no rational intelligences in the planetary worlds, we cannot suppose that so many grand and magnificent arrangements as we find existing would have been made; particularly, we cannot suppose that the motions of the planets and their satellites would have been so accurately adjusted as to perform their revolutions with so much precision as we find they do. The regularity and precision of these motions are evidently intended to serve as accurate measures of *time* or duration,—a circumstance which must always be a matter of importance to rational beings wherever existing, but which seems to be scarcely attended to, and perhaps not in the least appreciated, by merely sentient beings, such as the lower orders of animated nature which exist around us.

From what has been now stated, we may conclude that the inhabitants of the planets are not *purely spiritual* beings; for pure spirits, entirely divested of material vehicles, cannot be supposed to have a permanent connection with any material world or system; nor could they be supposed to be affected by air, light, colors, attraction, or other material influences, which operate on the surfaces of all the planetary bodies. If pure intelligences, disconnected with matter, exist in the universe, they must be conceived to have a more expansive range than the limits of any one globe, and those material agencies which affect the organs of sensitive existence cannot be supposed to operate upon them; and, consequently, their modes of perception must be altogether different from those of organized intelligences. We may therefore with certainty conclude that the intelligent beings connected with the planetary worlds, either of our own or of other systems, are furnished with *bodies*, or corporeal vehicles of some kind or other. These may differ in size and form in different planets; perhaps their size may depend on the amplitude of space which the different planets may contain. But I cannot acquiesce in a supposition lately thrown out by a certain reviewer, "that in some worlds the inhabitants may be as large as mountains, and in others, as small as emmets." In the one case, comparatively few inhabitants could live in a world where every one was a walking Mount Blanc or Mount Etna; and it would be contrary to all the known arrangements of the Creator; who appears to act on the principle of compressing into a small space the greatest degree of sensitive and intellectual enjoyment. Beside, such a huge mass of matter as a mountain is not only unnecessary, but in all probability would be highly injurious to the exercise of the intellectual faculties. In the other case, were rational beings as small as emmets, they could neither contemplate the beauties and sublimities of the scene of nature around them, nor the glories of the starry firmament; their range of vision could extend only a few feet or yards around them, and they never could be able to explore the nature, extent, and peculiarities of scenery of the world they inhabited. So that all such suppositions are evidently extravagant and absurd, being directly contrary to the proportion and harmony which exist in the universe, and which characterize all the arrangements of the Creator. In regard to the powers of locomotion, there may be considerable differences in different worlds. In many instances there is reason to believe their inhabitants are enabled to transport themselves from one region to another with a velocity far surpassing the locomotive powers of man. In the planet Venus some of the mountains are reckoned to be twenty-two miles in perpendicular elevation, from the top of which eminences the most sublime and diversified prospects must be enjoyed; and in order that its inhabitants may be enabled to ascend with ease such lofty elevations, it is not unreasonable to believe that they are endowed with powers of motion far superior to those of the inhabitants of our globe.

---

* For a particular description of the scenes here alluded to, the reader is referred to "Celestial Scenery," chap. viii.

3. The inhabitants of the planets are furnished with organs of sensation, particularly with *the organ of vision*. This may be certainly deduced from the fact, that there are connected with the planets arrangements for the equable *distribution of light*. The sun, the source of illumination, is placed in the center of the system for diffusing light in certain proportions over the surfaces of all the planets, their satellites, and their rings. Each planetary body revolves round its axis, in order that every part of its surface may alternately enjoy the benefit of the solar radiation. Around the larger planets are moons for the distribution of light in the absence of the sun; and one of them is invested with a double ring, which reflects the solar rays during the night both on the surface of the planet itself and on the surfaces of its moons. This diversified apparatus for the diffusion of light evidently appears to be an arrangement of *means* in order to the accomplishment of an important *end;* for it would be a reflection on the character of the All-wise Contriver to suppose that means have been arranged where no appropriate end is intended to be accomplished; but all the arrangements for the regular and equable diffusion of light have been made in vain, if there be no *eyes* or organs of vision on which light may act; for mountains, and vales, and barren deserts do not require its regular influence. That there are beings furnished with visual organs throughout all the worlds and systems of matter in the universe appears from the consideration, that not only in our own system, but among the myriads of fixed stars dispersed throughout immensity, provision is made for such organs in the existence of *light*, which is a substance that appears to be universally diffused throughout creation. It is found by experiment, that the light which radiates from the most distant star is of the same nature as that which emanates from the sun. It is refracted and reflected by the same laws, and consists of the same colors, as that which illuminates the bodies which compose the solar system, and which throws a luster on the objects immediately around us. The mediums of vision must therefore be acted upon by light, in the most distant regions of creation, in nearly the same manner as with us, although there may be numerous varieties and modifications of the visual organs, so as to render vision far more perfect and extensive than in the case of the inhabitants of our globe. We find that there is an immense variety in the modes of vision among the lower animals. Some of the smaller insects have their eyes nearly of a globular form and very small, so that they can see only a few inches around them; while the eyes of other animals, such as the eagle, are so constructed that they can perceive their prey at a great distance, and from a very elevated position. Some animals have only one or two visual organs or eye-balls, as man, birds, and quadrupeds; others have eight, as in the case of spiders; and others have several hundreds, and even thousands, of transparent globules, each of which is capable of forming a distinct image of any object, as is the case with flies, butterflies, and other insects. All these diversified constructions of the organs of vision, however, perform their functions according to the same invariable laws of optics.

But although light must act on the eyes of all organized beings in a manner somewhat similar, or at least analogous to what it does on our organs, yet there may be certain configurations of the organ of vision by which a more glorious and extensive effect is produced than by the human eye. The inhabitants of some other worlds, instead of being confined in their range of vision as we are, may be able to penetrate through space to an indefinite extent, and to perceive with distinctness all the prominent objects connected with neighboring worlds; and even the peculiarities of distant suns and systems may be within the range of their view. The *difference* between the eye of an insect, which sees only an inch or two around it, and the eye of a man, which can grasp at once an extensive landscape, is perhaps as great as the difference between the vigor and extent of human eyes and such organs of vision as I have now supposed. And who shall set boundaries to the mechanisms of infinite wisdom, especially when we consider the varieties which exist in our terrestrial system? It is not beyond the limits of probability that an inhabitant of Jupiter may be able to perceive and to trace all the variety of scenery connected with Saturn, and its rings and satellites, and to distinguish the planets that revolve around other suns, as distinctly as we perceive with a telescope the satellites with which that planet is attended. We have experimental proof that the inventions of art can extend the range of human vision. The rings of Saturn, the motions of its satellites, the changes which happen in the belts of Jupiter—which no unassisted eye could ever have discerned,—and millions of stars a thousand times more distant than the limits of natural vision, have been brought to view by the invention of the telescope; which shows that the extent of human vision is susceptible of an indefinite increase. And if man can thus improve his natural vision, we need not doubt that the Deity has infinite resources at his command, and that when he pleases, he can construct visual organs of such vast and extensive powers as far surpass the limits of our comprehension; and it is not improbable, from the variety already known to exist, that such organs are actually to be found throughout different regions of the universe. Our extent of vision by the telescope is found to depend on the extent of area contained in the object-glass, or speculum of that instrument, which enables the eye to take in a greater portion of rays from distant objects than it can do in its natural state; and therefore, if our eyes were formed with pupils of a large dimension, and with a corresponding degree of nervous sensibility in the retina, we might be enabled to penetrate into space to an extent of which we have no conception. Such modifications of vision, and thousands of others, are obviously within the power of Him who at first organized all the tribes of animated existence.

It is highly probable that it is one great design of the Creator to exhibit to all intelligent beings throughout creation a visible display of his glory through the medium of their visual organs; for where no organs of vision exist, the wonderful apparatus for the production and distribution of light so conspicuous throughout the universe, exists in vain; and, therefore, if it be allowed to reason from the means to the end, or from the cause to the effect, we must admit that the universal diffusion of light through infinite space, from an infinite variety of bodies, must be intended to produce vision through the medium of organs similar or analogous to ours; in order that rational beings may enjoy the pleasures arising from this sense, and be enabled to appreciate the wonders of the universe, and the perfections of its Creator. The variety of means and contrivances for the diffusion of *light* throughout creation is therefore a demonstrative evidence both of the *existence* of intelligent beings in other worlds, and that they are furnished with visual organs for the purpose of contemplating the objects which it renders visible.

4. The inhabitants of other worlds are invested with *locomotive powers.* This we may infer from the amplitude of space which every world contains, and from the consideration that they are social beings, and hold a regular intercourse with each other. We must, indeed, necessarily suppose that there are no rational beings confined to one spot or point of space, as a tree, a shrub, or any other vegetable; for if this were the case, there could be no improvement either in knowledge or in moral action, the capacity of the intellect could never be expanded, the variety of beauties and sublimities which distinguish all the works of God could never be properly contemplated, most of the pleasures peculiar to an intelligent being could never be enjoyed, and the manifold delights which flow from social intercourse and the contemplation of diversified scenes and objects could never be experienced. The supposition of an incapacity for local motion is therefore inconsistent with the idea of a rational being, and almost involves an absurdity. We find, moreover, that in many of the planets, particularly in Jupiter and Saturn, there is the most ample space provided for exercising the powers of locomotion; these two planets containing more than 220 times the area of the earth's surface, which affords a vast field for excursion, and for observation to their inhabitants. These locomotive powers may be very different from those of man, both in their fleetness and in their mode of operation. We have reason to believe that in many instances they will far exceed ours in swiftness, and in the ease with which they may be performed; for if birds and flying insects, and even certain quadrupeds, are endowed with powers of motion far more swift and energetic than those of man, it is highly probable that rational and social beings, in more expansive worlds than ours, are capable of traversing space with much more ease and agility than the human inhabitants of our globe, otherwise they could not be supposed for ages to accomplish a survey of the world in which they dwell, or to become acquainted with its leading features. Whether such motions, however, are performed on a principle analogous to that on which the wings of birds are constructed, or on any other principle to us unknown, is beyond our province to determine.

5. We may also infer that the inhabitants of other worlds are furnished with a sense corresponding to *the organ of hearing*, and *a faculty of emitting articulate sounds.* Without such a sense and faculty, it is scarcely possible to conceive that social intercourse, and a mutual interchange of sentiment and feeling could be carried on to any extent, or with any great degree of pleasure or improvement, among organized beings. Pure spirits may have modes of intercourse and of communicating thought peculiar to themselves, of which we can at present form no distinct conception; but organized intelligences must necessarily have some *material* mediums, or faculties, by which sentiments and emotions may be expressed and communicated. Some of the planets are found to be environed with atmospheres; and as air is the medium of sound in our terrestrial region, it doubtless serves a similar purpose in other worlds; and consequently we may conclude that the animated beings they contain are furnished with organs for the perception of sounds in all their modulations. In the representations given in the sacred records of the exercises of superior beings, they are exhibited as uttering articulate sounds, and joining in the harmonies of music When a multitude of angels descended on the plains of Bethlehem to announce the birth of Messiah to the shepherds, they uttered articulate sounds, and joined in musical strains which struck the ears of the shepherds, and conveyed a distinct impression of the meaning of the sentiments communicated; which circumstance leads us to conclude, that superior intelligences in other regions express sentiments and emotions in a manner somewhat similar to that in which we hold intercourse with one another, by the faculties of speech and hearing.

6. It might, perhaps, be inferred from the *rotation* of the planets—which produces the alternations of light and darkness—that their inhabitants are subject to something analogous to *sleep*, or stated intervals of repose. This may probably be the case in some of the planets, such as Mars or Mercury, which are unaccompanied with satellites; but we know too little of the peculiar circumstances of other worlds to warrant us to speak decisively on this point, as the bodies of the inhabitants of other planets may be so constructed as not to stand in need of being daily invigorated by repose as the bodies of men. Beside, the celestial scenery of some of the planets is so grand, diversified, and picturesque, that a considerable part of their studies and social pleasures may be prosecuted and enjoyed amidst the solemn grandeur and beautiful diversity of their nocturnal scenes, and their contemplations directed to the interesting objects then presented to their view. This is probably the case in the regions of Jupiter and Uranus,—particularly in Saturn, where seven moons may occasionally be beheld in the nocturnal heavens, all exhibiting different *phases*,—some of them changing their apparent

phases, magnitude, and motion with great rapidity; some of them entering into an eclipse; and others emerging from it; while two stupendous rings stretch across the concave of the sky, presenting every moment different objects on their surface in the course of their rapid diurnal revolution. Such scenes will, perhaps, be more interesting to the inhabitants of this planet than all the splendors of their noonday;* for all the objects on the surface of this planet, and likewise those on Jupiter and Uranus, will present a different aspect from what they do in the daytime. Being illuminated by the light reflected from a retinue of moons, and by the still more effulgent splendor emitted from the spacious rings, every object will appear enlightened and distinctly visible, a diversity of coloring will be exhibited by the diversity of reflected rays proceeding from the different moons and rings, and the shadows of objects will be increased and blended together, and thrown in different directions, according to the number and relative positions of the nocturnal luminaries which may happen to be above their horizon. On which account, I should be disposed to conclude that the inhabitants of such planets have their physical constitutions organized in such a manner by Divine Wisdom as to fit them for perpetual activity, without standing in need of any repose similar to that of sleep.

The above cursory remarks respecting the physical state of the planetary inhabitants have been deduced chiefly from the ascertained circumstances and phenomena of the planets, and from the general constitution and economy of the universe. Several other conclusions might likewise have been deduced, but I do not intend to enter into the regions of mere conjecture. As rational and intelligent beings, the inhabitants of other worlds must necessarily be considered as prosecuting the study of useful science in reference to all those departments of nature which lie open to their inspection, and that they exercise their mental faculties in such pursuits and investigations. If this be admitted, then we must necessarily conclude that they use all the requisite means for the investigation of truth, and for progressing in knowledge. If, for example, they engage in the study of astronomy (as we have reason to believe the inhabitants of all worlds do) they must make observations, both general and particular; and in order to do so with accuracy and precision, instruments of various descriptions are requisite, and the management of these requires the use of *hands*, or some bodily parts answering a similar purpose; for none of the lower animals on our globe that are deficient in such a member could perform the operations of art which man can perform by the use of his hands. If a horse or a bear were furnished with the same intellectual faculties as the human race, and still retain its present organization, it could make little or no progress either in science or art, without members corresponding to human hands; and therefore we may confidently conclude that members similar or analogous to these are common to us and to the planetary inhabitants. The study of astronomy likewise supposes an acquaintance with *geometry*. The truths of geometry must be the same in every region of the universe, and perhaps of equal utility to the inhabitants of the most distant worlds as to man on earth. They are truths which are eternal and unchangeable, and which no locality or circumstances within the limits of creation can possibly alter or modify; and therefore must be recognized, in a greater or less degree, by every rational being. The Creator himself has laid the foundation of this science, for he presents us in his works with geometrical figures of various descriptions,—with circles, squares, parallelograms, hexagons and polygons—with ellipses, spheres, spheroids, and other figures, and proposes them, as it were, to our study and contemplation. With geometry, *arithmetic* and other sciences are intimately connected, so that the study of the one supposes that of the other. In short, truth, and every branch of knowledge by which the mind of a rational being can be adorned, must be *substantially* the same in every world throughout the amplitudes of creation.

Some persons, however, may be disposed to object, that the inhabitants of other worlds may see all truths *intuitively*, and that they may have no need to use any means, as we are obliged to do, to acquire and to make progress in knowledge, and that they acquire all their knowledge at once without any exertions,—opinions which have been frequently broached by divines, in reference to the happiness of the future world. But there appears no foundation for such opinions. We have reason to believe that every intellectual being throughout creation *exerts* its powers for the acquisition of truth, and that its advancement in knowledge is *progressive;* for its faculties were bestowed for the very purpose that they might be exerted on all the different objects and manifestations of the Divinity within its reach; and if all knowledge were intuitive and required no exertion of the mental faculty, the individual would be reduced to something like a mere machine, and would be deprived of the pleasures which arise from mental research and investigation. There must likewise be a *progress* in knowledge, arising from the consideration of the immensity of the Divine Being, and of his works, and of the limited nature of finite intelligences. No finite being can ever grasp the incomprehensible Divinity, or the immensity and variety of his operations throughout boundless space; but it may always be *advancing* to a more comprehensive view of the perfections and the empire of the Eternal, and may thus go on from one degree of knowledge to another, gradually approximating *toward* perfection during all the periods of an immortal existence, but will never reach it; and its happiness is connected with this circumstance, that it will never reach perfection, or obtain a *full discovery* of all the glories of the Divinity. But this gradual progression and expansion of intellectual views will be a perennial source of felicity to all virtuous intelligences. Whereas, were the whole of their knowledge acquired at once, or after a short period of duration, the mind would flag, mental activity would cease, the prospect of future knowledge and enjoyment would be cut off, and misery to a certain extent would take possession of the soul.

In fine, although there are, doubtless, marked differences between the planetary inhabitants and the inhabitants of our globe, and although the natural scenery of those worlds may be considerably different from ours, yet it is not improbable, were we transported to those abodes, that we should feel more at home in their society and arrangements than we are now apt to imagine, provided we were once made acquainted with their language, or mode of communicating their ideas. For there are certain relations, sentiments, dispositions and virtues, which must be common to intellectual and moral beings, wherever existing throughout the material universe. In respect to bodily stature and appearance, we might be apt to suspect that there would be many striking differences in the aspect of the inhabitants of another planet, and that strange and novel forms of corporeal organization would everywhere be presented to view; yet it is just as probable that in such a world we should contemplate beings not much unlike ourselves, and animated by similar or analogous views, sentiments, and feelings, though placed in circumstances and surrounded with a scenery very different from those of our sublunary region.

---

* For a particular description of these scenes, the reader is referred to "Celestial Scenery," chap. viii.

Whether we may ever enjoy an intimate correspondence with beings belonging to other worlds, is a question which will frequently obtrude itself on a contemplative mind. It is evident that, in our present state, all direct intercourse with other worlds is impossible. The law of gravitation, which unites all the worlds in the universe in one grand system, separates man from his kindred spirits in other planets, and interposes an impassable barrier to his excursions to distant regions, and to his correspondence with other orders of intellectual beings. But in the present state he is only in the *infancy of his being;* he is destined to a future and eternal state of existence, where the range of his faculties and his connections with other beings will be indefinitely expanded. "A wide and boundless prospect lies before him," and during the revolutions of an interminable duration, he will, doubtless, be brought into contact and correspondence with numerous orders of kindred beings, with whom he may be permitted to associate on terms of equality and of endearing friendship. All the virtuous intelligences throughout creation may be considered as members of one *great family,* under the peculiar care and protection of the UNIVERSAL PARENT; and it is not improbable, that it is one grand design of the Deity to promote a regular and progressive intercourse among the several branches of his intelligent offspring, though at distant intervals and in divers manners, and after the lapse of long periods of duration.

Such an intercourse may be necessary, in order to the full expansion of the moral and intellectual faculties, and to the acquisition of all that knowledge which relates to the attributes of the Divinity, and the physical and moral government of the universe. For this purpose it may be necessary that branches of the universal family that have existed in different periods of duration, and in regions widely separated from each other, should be brought into mutual association, that they may communicate to each other the results of their knowledge and experience, the diversity of physical and moral circumstances in which they have been placed, and the different arrangements of God's moral government to which they have been respectively subjected. Such views correspond with the representations given in Scripture in reference to the heavenly state. The spirits of "just men made perfect" are represented as joining the society of "an innumerable company of angels," which are only another order of rational beings; and in the visions of celestial bliss, recorded in the book of Revelation, both men and the angelic hosts are exhibited as forming one society, and joining in unison in celebrating the perfections of Him who sitteth on the throne of the universe.

But should the laws of the physical system, and the immense distances which intervene between the several worlds, prevent such associations as I have now supposed, there may be another economy, superior to the physical, which may consist with the most extensive and intimate intercourse of all rational and virtuous beings. There may be a *spiritual* economy established in the universe, of which the physical structure of creation is the basis or platform, or the introductory scene in which rational beings are trained and prepared for being members of the higher order of this celestial or intellectual economy. It appears highly probable that the first introduction of every rational creature into existence is on the scene of a *physical* economy. The diversified scenes and relations of the material world appear to be necessary, in the infancy of being, to form a substratum for thought, or to afford scope for the exercise of the moral and intellectual powers, or materials on which these powers may operate, and likewise for exhibiting a *sensible* display of the character and perfections of the Almighty.—The knowledge which may thus be acquired of the scenes and relations of the universe, and the attributes and moral government of its Omnipotent Author, in the course of myriads of ages, must be great and extensive beyond what we can well conceive. This knowledge and experience of physical objects and relations may prepare the rational soul for entering on the confines of a higher and nobler economy, where *immaterial* scenes and relations, and particularly the attributes of Divinity, abstractly considered, may form the chief objects of research and contemplation. Under such a state of economy, we may conceive that intellectual beings, to whatever portion of the material universe they originally belonged, may hold the most intimate converse with one another, by modes peculiar to that economy, and which are beyond the conceptions of the inhabitants of the physical universe; so that distance in point of space shall form no insuperable barrier to the mutual communication of sentiments and emotions.

On grounds similar to those now stated, we might conceive it as not altogether improbable, that the spiritual principle which animates the lower orders of animated nature, and which in some cases bears a near resemblance to the reason of man, may be susceptible of indefinite expansion and improvement by being connected with a superior organization, and that such beings may ultimately pass through various gradations of rank in the physical and intellectual economy, until they arrive at a station superior to that of the most enlightened and improved human beings. But as we are now bordering on the regions of doubt and uncertainty, suffice it to say, that it appears highly probable, from a consideration of the Divine benevolence, of the relations which subsist throughout the physical and intelligent system, and of the intimations contained in the records of revelation, that virtuous and holy intelligences, from different regions of the material creation, as brethren of the same great family, shall, at one period or another, hold the most intimate converse and communion, and rehearse to each other their mutual history and experience Such intercourse would evidently enhance that felicity which it is the great design of the Creator to communicate, and the means by which it may be effected are obviously within the limits of infinite Wisdom and Omnipotence.

ON THE MORAL STATE OF THE INHABITANTS OF OTHER WORLDS.

The moral state of intellectual beings in other worlds is a subject of still greater interest and importance than their physical state and constitution, and the scenes of nature with which they are surrounded; for on the moral temperament of such beings, and the passions and affections they display, will chiefly depend the happiness of the intelligent system throughout every region of the universe. It is possible to suppose a region of creation furnished with everything that is grand, beautiful and magnificent, and calculated to gratify in the highest degree the senses and imagination, and yet the abode of wretchedness and misery. If passions and dispositions similar to those which actuate the most vicious and depraved class of mankind were universally to prevail in any world, however beautiful and sublime its physical arrangements, true happiness would be banished from its society, and misery, in all its diversified ramifications, would be found pervading its abodes. Even the tempers and dispositions which are frequently exhibited in polished society, and by some men who call themselves Christians and philosophers,—jealousy, emulation, envy, pride, revenge, selfishness, and such like,—were they to reign uncontrolled in any region, would soon transform intellectual beings into an assemblage of fiends, and banish true enjoyment from every department of the social system.

If these sentiments be admitted, it will follow, that were we permitted to range through any of the planetary worlds, the pleasures and enjoyments of such an excursion would chiefly depend on the character and dispositions of those who accompanied us, and of the inhabitants of the planet through which we roamed. Were we to be treated by the inhabitants of another world in the same way as Mr. Park was treated by the Moors when he was traversing the wilds of Africa, or as a poor wretched foreigner is sometimes treated in our own country, we should find little enjoyment amidst all the beauties and novelties of scenery which might meet our eye in such a world, for upon the affections and conduct of intelligent beings toward one another must depend the happiness of individuals, and of the whole social system throughout every department of creation.

It is probable that the greater part of the inhabitants of all worlds are in a state of innocence, or, in other words that they remain in that state of moral rectitude in which they were created; for we may assume it as an axiom that every rational being, when first ushered into existence, is placed in a state of innocence or moral rectitude, without any natural bias to moral evil. To suppose the contrary would be to admit that the Divine Being, who is possessed of perfect holiness and rectitude, infuses into rational beings at their creation a principle of sin, or a tendency to moral evil, which would be inconsistent with every scriptural view we can take of the character of God. Such beings, therefore, so long as they continue in their primeval rectitude, are in a state of happiness; and every arrangement of the Creator in relation to them must be conceived as having a direct tendency to promote their sensitive and intellectual enjoyment. Moral evil, however, has been introduced into the universe, and we know by experience many of its malignant and miserable effects. For anything we know to the contrary, the operation of this principle *may be felt* in some other worlds beside our own, though we have reason to believe, from a consideration of Divine goodness, that its effects are not very extensive. Its introduction into the world has doubtless been permitted in order to bring about a greater good to the universe at large than could have been accomplished without it, in order to exhibit to the intelligent system a display of the miserable and extensive effects which necessarily flow from a violation of the original moral laws given forth by the Creator, and to demonstrate the indispensable necessity of a universal adherence to these laws, in order to secure the harmony and the happiness of the intelligent universe.

In conformity to the axiom stated above, we must necessarily suppose that rational beings, wherever existing, were created in perfect moral purity, and had a law or laws impressed upon their minds congenial to the holiness of the Almighty Creator, and calculated to promote the moral order of the intelligent system, and consequently the happiness of every individual belonging to it. *Moral order* consists in the harmonious arrangement, disposition, and conduct of intelligent beings, corresponding to the relations in which they stand to one another and to their Creator, and calculated to promote their mutual happiness.—Wherever moral order prevails, every being holds its proper station in the universe, acts according to the nature of that station, uses its faculties for the purpose for which they were originally intended, displays dispositions and emotions toward fellow-creatures and the Creator corresponding to the respective relations in which they stand, and endeavors to promote enjoyment among all surrounding beings.* For the purpose of securing moral order, certain moral laws must be supposed to be promulgated by the Creator, or at least written upon the hearts of all rational beings, as principles of action, to regulate all the movements of the intelligent system. These laws must be *substantially* the same as to their general bearings throughout all the worlds in the universe.

But, it may be asked, what are those general laws to which I allude, and have they ever been promulgated to man upon earth? I answer, they have actually been revealed to the inhabitants of our globe by the highest authority, and reason can demonstrate their applicability to all worlds. They are these—"THOU SHALT LOVE THE LORD THY GOD WITH ALL THY HEART, AND WITH ALL THY MIND, AND WITH ALL THY STRENGTH. This is the first and great commandment. And the second is like unto it: THOU SHALT LOVE THY NEIGHBOR AS THYSELF." These laws are not to be considered as confined merely to the regulation of the affections and actions of human beings, but to every individual of the moral system, wherever existing; for we cannot for a moment suppose that laws directly opposite to these would be given by the Creator to any class of intelligences. It would be inconsistent with everything we know of the character of the Divinity to imagine that he would promulgate to any class of beings such laws as these:—"Thou shalt hate thy Creator," and "thou shalt hate all thy fellow-creatures." And if such an idea would evidently involve in it a glaring inconsistency and absurdity, then it follows that the very opposite of such injunctions must be the general principles which govern the inhabitants of all worlds that have retained their allegiance to their Creator. There is not a single being possessed of a rational nature, either in the planetary system to which we belong or to any other system throughout the sidereal heavens, but is under indispensable obligations to regulate its conduct by the two general laws or principles to which we have referred, and to yield a complete and unreserved obedience to all that is included in such requisitions. Wherever such obedience is complete, order, harmony, and happiness are the natural and necessary results; but could we suppose these laws reversed, and the inhabitants of any worlds to act on principles directly opposite, a scene of anarchy, confusion, and misery would ensue, which would completely disorganize the social system, and render existence a curse rather than a blessing; and in worlds where those laws are *partially* violated, as in the world in which we dwell, disorder and misery will be the result in proportion to the frequency and extent of their violation.

---

* For a particular illustration of *moral order*, the reader is referred to "The Philosophy of Religion," *Preliminary Definitions*, Sect. i.

These are the laws by which not only man on earth, but all "the principalities and powers of heaven," are governed and directed, and by which they are bound to regulate all their thoughts, affections, and conduct. The lowest orders of rational existence come within the range of these universal laws, and the highest orders of the seraphim are not beyond their control. As the law of gravitation extends its influence throughout all the planetary worlds, and even to the remotest stars, uniting the whole in one harmonious system, so the law of universal *love* diffuses its influence over the intelligent universe, uniting the individuals who are subject to its sway in one harmonious and happy association. Hence it follows, that were we completely animated by this noble principle, and were we permitted to visit those worlds where it reigns supreme, and to mingle with their inhabitants, we should be recognized as friends and brethren, and participate of all those pleasures and enjoyments of which it is the source. The full recognition, then, of the laws to which we have referred, and their complete and uninterrupted influence over the moral powers, may be considered as qualifying the individual for being a citizen of the great moral universe, and for associating with all holy beings throughout the wide empire of omnipotence, should he ever be permitted, at any period of duration, to visit other worlds, and mingle with other orders of rational intelligences.*

These laws, in reference to the inhabitants of our world, diverge into numerous ramifications. The precepts of the moral law, or the ten commandments, are so many branches of moral duty flowing from these first principles; and in the discourses of our Saviour and the practical parts of the apostolic epistles they diverge into still more specific and minute ramifications, bearing upon all the diversified relations of life and the various circumstances connected with moral conduct.—But all the particular rules and precepts alluded to are resolvable into the general principles or affections stated above, and bear the same relations to each other as the trunk of a tree to its branches, or as a fountain to the diversified streams which it sends forth. In other worlds relations may exist different from those which are found in human society, and consequently particular precepts, different from ours, may form a part of their moral code, while certain relations which obtain among us may have no place among other orders of beings, and of course, the precepts which particularly bear upon such relations will be in their circumstances altogether unnecessary. But we may rest assured that all the particular precepts, applicable to whatever circumstances and relations may exist in other regions of creation, will be founded on the universal principles to which we have adverted, and be completely conformable to their spirit, and to the benevolent designs they are intended to accomplish.

In all those worlds where the love of God and of fellow-intelligences reigns supreme, the inhabitants may be conceived to make rapid improvements in knowledge; for the malignant principles and passions which prevail among men have, in numerous instances, been the means of retarding the progress of useful science and its diffusion throughout society. But where love in all its emanations pervades every mind, society will unite and harmonize in the prosecution of every plan by which the intellectual faculty may be irradiated and happiness diffused. Beside, in such a state of society, truth will be forever triumphant and falsehood unknown. Every fact will be fairly and truly exhibited without deception, or the least tendency to misrepresentation or exaggeration. There will be the most complete reliance on personal evidence in regard to every fact and circumstance which has been witnessed by any individuals; for want of which confidence in our world, the rational inquirer has been perplexed by the jarring statements of lying travelers and pretended philosophers; erroneous theories have been framed, the mists of falsehood have intercepted the light of truth, the foundations of true knowledge undermined, and science arrested in its progress toward perfection. All such evils, however, will be unknown in worlds where the inhabitants have arrived at moral perfection.

In fine, from what has been now stated, we may conclude that the *spirit*, the *principle*, and *essence* of our holy religion, as delineated in the Scriptures, must be common to all the inhabitants of the universe who have retained their primeval rectitude and innocence.

---

* For more particular details on this subject, the reader is referred to "The Philosophy of Religion;" particularly Chapt. ii, Sect. vi.

CHAPTER XIX.

A SUMMARY VIEW OF THE UNIVERSE.

Having in the preceding pages afforded a few sketches in reference to the principal facts connected with the sidereal heavens, which constitute the most extensive portion of creation within the limits of our knowledge, it may not be inexpedient to take a summary view of the range of objects to which our attention has been directed, in order to direct our occasional reflections on this subject, and to enable us to form an approximate, though faint and limited, idea of that universe over which Omnipotence presides, and of the perfections of its adorable Author.

We can obtain an approximate idea of the universe, only by commencing a train of thought at those objects with which we are more immediately conversant, and ascending gradually to objects and scenes more distant and expansive. We are partly acquainted with the objects which constitute the landscape around us, of which we form a part,—the hills, the plains, the lofty mountains, the forests, the rivers, the lakes, and the portions of the ocean that lie immediately adjacent. But all the range of objects we can behold in an ordinary landscape forms but a very small and inconsiderable speck, compared with the whole of the mighty continents and islands, the vast ranges of lofty mountains, and the expansive lakes, seas, and oceans which constitute the surface of the terraqueous globe. It would be requisite that more than *nine hundred thousand landscapes*, of the extent we generally behold around us, should be made to pass in review before, and a sufficient time allowed to take a distinct view of the objects of which they are composed, ere we could form an adequate conception of the magnitude and the immense variety of objects on the whole earth. Were only twenty minutes allotted for the contemplation of every landscape, and ten hours every day, it would require ninety years of constant observation before all the prominent objects on the surface of the globe could thus be surveyed. Were it possible to take a distinct mental survey of such a number of landscapes, we might acquire a tolerable conception of the amplitude of our globe, and it would serve as a standard of comparison for other globes which far excel it in magnitude. But, I believe, very few persons are capable of forming, *at one conception*, a full and comprehensive idea of the superficial extent of the world in which we dwell, whose surface contains no less than one hundred and ninety-seven millions of square miles. The most complete conception we can form must indeed fall very far short of the reality.

But however ample and correct our conceptions might be, and however great this earth might appear in the view of the frail beings that inhabit it, we know that it is only an inconsiderable ball, when compared with some of the planetary bodies belonging to our own system. One of these bodies would contain within its dimensions nine hundred globes as large as this earth,—another, fourteen hundred of similar globes; and were five hundred globes, as large as that on which we dwell, arranged on a vast plain, the outermost ring of the planet Saturn, which is 643,000 miles in circumference, would inclose them all. Such are the vast dimensions of some of those bodies, which appear only like lucid specks on the concave surface of our sky. This earth, however, and all the huge planets, satellites, and comets, comprised within the range of the solar system, bear a very small proportion to that splendid luminary which enlightens our day. The sun is five hundred times larger than the whole, and would contain within its vast circumference thirteen hundred thousand globes as large as our world, and more than sixty millions of globes of the size of the moon. To contemplate all the variety of scenery on the surface of this luminary, would require more than fifty-five thousand years, although a landscape of five thousand square miles in extent were to pass before our eyes every hour. Of a globe of such dimensions, the most vigorous imagination, after its boldest and most extensive excursions, can form no adequate conception. It appears a kind of universe in itself; and ten thousands of years would be requisite before human beings, with their present faculties, could thoroughly investigate and explore its vast dimensions and its hidden wonders.

But great as the sun and his surrounding planets are, they dwindle into a point when we wing our flight toward the starry firmament. Before we could arrive at the nearest object in this firmament, we behooved to pass over a space at least twenty billions of miles in extent,—a space which a cannon ball, flying with its utmost velocity, would not pass over in less than four millions of years. Here every eye, in a clear winter's night, may behold about a thousand shining orbs, most of them emitting their splendors from spaces immeasurably distant; and bodies at such distances must necessarily be of immense magnitude. There is reason to believe that the least twinkling star which our eyes can discern is not less than the sun in magnitude and in splendor, and that many of them are even a hundred or a thousand times superior in magnitude to that stupendous luminary. But bodies of such amazing size and splendor cannot be supposed to have been created in vain, or merely to diffuse a useless luster over the wilds of immensity. Such an idea would be utterly inconsistent with the perfections of the Divinity, and all that we know of his character from the revelations of his word. If this earth would have been "*created* in vain," had it not been inhabited,* so those starry orbs, or, in other words, those magnificent suns would likewise have been created in vain, if retinues of worlds and myriads of intelligent beings were not irradiated and cheered by their benign influence.

---

* Isaiah xlv, 18.

These thousand stars, then, which the unassisted eye can perceive in the canopy of heaven, may be considered as connected with at least *fifty thousand worlds;* compared with the amount of whose population all the inhabitants of our globe would appear only as "the smallest dust of the balance." Here the imagination might expatiate for ages of ages in surveying this portion of the Creator's kingdom, and be lost in contemplation and wonder at the vast extent, the magnitude, the magnificence, and the immense variety of scenes, objects, and movements which would meet the view in every direction; for here we have presented to the mental eye, not only single suns and single systems, such as that to which we belong, but suns revolving around suns, and systems around systems,—systems not only double, but treble, quadruple, and multiple, all in complicated but harmonious motion, performing motions more rapid than the swiftest planets in our system, though some of them move a hundred thousand miles every hour,—finishing periods of revolution, some in 30, some in 300, and some in 1600 years. We behold suns of a blue or green luster revolving around suns of a white or a ruddy color, and both of them illuminating with contrasted colored light the same assemblage of worlds. And if the various orders of intelligences connected with these systems were unvailed, what a scene of grandeur, magnificence, variety, diversity of intellect, and of wonder and astonishment, would burst upon the view! Here we might be apt to imagine that the whole glories of the Creator's empire have been disclosed, and that we had now a prospect of universal nature in all its extent and grandeur.

But although we should have surveyed the whole of this magnificent scene, we should still find ourselves standing only on the outskirts, or the extreme verge of creation. What if all the stars which the unassisted eye can discern be only a few scattered orbs on the outskirts of a cluster immensely more numerous? What if all this scene of grandeur be only as a small lucid speck compared with the whole extent of the firmament? There is demonstrative evidence from observation that this is in reality the case. In one lucid circle in the heavens, scarcely perceptible on a cursory view of the firmament, there are twenty thousand times more stars distinguishable by the telescope than what the naked eye can discern throughout the visible canopy of heaven. The Milky Way, were it supposed to contain the same number of stars throughout its whole extent as have been observed in certain portions of it, would comprise no less than 20,191,000 stars; and as each of these stars is doubtless a sun, if we suppose only fifty planets or worlds connected with each, we shall have no less than 1,009,550,000, or more than *a thousand millions* of worlds contained within the space occupied by this lucid zone. Here an idea is presented which completely overpowers the human faculties, and at which the boldest imagination must shrink back at any attempts to form an approximate conception. A thousand millions of worlds! We may state such a fact in numbers or in words, but the brightest and most expansive human intellect must utterly fail in grasping all that is comprehended in this mighty idea; and perhaps intelligences possessed of powers far superior to those of man are inadequate to form even an approximate conception of such a stupendous scene. Yet this scene, magnificent and overpowering as it is to limited minds such as ours, is not the scene of the universe; it is only a comparatively insignificant speck in the map of creation, which beings at remote distances may be unable to detect in the canopy of their sky, or at most will discern it only as an obscure point in the farthest extremities of their view, as we distinguish a faint nebulous star through our best telescopes.

Ascending from the Milky Way to the still remoter regions of space, we perceive several thousands of dim specks of light which powerful telescopes resolve into immense clusters of stars. These *nebulæ,* as they are called, may be considered as so many milky ways, and some of them are supposed even to "outvie our Milky Way in grandeur." Above three thousand of these nebulæ have been discovered; and if only two thousand be supposed to be resolvable into starry groups, and to be as rich in stars at an average as our Milky Way, then we are presented with a scene which comprises 2000 times 20,191,000, or 40,382,000,000, that is, more than *forty thousand millions* of stars. And if we suppose, as formerly, fifty planetary globes to be connected with each, we have exhibited before us a prospect which includes 2,019,100,000,000, or two billions, nineteen thousand one hundred millions of worlds. Of such a *number* of bodies we can form no distinct conception, and much less can we form even a rude or approximate idea of the *grandeur* and *magnificence* which the whole of such a scene must display. Were we to suppose each of these bodies to pass in review before us *every minute,* it would require more than three millions, eight hundred and forty thousand years of unremitting observation before the whole could be contemplated even in this rapid manner. Were an hour's contemplation allotted to each, it would require two hundred and thirty millions, four hundred thousand years until all the series passed under review; and were we to suppose an intelligent being to remain fifty years in each world for the purpose of taking a more minute survey of its peculiar scenery and decorations, 100,955,000,000,000, or a hundred billions, nine hundred and fifty-five thousand millions of years would elapse before such a survey could be completed; a number of years which to limited minds seem to approximate to something like eternity itself.

Still, *all this countless assemblage of suns and worlds is not the universe.* Although we could range on the wings of a seraph through all this confluence of sidereal systems, it is more than probable that we should find ourselves standing only on the verge of creation, and that a boundless prospect, stretching toward infinity on every side, would still be presented to view; for we cannot suppose for a moment that the empire of Omnipotence terminates at the boundaries of human vision, even when assisted by the most powerful instruments. Other intelligences may have powers of vision capable of penetrating into space a hundred times farther than ours when assisted with all the improvements of art; but even such beings cannot be supposed to have penetrated to the uttermost boundaries of creation. Man, in future ages, by the improvements of optical instruments, may be able to penetrate much farther into the remote regions of space than he has hitherto done, and may descry myriads of objects which have hitherto remained invisible in the unexplored regions of immensity. Ever since the invention of the telescope, one discovery has followed another in almost regular succession. In proportion to the increase and activity of astronomical observers, and the improvement of the instruments of observation, the more remote spaces of creation have been explored, and new scenes of the universe laid open to human contemplation. And who shall set boundaries to the improvements and discoveries of future and more enlightened generations? Before the invention of the telescope, it would have been foolish to have asserted that no more stars existed than those which were visible to the naked eye; and after Galileo had discovered with his first telescope hundreds of stars which were previously unknown, it would have been equally absurd to have maintained that the telescope would never be further improved, and that no additional stars would afterward be discovered. It would be a position equally untenable to maintain, that we shall never be able to descry objects in the heavens beyond the boundaries which we have hitherto explored, since science has only lately commenced its rapid progress, and since man is little more than just *beginning* to employ his powers in such investigations.

But however extensive may be the discoveries of future ages, we may lay it down as an axiom, that neither man nor any other rank of finite beings will ever be able to penetrate to the further boundaries of creation. It would be presumptuous to suppose that a being like man,—whose stature is comprehended within the extent of two yards, who vanishes from the sight at the distance of a German mile, whose whole habitation sinks into an invisible point at the distance of Jupiter, who resides on one of the smallest class of bodies in the universe, and whose powers of vision and of intellect are so limited,—should be able to extend his views to the extreme limits of the empire of the Eternal, and to descry all the systems which are dispersed throughout the range of infinitude. It is more reasonable to believe that all that has yet been discovered of the operations of Omnipotence that lie within the boundaries of human vision, is but a very small portion of what actually exists within the limits of creation; that the two billions and nineteen thousand millions of worlds which we have assumed as the scene of the visible universe, are only as a single star to the whole visible firmament, or even as a single grain of sand to all the myriads of particles which cover the sea-shores and the bed of the ocean, when compared with what lies beyond the utmost range of mortal vision; for who can set bounds to infinitude, or to the operations of Him whose power is omnipotent, "whose ways are unsearchable," and "whose understanding is infinite?" All that we have yet discovered of creative existence, vast and magnificent as it appears, may be only a small corner of some mightier scheme which stretches throughout the length and breadth of immensity,—of which the highest created intellect may have only a few faint glimpses, which will be gradually opening to view throughout the revolutions of eternity, and which will never be fully explored during all the periods of an interminable existence. What is seen and known of creation may be as nothing compared with what is unseen and unknown; and as the ages of eternity roll on, the empire of the Almighty may be gradually expanding in its extent, and receiving new additions to its glory and magnificence.

Hence we may conclude that there is no created being, even of the highest order of intelligences, that will ever be able to survey the whole scene of the universe. Of course, man, though destined to immortality, will never acquire a complete knowledge of the whole range of the Creator's operations, even during the endless existence which lies before him; for his faculties, however much expanded in that state, will be utterly inadequate to grasp a scene so boundless and august. It will be a part of his happiness that he will never be able to comprehend the universe; for at every period of his future existence he will still behold a boundless prospect stretched out before him, with new objects continually rising to view, in the contemplation of which, innumerable ages may roll away without the least apprehension of ever arriving at the termination of the scene. Were a superior intelligence ever to arrive at such a point, from that moment his happiness would be diminished, his intellectual powers would lose their energy, his love and adorations of the Supreme would wax faint and languid, and he would feel as if nothing new and transporting were to be added to his enjoyments throughout all the periods of his future existence. But the immensity of the universe, and the boundless nature of the dominions of "the King Eternal," will forever prevent any such effects from being produced in the case of all virtuous and holy intelligences.

Beside the numerous bodies to which we have above alluded, there are several other objects which require to be contemplated, in order to amplify our views of the visible universe. Those nebulous specks in the remote regions of the heavens termed *planetary nebulæ* have never yet been resolved into stars, and are in all probability bodies of a different nature from the Milky Way and other sidereal systems. Their magnitude is astonishing, since some of them would fill a cubical space equal to the diameter of the orbit of Uranus, which would contain 24,000,000,000,000,000,000,000,000,000, or twenty-four thousand quartillions of solid miles; that is, they are sixty-eight thousand millions of times larger than the sun. Such bodies present to our view *magnitudes* more astonishing than any others to be found within the range of the visible creation, and overwhelm the mind with wonder and amazement at what can possibly be their nature and destination. Several other nebulæ are no less wonderful, such as that in the constellation of Orion which even surpasses in magnitude the dimensions now stated. It has been computed to be 2,200,000,000,000,000,000, or two trillions, two hundred thousand billions of times larger than the sun,—a magnitude which we can scarcely suppose within the power of any finite being to grasp or to comprehend. For what end such huge masses of matter were created must remain a mystery to mortals so long as they are confined to this sublunary scene. Perhaps they are intended to give us a glimpse of objects and arrangements in the Divine economy altogether different from those we perceive in the planetary system, and in the other parts of the sidereal heavens. But whatever may be their ultimate destination, we may rest assured that they serve a purpose in the plan of the Divine administration worthy of their magnitude, and of the perfections of Him by whom they were created. They were brought into existence by the same power which reared the other parts of creation; and as power is always accompanied with wisdom and goodness, they must have an ultimate reference to the accommodation and happiness of rational beings, under an economy, perhaps, widely different from that of the planetary and other systems.

Having taken a cursory view of the magnitude of the numberless bodies scattered through the regions of space, let us now consider the *motions* which are incessantly going forward in every part of the universe; for all the myriads of globes and systems to which we have alluded are in rapid and perpetual motion; and we have no reason to believe that there is a single quiescent body throughout the immensity of creation. We have here planets revolving around suns, planets revolving around planets, suns performing their revolutions around suns, suns revolving around the centers of sidereal systems, and, in all probability, every system of creation revolving round the center and *Grand Mover* of the whole. The rate of these motions, in every known instance, is not less than several thousands of miles every hour, and in many instances, thousands of miles in a minute. The motions which are found among the planetary globes appear, at first view, altogether astonishing, and almost to exceed belief, when we consider the enormous size of some of these bodies. That a globe a thousand times larger than our world should fly at the rate of thirty thousand miles an hour, and carry along with it a retinue of other mighty globes in its swift career, is an object that may well strike us with wonder and amazement. But the fixed stars—though to a common observer they appear exactly in the same positions with regard to each other—are found, in some instances, to be carried forward with motions far more rapid than even the bodies of the planetary system, though their magnitude is immensely superior. We have already seen that the star 61 Cygni, whose apparent motion is five seconds annually, and consequently imperceptible to a common observer, yet at the distance at which the star is known to be placed, this motion is equivalent to one thousand five hundred and fifty-two millions of miles in a year; four millions, two hundred and fifty-two thousand miles a day, and one hundred and seventy-seven thousand miles an hour. Other stars are found to move with velocities nearly similar, as μ Cassiopeia, which moves above three millions of miles a day, which is at the rate of two thousand one hundred and sixty miles every minute. These are motions altogether incomprehensible by human beings, especially when we take into consideration the enormous magnitude of the stars, some of which may be a thousand times larger than all the planets and comets belonging to our system. They display the amazing and uncontrollable ENERGIES OF OMNIPOTENCE, and afford a distinct source of admiration and astonishment in addition to all the other wonders of the universe. If, then, we would endeavor to attain a comprehensive idea of the motions going forward throughout the spaces of immensity, we must not only conceive of planets revolving around luminous centers, but of suns revolving around suns,—of suns and systems revolving around the centers of the nebulæ to which they respectively belong,—of all the systems and nebulæ of the universe revolving in immense circumferences around the throne of the Eternal, the great center of all worlds and beings,—of each sun, and planet, and system, notwithstanding, pursuing a course of its own in different directions, and in numerous instances acted upon by different forces,—in short, of the ten thousand times ten thousands of luminous and opaque globes, of every rank and order, within the circuit of creation,—all performing their rapid but harmonious motions throughout every region of space, and without intermission, in obedience to the laws of their Creator.

Again, we cannot be supposed to have attained a comprehensive conception of the universe, without taking into account the sensitive and intellectual beings with which it is replenished. We ought never to consider the numerous orbs revolving throughout infinite space as mere masses of rude matter, arranged into systems merely to give a display of Almighty Power, but as means for accomplishing a higher and nobler end,—the diffusion of happiness among countless orders of intelligent existence. And as this idea must necessarily be admitted, what a *countless* multitude of percipient beings must people the amplitudes of creation! On our globe there are supported at least 800 millions of human beings; but it is capable of supporting twenty times that number, or sixteen thousand millions, if all its desolate wastes were cultivated and peopled. Beside man, there are numerous orders of other sensitive beings; there are at least 500 species of quadrupeds, 4000 species of birds, 3000 species of fish, 700 species of reptiles, 50,000 species of insects, beside thousands which the microscope alone can enable us to perceive—at least sixty thousand species in all. If every species contain about 500 millions of individuals, then there will be no less than 30,000,000,000,000, or thirty billions of individuals belonging to all the different classes of sensitive existence on the surface of our globe.

If this earth, then, which ranks among the smaller globes of our system, contain such an immense number of living beings, what must be the number of sentient and intellectual existence in all the worlds to which we have alluded! We assumed, on certain data, that 2,019,100,000,000, or two billions of worlds, may exist within the bounds of the visible universe; and, although no more beings should exist in each world, at an average, than on our globe, there would be the following number of living inhabitants in these worlds, 60,573,000,000,000,000,000,000,000; that is, sixty quartillions, five hundred and seventy-three thousand trillions, a number which transcends human conception. Among such a number of beings, what a variety of orders may exist, from the archangel and the seraph to the worm and the microscopic animalculum! What a diversity of ranks in the intellectual scale, from the point of the human faculties to the highest order of created beings, may be found throughout this immensity of existence! Some, perhaps, invested with faculties as far surpassing those of man as man surpasses in intellectual energy the worms of the dust, and still approximating nearer and nearer to the Deity. What a variety may exist among them in the form, organization, senses, and the movements of their corporeal vehicles! What a wonderful and interesting scene would their history disclose, were the whole series of events in the Divine administration toward them laid open to our view!—the different periods in duration at which they were brought into existence; the special laws of social and moral order peculiar to each class of intelligences; the modes of improving the intellect, and the progress they have made in universal knowledge; the scenes of glory or of terror through which any particular classes of beings might have passed; the changes and revolutions that may await them; and the final destination to which they are appointed. These and numerous other circumstances connected with the moral and intellectual universe open to view a source of knowledge, and a subject of sublime investigation, which superior intellects might prosecute without intermission, with increasing admiration and rapture, and never arrive at the termination of their pursuits during all the periods of an endless existence.

Such is a summary view of the universe, in so far as its scenes lie open to our knowledge and investigation. The idea it presents is altogether overpowering to the human faculties, but it is nothing else than what we should naturally expect, when we consider that the Being who formed it is self-existent and eternal; possessed of infinite wisdom, almighty power, and boundless goodness; and fills the infinity of space with his presence. It is like himself, boundless, and incomprehensible by finite minds; but exhibits to every order of intelligent beings a *sensible display* of "His Eternal Power and Godhead." Without the existence of such a universe, the infinite attributes of the Almighty could not be fully recognized and appreciated by his intelligent offspring. But here we behold, as in a mirror, the invisible perfections of the Divinity, "whom no man hath seen or can see," adumbrated, as it were, and rendered visible, in every part of creation, to the eyes of unnumbered intelligences; for there is no point of space in which a rational being could be placed, in which he would not find himself surrounded with sensible evidences and displays of the operations of an all-wise, an all-powerful, and incomprehensible Deity. "He has not left himself without a witness" to his existence, and his incessant energies, in any parts of his dominions, or to any order of his creatures, wherever existing. "If we should ascend to heaven he is there." If we should descend to the lower regions, he is there also to be seen in his operations.—"If we take the wings of the morning," and fly along with the sun from east to west, and continue our course without intermission through regions of space invisible to mortal eye, "even there his hand would lead us, and his right hand uphold us." "Darkness," unfolds the grandeur of his operations and the glories of his nature, as well as the "light" of the orb of day. Though, on the wings of a seraph we could fly in every direction through boundless space, we should everywhere find ourselves encompassed with his immensity, and with the manifestations of his presence and agency. Of such a Being, and of the universe he has formed, we may exclaim in the language of an inspired writer—"O the depth of the riches both of the wisdom and of the knowledge of God! How unsearchable are his operations, and his ways past finding out!"

Of this universe we can only form an approximate idea by comparing one small portion of it with another, and by allowing the mind to dwell for a considerable time on every scene we contemplate. We must first endeavor to acquire a comprehensive conception of the magnitude of the globe on which we dwell, and the numerous diversity of objects it contains; we must next stretch our view to some of the planetary globes, which are a thousand times greater in magnitude; and to such an orb as the sun, which fills a space thirteen hundred thousand times more expansive. Ranging through the whole of the planetary system, we must fix our attention on every particular scene and object, imagine ourselves traversing the hills, and plains, and immense regions of Jupiter, and surveying the expansive rings of Saturn in all their vast dimensions and rapid motions, until we have obtained the most ample idea which the mind can possibly grasp of the extent and grandeur of the planetary system. Leaving this vast system, and proceeding through boundless space until all its planets have entirely disappeared, and its sun has dwindled to the size of a small twinkling star, we must next survey the thousand stars that deck the visible firmament, every one of which must be considered as a SUN, accompanied with a system of planets no less spacious and august than ours. Continuing our course through depths of space immeasurable by human art, we must penetrate into the center of the Milky Way, where we are surrounded by suns, not only in thousands, but in *millions*. Here the imagination must be left for a length of time, to expatiate in this amazing and magnificent scene, and try if it can form any faint idea of twenty millions of suns, surrounded with a thousand millions of planets. Suppose one of these bodies to pass before the eye or the imagination every minute, it would require 1900 years before the whole could pass in review, and each produce a distinct impression as a separate object.

In a scene like this, the boldest imagination is overpowered and bewildered, amidst number and magnitude, and feels utterly incompetent to grasp the ten thousandth part of the overwhelming idea presented before it. Winging our flight from the Milky Way, over unknown and immeasurable regions, regions where infinitude appears opening upon us in awful grandeur, we approach some of those immense starry clusters called NEBULÆ, every one of which may be considered as another milky way, with its ten thousands and millions of suns. Here the imagination must make a solemn pause, and take a wider stretch, and summon up all its powers, and force, and vigor; for here we have not merely *one* milky way, with its millions of stars, to contemplate, but *thousands*. If the immense splendor and amplitude of one milky way overwhelms us with amazement, and with an emotion almost approaching to terror, what an overpowering effect should two thousand of such scenes, which have already been discovered, produce upon minds so feeble and limited as ours! Such a scene not only displays to us, beyond every other, the incomprehensible *energies of Omnipotence*, but seems to intimate that there are created beings existing in the universe, endowed with powers of intelligence capable of forming a much more approximate idea of such objects than beings such as man, who may be considered as standing near the lowest point of the scale of intellectual existence. These "thrones and dominions, principalities and powers of Heaven," may be able to form a comprehensive conception of such a scene as the Milky Way, which baffles the utmost efforts of the human faculties.

Soaring beyond all these objects, we behold, as it were, a new universe in the immense magnitude of the planetary and other nebulæ, where separate stars have never been perceived; and beside all these, there may be thousands and ten thousands, and millions of opaque globes of prodigious size, existing throughout every region of the universe, and even in that portion of it which is within the limits of our inspection, the faintness of whose light prevents it from ever reaching our eyes. But, far beyond all such objects as those we have been contemplating, a boundless region exists, of which no human eye has yet caught a glimpse, and which no finite intelligence has ever explored. What scenes of power, of goodness, of grandeur, and magnificence, may be displayed within this unapproachable and infinite expanse, neither men nor angels can describe nor form the most rude conception. But we may rest assured that it is not an empty void; but displays the attributes of the Deity in a manner no less admirable and glorious, and perhaps much more so, than all the scenes of creation within the range of our vision. Here, undoubtedly, is that splendid region so frequently alluded to in the Scriptures, designated by the emphatic name, "THE HEAVEN OF HEAVENS," evidently importing that it is the most glorious and magnificent department of creation. Countless myriads of beings, standing at the highest point of the scale of intellect, and invested with faculties of which we have no conception, must inhabit those regions; for we are positively informed that "hosts of intelligent beings reside in such abodes, and that "these hosts of the heaven of heavens worship God." But here our contemplations must terminate. Here imagination must drop its wings, since it can penetrate no further into the dominions of Him who sits on the throne of immensity. Overwhelmed with a view of the magnificence of the universe, and of the perfections of its Almighty Author, we can only fall prostrate in deep humility and adoration, and exclaim, "Great and marvelous are thy works, Lord God Almighty! Thou art worthy to receive glory, and honor, and power; for thou hast created all worlds, and for thy pleasure they are and were created."

I shall conclude this subject with the following remarks:

1. All the vast systems to which we have alluded are the workmanship of an Infinite and Eternal Being, and display the grandeur of his perfections. It is impossible that such an amazing universe, arranged with such exquisite order, and all the bodies it contains moving with such regular and rapid motions, could have formed itself, or been produced by the fortuitous concourse of atoms. The very surmise that such a thing was possible is one of the wildest hallucinations that ever entered the human mind It is a first principle connected with the constitution of every intellectual nature, and without the admission of which there can be no reasoning, that there is "a connection between cause and effect," and that "every effect must have a corresponding cause adequate to its production." The universe is an *effect*, the most sublime and glorious which the human mind can contemplate, and the natural and *necessary* conclusion which it almost instinctively draws is, that it is the production of an Eternal, Intelligent, and Almighty Being. This is a conclusion which has been deduced by men of all nations, and in every period of the world. "There is no nation or people," says Cicero, "so barbarous and ignorant as not to acknowledge a powerful and Supreme Divinity."

It is as natural for the human understanding, in its original and unbiased state, when contemplating the frame of the universe, to infer the existence of a Deity, as it is the property of the eye to distinguish light and colors, and of the ear to distinguish sounds. The principle from which this conclusion is deduced is exactly the same as that by which, from the contemplation of a building, we infer a builder, and from the elegance and utility of every part of the structure, we conclude that he was a wise and skillful architect; or that by which, from an inspection of a clock or watch, or any other piece of useful machinery, we infer not only the existence, but the qualities and attributes, of the contriver and artificer. The man who is incapable of at once deducing such conclusions ought to be regarded as destitute of the reasoning faculty; and if we thus necessarily infer the cause from the effect in the case of human art, can we for a moment hesitate to ascribe the production of this amazing universe which surrounds us, to a Being of infinite knowledge, wisdom, and power, adequate to bring into existence such an immense and wonderful machine, and to preserve it in harmony, from age to age, amidst all its diversified and complicated movements? That ever a doubt was entertained on this subject is a plain proof that man has lost, in part, that light of reason and intelligence with which he was originally indued, or that he is sometimes urged on by depraved passions and a pride of singularity to utter sentiments which he does not sincerely believe. As Cicero long ago declared—"He who thinks that the admirable order of the celestial orbs, and their constancy and regularity, on which the conservation and good of all things depend, to be void of a mind that governs them, he himself deserves to be accounted void of a mind." It is "the *fool*" alone, in the strictest sense of the word, whatever may be his pretended learning, who dares to declare "there is no God."

And as the universe demonstrates the *existence*, so it displays the *attributes* of the Eternal. The manifestation of himself to numberless orders of intelligent beings must have been the great end intended in bringing the universe into existence. This manifestation is made chiefly in *actions*—in actions which display greatness, wisdom, and goodness, beyond all bounds. His greatness appears from the immensity of *power* which the universe exhibits. The power necessary to move a single planet in its course far transcends human conception. What, then, must be the energy and extent of that power which set in motion and still upholds all the planets, worlds, and systems dispersed throughout the spaces of infinitude! The highest created intelligence must be utterly overwhelmed and confounded when it attempts to contemplate or to grasp an idea of Omnipotence. His knowledge, wisdom, and unceasing agency are no less conspicuous in the arrangement and direction of everything that exists in heaven and on earth. As his presence pervades all space, so his agency is displayed in the minutest movement of every part of the vast whole. This great and incomprehensible Being moves every atom, expands every leaf of the forest, decks every flower, conveys the sap through the ramifications of every tree, conducts every particle of vapor to its appointed place, directs every ray of light from the sun and stars, every breath of wind, every flash of lightning, every movement of the meanest worm, and every motion of the smallest microscopic animalculum; while at the same time he supports the planets in their courses, guides the comet in its eccentric career, regulates the movements of millions of resplendent systems, and presides in sovereign authority over unnumbered hosts of intelligent existence; directing all the mysterious powers of knowledge, virtue, and moral action to subserve the purposes of his will, and accomplish the ends of his moral government. In every department of this universe, likewise, his *goodness* is displayed to unnumbered orders of beings, sentient and intellectual; for all the powers of intelligence and action possessed by every creature in heaven and on earth, from the archangel to the worm, and all the happiness they now or ever will enjoy, are derived from him as the uncreated source of all felicity.

Under this glorious and stupendous Being we live and move; our comforts and enjoyments, while passing through this transitory scene, are wholly in his hands, and all our prospects and enjoyment beyond the range of our earthly career are dependent on his mercy and favor. His omnipotent arm supports us every moment; every breath we draw, every pulse that beats within us, every muscular power we exert, every sound that strikes our ears, and every ray of light that enters our eye-balls is dependent on his sovereign will. All that we hope for beyond the limits of time and throughout the revolution of eternity depends upon his power, his wisdom, his benevolence and his promises. Were he to withhold the powers and agencies under which we now live and act, we could neither think nor speak, hear nor see, feel nor move; the whole assemblage of living beings in our world would be changed into immovable statues, and this earth transformed into a barren waste and an eternal solitude. To the service of this glorious Being all the powers and faculties with which he has endowed us ought to be unreservedly consecrated. As his highest glory and blessedness consist in bestowing benefits on his intelligent offspring, so we ought to be imitators of him in his boundless beneficence, by endeavoring to communicate happiness to all around us. "To do good, and to communicate, forget not; for with such sacrifices God is well pleased." To him, as the "Father of our spirits and the former of our bodies," is due the highest degree of our love and gratitude; on him we ought to rely for every blessing, and humbly resign ourselves to his disposal under every event; for "all things are of God," and all are conducted with supreme and unerring wisdom and goodness to an end immortal and divine.

2. The immensity and magnificence of the universe and the attributes of Deity it displays are considerations which ought to be taken into account in all our views of religion. There is a class of men who, in prosecuting scientific pursuits, wish to discard everything that has a bearing on religion when deduced from the investigations of science, and can scarcely refrain from a sneer, when the arrangements in the economy of nature are traced to the agency of their All-wise and Omnipotent Creator; as if the objects which science professes to investigate had no relation to the views we ought to entertain of the Divinity, and ought never to be traced to their great first cause. On the other hand, there are many professed religionists who, from mistaken notions of piety, would set aside the study of the works of God, as having no connection whatever with the exercises of piety and the business of religion, and as even injurious to their interests. Both these classes of men verge toward extremes which are equally inconsistent and dangerous. The amazing fact, that creation consists of a countless number of magnificent systems and worlds beyond the comprehension of finite minds, ought not thus to be recklessly set aside in our views of God and of religion; for they are all the workmanship of ONE BEING, and they are connected together as parts of ONE grand system, of which the God we profess to worship is the supreme and universal governor. They present to the view of all intelligences the most glorious displays of his character and perfections, and consequently demand from us a corresponding sentiment of admiration and reverence, and a corresponding tribute of homage and adoration. Such enlarged prospects of the universe are therefore available for the loftiest purposes of religion and piety, and ought to enter as an element into all our views of the administration of the Almighty, and of that worship and obedience he requires from his rational offspring, unless we would be contented to render him a degree of homage far inferior to that which the manifestation of his attributes demands.

God is known only by the manifestations which he makes of his character and perfections. The highest created intelligences can know nothing more of the Divinity than what is derived from the boundless universe he has presented to their view, the dispensations of his providence to certain orders of beings, and the special revelations he may occasionally vouchsafe, on certain emergencies, to particular worlds. Had man continued in primeval innocence, the contemplation of the vast creation around him, with all its diversified wonders and beneficent tendencies, would have led him to form correct views of the attributes of his Almighty Maker, and of the moral laws by which his conduct should be regulated; but it does not follow, that because the study of nature is now of itself an insufficient guide to the knowledge of the Creator and the enjoyment of eternal felicity, such studies are either to be thrown aside, or considered as of no importance in a religious point of view. To overlook the astonishing scene of the universe, or to view it with indifference, is virtually to "disregard the works of Jehovah, and to refuse to consider the operations of his hands." It is a violation of Christian duty, and implies a reflection on the character of the Deity, for any one to imagine that he has nothing to do with God considered as manifested in the immensity of his works; for his word is pointed and explicit in directing the mind to such contemplations. "Hearken unto this; stand still, and consider the wonderful works of God." "Lift up thine eyes on high, and behold who hath created these orbs." "Remember that thou magnify his works which men behold." "Great and marvelous are thy works, Lord God Almighty! Thy saints shall speak of the glory of thy kingdom and talk of thy power, to make known to the sons of men thy mighty operations and the glorious majesty of thy kingdom."

3. The Christian revelation, throughout all its departments, is not only consistent with the views we have taken of the universe, but affords direct evidence of the magnificence of creation, and of the myriads of beings with which it is peopled. Of this position we have exhibited some proofs in the remarks and illustrations contained in Chapter XVII, which show at the same time the harmony which subsists between the discoveries of revelation and the discoveries which have been made in the system of nature. There is no other system of religion or pretended revelation that was ever propagated in the world to which such a characteristic belongs. If we examine the Mahomedan Koran, the Shasters of Bramah, the system of Confucius, the mythology of the Greeks and Romans, and every other Pagan code of religion, we shall find interspersed throughout the whole of them numerous sentiments, opinions, and pretended facts at utter variance with the true system of nature, and to what are known to be the established laws of the universe. This is strikingly exemplified in the extravagant stories and descriptions contained in the pretended revelations of Mahomet, and the absurd notions respecting the creation contained in the sacred books of the Hindoos, which assert that the universe consists of seven heavens and seven worlds, which are all at a future period to be absorbed into God; with many other absurdities. In opposition to all such foolish and absurd opinions, the inspired writings, when properly understood, and rationally interpreted according to the rules of just criticism, are uniformly found to be perfectly consistent with the discoveries of science, and the facts which are found to exist in the system of the universe; and this correspondence and harmony ought to be considered as a strong presumptive evidence that the revelations of Scripture and the scenes of the material universe proceed from the same All-wise and Omnipotent Author.

CHAPTER XX.

ON COMETS.

As this class of the celestial bodies forms a part of the solar system, it might have been more appropriate to have introduced the subject into our volume entitled, "Celestial Scenery," which has for its principal object a description of the bodies connected with that system; but as that work swelled to a greater size than was at first foreseen, it was judged expedient to postpone the consideration of comets to the present volume. As our knowledge of these bodies, however, is very limited, and no discoveries have yet been made which might lead us to form a decisive opinion of their nature and destination, I shall content myself with giving a brief detail of some of the leading facts which have been ascertained respecting them.

The word *comet* literally signifies a *hairy star;* because such bodies are generally accompanied with a nebulosity, or train, which has the appearance of luminous hair. The luminous point near the center of a comet, which is the most brilliant, is called the *nucleus.* The haze or nebulosity which surrounds the nucleus is called the hair, and sometimes the *envelope;* and the nucleus and hair combined constitute what is usually termed the *head* of the comet. The luminous train, extending sometimes to a great distance from the head, is called the *tail* of the comet. These bodies have occasionally appeared in the heavens in all ages. The ancients were divided in their opinion respecting them; some considering them as wandering stars; others, as meteors kindled in the atmosphere of the earth, subsisting for a time, and then dissipated; and others viewed them as prodigies indicating wars, famines, inundations, or pestilences. Aristotle, who believed that the heavens were incorruptible and unchangeable, maintained that comets were generated when they first made their appearance, and were destroyed when they ceased to be visible, and consequently that they could not be reckoned to belong to the heavenly bodies, but were only meteors or exhalations raised into the upper regions of the air, where they blazed for awhile, and disappeared when the matter of which they were formed was consumed. And as the opinions of this ancient sage had a powerful influence on the philosophers and astronomers of later times,—as his assertions were frequently regarded as little short of demonstrations,—few persons had the boldness and independency of mind to call in question the positions he maintained on any subject discussed in his writings.

It was not before the time of the celebrated astronomer, Tycho Brahe, that the nature of comets began to be a little understood, and that they were considered as moving in the planetary regions. This astronomer observed with great diligence the famous comet which appeared in 1577; and from many accurate observations during the time of its appearance, found that it had no sensible diurnal parallax, and therefore was not only far above the limits of our atmosphere, but beyond the orbit of the moon itself. Its motions were likewise particularly observed by Hagecius, at Prague, in Bohemia, at the same time that they were observed by Tycho, at Uraniburg. These two places differ six degrees in latitude, and are nearly under the same meridian, and both measured the distance of the comet from the same star, which was in the same vertical circle with the comet; yet both observers found their distances the same, and consequently they both viewed the comet in the same point of the heavens, which could not have happened unless the comet had been in a higher region than the moon. After Tycho, Kepler had an opportunity of making observations on the comets which appeared in 1607 and 1618, and from all his observations he deduced this conclusion, "that comets move freely through the planetary orbs." From this period comets began to be more accurately observed, and to be considered as constituent parts of the solar system; and at length the illustrious Newton demonstrated that their motions are performed in long ellipses, having the sun in one of their foci.

Before proceeding to inquire into the nature and physical constitution of these bodies, I shall present the reader with

A BRIEF SKETCH OF THE HISTORY OF THE MOST REMARKABLE COMETS WHICH HAVE APPEARED IN MODERN TIMES.

One of the most remarkable comets which have appeared in modern times is that which made its appearance toward the close of the year 1680, and which was particularly observed by most of the astronomers of Europe. This comet, according to the accounts given by the astronomers of that period, appeared to descend from the distant regions of space with a prodigious velocity, almost perpendicular to the sun, and ascended again in the same manner from that luminary with a velocity retarded as it had before been accelerated. It was observed, particularly at Paris and Greenwich, by Cassini and Flamstead, by whom it was seen in the morning from the 4th to the 25th of November, 1680, in its descent toward the sun; and after it had passed its *perihelion,** in the evening, from the 12th of December to the 9th of March, 1681. The many exact observations made on this comet enabled Sir I. Newton to discover that so much of its orbit as could be traced by the motion of the comet, while it was visible, was, as to sense, a *parabola,* having the sun in its focus, and that it was one and the same comet that was seen all that time. This comet was remarkable for its very near approach to the sun. At its perihelion, it was not above a sixth part of the sun's diameter from its surface; that is, about

---

* The *perihelion* is that point in the orbit of any planet or comet which is nearest to the sun. It is also called the *lower apsis.* The *aphelion* is that point in the orbit which is farthest from the sun; called, also, the *higher apsis*

146,000 miles from the surface of that luminary, and 584,000 from its center. According to Sir Isaac Newton, the velocity of this comet when nearest the sun, was 880,000 miles an hour. On taking its perihelion distance, as given by M. Pingre, Mr. Squire found, by two different calculations, that its velocity in its perihelion was no less than 1,240,000 miles an hour! This velocity was so great that, if continued, it would have carried it through 124 degrees in an hour; but its actual hourly motion during that interval, before and after it passed the perihelion, was 81 degrees, 47 minutes. At this period, the diameter of the sun, as seen from the comet, must have subtended an angle of more than a hundred degrees, which must nearly have filled its whole hemisphere.

From Dr. Halley's determination of its orbit, it appears that when in its aphelion, or greatest distance from the sun, it cannot be less than 13-000,000,000, or thirteen thousand millions of miles distant from that luminary; that is, seven times the distance of Uranus. According to the same astronomer, this comet, in passing through its southern node, came within the length of the sun's semidiameter of the orbit of the earth, that is, within 440,000 miles; and he remarks, "had the earth been then in that part of its orbit nearest that node of the comet, their mutual gravitation must have caused a change in the plane of the earth's orbit, and in the length of our year; and if so large a body with so rapid a motion were to strike the earth, a thing by no means impossible, the shock might reduce this beautiful frame to its original chaos." Modern observations, however, render such deductions somewhat improbable. The *period* of this comet is supposed to be about 575 years. It is conjectured that it is the same comet which appeared in 1106, in the reign of Henry I, that was seen during the consulate of Lampadius and Orestes, about the year 531, and in the forty-fourth year before Christ, in which year Julius Cæsar was murdered. Its nucleus was computed to be about ten times as large as the moon. Its tail extended over a space of seventy degrees in extent.

This is the comet, to the near approach of which to the earth, Mr. Whiston attributed the universal deluge in the time of Noah. His opinion was, that the earth, passing through the atmosphere of the comet, attracted from it a great part of the water of the flood; that the nearness of the comet raised a great tide in the subterranean waters; that this could not be done without making fissures or cracks in the outer crust of the earth; that through these fissures the subterraneous waters were forced; that along with the water much slime or mud would rise, which, after the subsiding of the water partly into the fissures and partly into the lower parts of the earth to form the sea, would cover over to a considerable depth the antediluvian earth; and thus he accounts for trees and bones of animals being found at very great depths in the earth. The same comet, he supposed, when coming near the earth after being heated to an immense degree in its perihelion, would be the instrumental cause of that great catastrophe, the general conflagration. Modern geological researches, however, render all such hypotheses utterly untenable.

2. Another comet which has obtained a certain degree of celebrity is that which appeared in 1682, and is usually distinguished by the name of *Halley's comet.* This comet appeared with considerable splendor, and exhibited a tail thirty degrees in length. On calculating its elements from its perihelion passage, Dr. Halley was led to conclude that it was identical with the great comets which appeared in 1456, 1531, and 1607, whose elements he had also ascertained. The intervals between these periods being about seventy-five or seventy-six years, he was led to conclude that this was the period of the revolution of the comet, and ventured to predict that it would again return about the latter part of the year 1758. As this was the first comet whose return had been predicted, when the time of its expected appearance approached, astronomers became anxious to ascertain whether the attraction of the larger planets, Jupiter and Saturn, might not interfere with its orbitual motion, and prevent it from arriving at its perihelion as soon as the time predicted. Clairaut, an eminent French mathematician, after many intricate and laborious calculations in reference to the subject, concluded that the attraction of Saturn would lengthen the period 100 days, and the action of Jupiter 518, making in all 618 days, by which the expected return would happen later than if no such influence had taken place; so that instead of the period being 74 years, 323 days, it ought to be 76 years, 211 days; and as the comet passed its perihelion on September 14, 1682, it ought to reach the same point on April 13, 1759. These calculations were read before the Academy of Sciences, on the 14th of November, 1758; but Clairaut gave notice that, being pressed for time, he had neglected in his calculations small values, which collectively might amount to about thirty days, in the seventy-six years. These predictions were accordingly verified, for the comet appeared about the end of December, 1758, and arrived at its perihelion on the 13th of March, 1759, only thirty days before the time fixed by the calculations of Clairaut, who, upon repeating the process by which he had arrived at the result, reduced this error to nineteen days. The same comet again made its appearance, according to prediction, in 1835, of which a particular account will be given in the sequel.

3. Another remarkable comet made its appearance in 1744, which excited a considerable degree of attention. It was first seen at Lausanne, in Switzerland, December 13, 1743; from that period it increased in brightness and magnitude as it approached nearer the sun. On the evening of January 23, 1744, it appeared exceedingly bright and distinct, and the diameter of its nucleus was nearly equal to that of Jupiter. Its tail then extended above 16 degrees from its body, and was supposed to be about 23 millions of miles in length. On the 11th of February, the nucleus, which had before been always round, appeared oblong in the direction of the tail, and seemed divided into two parts by a black stroke in the middle. One of the parts had a sort of beard, brighter than the tail; this beard was surrounded by two unequal dark strokes, that separated the beard from the hair of the comet; these odd phenomena disappeared the next day, and nothing was seen but irregular obscure spaces like smoke in the middle of the tail, and the head resumed its natural form. On the fifteenth of February, the tail was divided into two branches, the eastern about 8 degrees long, the western 24. On the 23d the tail began to be bent. It showed no tail until it was as near the sun as the orbit of Mars, and it increased in length as it approached nearer that luminary. At its greatest length, it was computed to equal a third part of the distance of the earth from the sun.* This was one of the most brilliant comets that had appeared since that

---

* Memoirs of the Academy of Sciences for 1744.

of 1680. Its tail was visible for a long time after its body was hid under the horizon: it extended 20 or 30 degrees above the horizon, two hours before sunrise.

4. In the month of June, 1770, Messier discovered a comet, the motions of which appear to be involved in a considerable degree of mystery.—The comet continued visible for a long time.—Lexell ascertained, from observation, that it described an ellipse around the sun, of which the greater axis was only three times the diameter of the earth's orbit, which corresponds with a revolution of 5½ years. It was therefore expected that it would again frequently make its appearance; but it has never since been visible, although it made a pretty brilliant appearance in 1770.—The National Institute of France, not many years ago, requested M. Burkhardt to repeat all the calculations with the utmost care; and the result of his labor has been a complete confirmation of the elements obtained by Lexell. What has become of this comet it is difficult to conjecture. Its aphelion, or greatest distance from the sun, was reckoned to be not far beyond the orbit of Jupiter, and that it approached as near to the earth as the moon, and ought to have appeared twelve times since the year 1770. M. Arago attempts to solve the difficulty by affirming that its orbit was then totally different from that which it has since pursued; that its passage to the point of perihelion in 1776, when it was expected, took place by day, and before the following return, the form of the orbit was so altered that had the comet been visible from the earth, it would not have been recognized; that before 1777, during the whole progress of its revolutions, its shortest distance from the sun was 199,000,000 leagues, and that after 1779, the minimum distance became 131,000,000 leagues, which was still too far removed for the comet to be perceptible from the earth. Sir David Brewster attempts to account for its disappearance by supposing that it must have been attracted by one of the planets whose orbit it crossed, and must have imparted to it its nebulous mass; and that it is probable the comet passed near Ceres and Pallas, and imparted to them those immense atmospheres which distinguish them from all the other planets. Whether any of these opinions be tenable and sufficient to solve the difficulty, is left entirely with the reader to determine.

5. Another comet which has engaged the particular attention of astronomers during the last twenty years, is distinguished from all preceding comets by the *shortness of its periodic revolution.* It is usually denominated *Encke's comet*, so called from Professor Encke, of Berlin, who first ascertained its periodical return. It was discovered at Marseilles, on the 26th November, 1818, by M. Pons, and its parabolic elements were presented to the Board of Longitude, at Paris, by M. Bouvard, on the 13th of January, 1819. It was immediately remarked that the result of Bouvard's calculations was too similar to the elements of a comet which appeared in 1805, not to consider that and the one of 1818 as the same body; and M. Encke soon after established, by incontestable calculations, that this comet took only about 1200 days, or three years and three-tenths, to travel through the whole extent of its elliptic orbit. This was considered as a very extraordinary result, as an opinion had previously prevailed that the period of a revolution of a comet must *necessarily* be long. It now appears that this comet was first seen by Messier and Mechain in 1786; afterward by Miss Herschel in 1795; and its subsequent returns were observed by different astronomers in 1805 and 1819, all of whom, at those periods, supposed that the four comets were four different bodies. The elements of this comet, and the short period of its revolution, are now incontrovertibly established; for its reappearance in the southern hemisphere in June, 1822, took place very nearly in the positions previously calculated. The agreement was not less remarkable in 1825; and in 1828, the third period of its announced return, it occupied the places assigned to it by Encke the year preceding. It likewise appeared in 1832, 1835, and 1838.

This comet is very small; its light is feeble; it has no tail; it is invisible to the naked eye, except in very favorable circumstances, but may be seen with a small magnifying power. It revolves in an elliptical orbit of considerable eccentricity, having an inclination to the plane of the ecliptic of 13⅓ degrees. On comparing the intervals between the successive perihelion passages of this comet, a singular fact has been elicited, namely, that its periods are continually diminishing, and its mean distance from the sun shortening by slow but regular degrees. This is supposed by M. Encke to be produced by a resistance experienced by the comet from a very rare ethereal medium pervading the regions through which it moves; since such resistance, by diminishing its actual velocity, would diminish also its centrifugal force, and thus give the sun more power over it to draw it nearer. It is therefore the opinion of Sir J. Herschel, that "it will probably fall ultimately into the sun, should it not first be dissipated altogether, a thing no way improbable, when the lightness of its materials is considered, and which seems authorized by the observed fact of its having been less and less conspicuous at each reappearance." The acceleration of this comet is about two days in each revolution; and the frequent opportunities of observation which will occur, in consequence of the shortness of its period, may lead to new and interesting conclusions in relation to the nature of these bodies.

6. Beside the above, another periodical comet has lately been discovered, which is distinguished by the name of *Biela's* and sometimes *Gambart's comet.* This comet was perceived at Johannisberg, on the 27th Feb., 1826, by M. Biela; and by M. Gambart, at Marseilles, ten days afterward. Gambart, without delay, calculated its parabolic elements from his own observations, and by inspecting a general table of comets, he recognized that it was not its first appearance, but that it had been already observed in 1789, and 1795. Messrs. Clausen and Gambart undertook the computation of the comet's revolution, and found, each of them nearly at the same time, that the new comet made its entire revolution round the sun in a period of about seven years. It was afterward found, more accurately, to be 2460 days, or nearly 6¾ years. M. Damoiseau calculated the perturbations of this comet, and predicted that it would cross the plane of the earth's orbit on the 29th of October, 1832, *a little before midnight*, at a point about 18,480 miles within the orbit of the earth. According to this prediction, the comet actually made its appearance in 1832 about the time now specified. Its next appearance was calculated to happen in 1839; and it was reckoned that it would arrive at its perihelion on the 23d July of that year.

The predicted appearance of this comet in 1832 seems to have produced considerable alarm, particularly in France. Some German journalists predicted that it would cross the earth's orbit near the point at which the earth would be at the time, and cause the destruction of our globe. Such was the degree of alarm excited on this occasion, that M. G * * *, a Professor in Paris, put the question to the Academy of Sciences, whether it did not feel itself bound in duty to refute, as speedily as possible, this assertion. "Popular terrors," he observed, "are productive of serious consequences. Several members of the Academy may still remember the accidents and disorders which followed a similar threat, imprudently communicated to the Academy by M. de Lalande, in May, 1773. Persons of weak mind died of fright, and women miscarried. There were not wanting people who knew too well the art of turning to their advantage the alarm inspired by the approaching comet, and *places in paradise were sold at a very high rate.* The announcement of the comet of 1832 may produce similar effects, unless the authority of the Academy apply a prompt remedy; and this salutary intervention is at this moment implored by many benevolent persons." It was supposed by some, that if any disturbing cause should delay the arrival of the comet for one month, the earth must pass directly through its head.

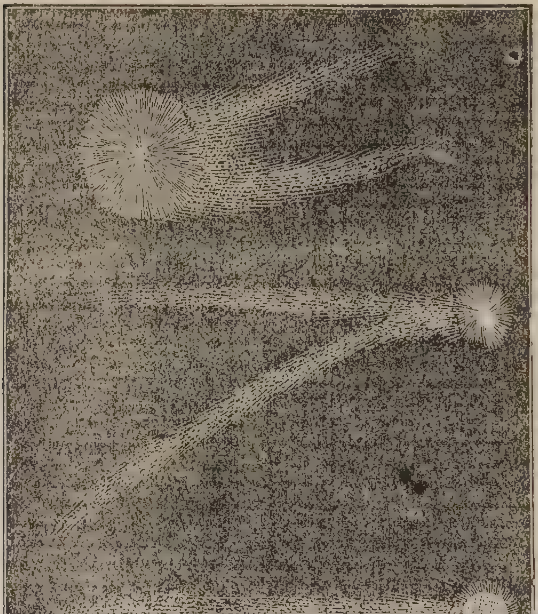
In order to dispel such fears, and to illustrate the nature of these bodies, M. Arago published an excellent and popular treatise on comets in the "*Annuaire*" of 1832. He showed that the result of the calculation was, that the passage of the comet ought to proceed *a little within our orbit*, and at a distance from that curve, which is equal to *four terrestrial radii and two-thirds*, or about 37,000 miles; that on the 29th October, 1832, *a portion of the earth's orbit* might be included within the nebulosity of the comet; but that the earth would not arrive *at the same point* of its orbit until the morning of the 30th November, or more than a month afterward; and consequently that the earth would be more than twenty millions of French leagues (or fifty millions of British miles) distant from the comet. He adds, that "if the comet, instead of crossing the plane of the ecliptic on the 29th October, had not arrived there until the morning of the 30th November, it would have undoubtedly mingled its atmosphere with ours, and perhaps even have struck us!" The earth is considered in more danger, if danger there be, from this comet and that of Encke than from any other. Encke's comet crosses the orbit of the earth sixty times in the course of a century, and there is certainly a *possibility* that it might come into collision with the earth, but the probability of its doing so is very small; and, beside, this comet and that of Gambart are so extremely rare, that little danger is to be apprehended, even although a contact were to take place. Gambart's is a small, insignificant comet, without a tail, or any appearance whatever of a solid nucleus, and is not distinguishable by the naked eye.

7. *The Comet of* 1807. This was the first comet on which I had an opportunity of making observations. My first observation was on the evening of October the 8th, 1807, a little after sunset, when it appeared in a north-westerly direction, not far distant from Arcturus, which was then only a little above the horizon. To the naked eye it appeared somewhat like a dim nebulous star of the second magnitude, with a beam of light on one side of it. Through a telescope, its tail presented a pretty brilliant appearance, and occupied a space of considerably more than a degree in length. The coma seemed to have a roundish, but dim and undefined appearance, and appeared more indistinct as the magnifying power was increased. When viewed with an achromatic telescope of thirty-one inches focal distance, and a power of thirty, it presented a very distinct and beautiful appearance, and the nucleus, coma, and tail, nearly filled the field of view. When a power of sixty was applied, it was much more indistinct than with the former power and in all the subsequent observations the lower power was generally preferred. In the course of five or six weeks, or about the middle of November, it disappeared to the naked eye. I traced it with the telescope, as often as the weather would permit, for two or three months after it had become invisible to the unassisted sight, and found that its apparent motion was pretty rapid, and toward the north-east. About the middle of January, 1808, at eleven, P. M., it appeared in a direction north-east by north; and at this time it appeared through the telescope like a small nebulous star, or like those species of comets called *bearded* comets, having no trace of anything similar to a tail. The last time I saw it was about the end of January, when it was still distinctly visible, like a nebulous star; but cloudy weather for nearly a fortnight prevented any further observations, and I saw it no more. On the evening in which I had the last peep of it, I detected another comet within eight or ten degrees of it, which appeared like a star of the third magnitude, and exhibited a pretty brilliant appearance through the telescope. It had no tail, like the former comet, but appeared surrounded with radiant hairs like the *glory* which painters represent around the head of our Saviour. It continued visible for several weeks; but I have not seen any particular notices of this second comet, or any special observations on it, which have been recorded by astronomers.

This comet appears to have been first noticed by Herschel and Schroeter about the 4th of October, 1807, who continued their observations upon it for several months. According to Schroeter's observations and estimates, the diameter of the nucleus of this comet was about 4600 miles, or nearly the size of the planet Mars, and appeared to be of considerable density; the diameter of its coma, 120,000 miles, but liable at different times, to variations of increase and decrease; and its rate of motion, at certain periods, 1,333,380 miles a day, or 55,557 miles an hour. Its tail was divided in a very unusual manner into two separate branches; the north side continued much brighter and better defined than the other, and was also invariably convex, while the other side was concave. But what was deemed most remarkable was the variation in length and the *coruscations* of the tail. Something like coruscation had been observed by the naked eye in the case of preceding comets, and such phenomena appear to have been confirmed by the observations of Schroeter. In less than one second, streamers shot forth to two and a half degrees in length; they as rapidly disappeared and issued out again, sometimes in proportions and interrupted like our northern lights. Afterward the tail varied both in length and breadth, and in some of the observations, the streamers shot from the whole expanded end of the tail, sometimes here, and sometimes there, in an instant, two and a half degrees long, so that within a single second they must have shot out a distance of 4,600,000 miles. Their light was also sometimes whiter and clearer at the end than at the base, as is occasionally seen in the northern lights. Some have objected to the extreme rapidity of the streamers as here stated, but the fact of coruscations having been seen appears to be confirmed by the observations of this celebrated and accurate observer. The observations of Herschel on this comet differ in some respects from those of Schroeter, particularly in the estimate he makes of the size of the nucleus, which he reckons to be considerably smaller than what has been stated above.

Fig. 78 is a view of this comet as seen on the night of October 21st by Schroeter. Fig. 79 is a view of the same comet as seen by Bessel, October 22d, at eight in the evening; both which exhibit its divided tail.

Fig. 78.



8. The most remarkable comet which has appeared in modern times, since that of 1680, was *the comet* of 1811. About the beginning of September in that year, about eight or nine in the evening, as I was taking a random sweep with my telescope over the north-western quarter of the heavens, an uncommon object appeared to pass rapidly across the field of view, which on examination appeared to be a splendid comet. Not having heard of the appearance of any such body at that time, I was led to imagine that I had fortunately got the first peep of this illustrious stranger; but I afterward learned from the public prints that it had been seen a day or two before by Mr. Neitch, in the neighborhood of Kelso, who appears to have been the first that observed it in this country. This comet appeared with peculiar splendor, and was visible, even to the naked eye, for more than three months in succession, and excited universal attention. It afforded to astronomers more opportunities for observation of its physical aspect and constitution, and for determining the elements of its orbit, than almost any other comet that had previously appeared. The two celebrated observers, Herschel and Schroeter, made numerous and very particular observations on the phenomena and motions of this comet, which were continued every clear evening for the space of nearly five months. Some of these observations, along with the remarks and deductions connected with them, are extremely interesting to the astronomical observer; but my limits will permit only a statement of the general results.

Some of the results deduced by Schroeter are the following:—That the central globe of light, or what he calls the nucleus, was 50,000 miles in diameter, or nearly six and a half times the diameter of the earth, which he deduced from the mean of twenty-seven measurements, which gave 1′ 49″ as the mean angular diameter of the body; that this great body was in all probability chiefly fluid, though its central parts might consist of denser substances; and that there was reason to believe that it shone with its own native light. The *coma* was extremely rarefied in comparison with the nucleus, resembling a very faint whitish light, scattered in separate portions. It was divided into two; one immediately encompassing the nucleus, the other of a more faint and grayish light, sweeping round it at a distance, and forming the double tail which the comet presented. The *train*, or *head vail*, as he terms it, swept around the nucleus, at a distance equal to its breadth, and appeared as unconnected as the ring of Saturn with its body, and which sometimes appeared darker than the open sky. The diameter of this exterior part of the head was 34′ 15″, or about 947,000 miles, which is larger than the diameter of the sun, and which he thinks must have formed a hollow cone around the nucleus, and which he thought indicated a force of a repulsive nature residing in the nucleus. Between the 4th and 6th of December a great revolution took place; the rarefied nebulous matter, which had for three months been so unusually repelled from the nucleus on every side, to a distance of about one-fifth of the diameter of the head, or 190,000 miles, was again attracted to it, affording an incontrovertible proof of physical action upon a great scale, arising doubtless from the same causes which produce the other phenomena of nature. The double tail of this comet was exceedingly faint compared with the nucleus and coma. On the 23d of October, it extended fully eighteen degrees, notwithstanding its oblique position, the angle at the sun being then 61° 23′; at the earth, 69°; and at the comet, 49° 37′. Had it been viewed at right angles, it would have subtended an angle of 36° 36′, equivalent to more than 60,000,000 of miles, which is more than half the distance from the earth to the sun. *Coruscations*, similar to those which appeared in the tail of the comet of 1807, were likewise perceived, particularly on October the 16th, when a small tail instantaneously appeared, then vanished, and reappeared, which was in length equal to three times the diameter of the comet's head, or 2,373,000 miles. Other displays of the same kind took place on the 7th of November and the 18th of December. These facts, of the reality of which Schroeter entertained not the least doubt, must be considered as very curious and extraordinary phenomena.[*]

Herschel's observations nearly agree with those of Schroeter, excepting that he estimates the diameter of the nucleus as very much smaller than what is stated above. He estimates the *greatest length* of the tail, as seen on the 15th of October, to have been 100,000,000, or a hundred millions of miles, which consequently extended over a space larger than that which intervenes between the earth and the sun; and its *breadth*, as deduced from the observations of October the 12th, nearly fifteen millions of miles. He calculated its distance when nearest to the earth to be about 113 millions of miles. He concluded that the solid matter of the comet was spherical, that it shone in part by its own native light, and that it probably had a rotation round its axis. From the most accurate observations of the motion of this comet, its period of revolution has been calculated to exceed 3000 years. Bessel computes it at 3383 years; and several other astronomers conceive its period to be considerably longer, even exceeding 4000 years.

9. *Reappearance of Halley's Comet in* 1835. The return of this comet was calculated by Messrs. Damoiseau and Pontecoulant; the former of whom calculated its return to the perihelion on the 4th, and the latter on the 7th of November, 1835, and it actually arrived at that point only a few days after these periods, namely, on the 16th of November. It was first seen on the continent in the month of August that year, but does not appear to have been noticed in the northern parts of Britain until more than a month afterward. Its expected reappearance excited universal attention throughout Europe. Soon after the middle of September, as I was taking a sweep with a two feet telescope over the north-eastern quarter of the heavens, near the point where I expected its appearance, I happened to fix my eye on this long-expected visitor, which appeared very small and obscure. I immediately directed an excellent three and a half feet achromatic telescope, with a diagonal eye-piece, magnifying about thirty-four times, to the comet, when it was distinctly seen, and appeared of a considerable diameter, but still somewhat hazy and obscure. I afterward applied a power of forty-five, and another of ninety-five: but it was seen most distinctly with the lower power. With ninety-five it appeared extremely obscure, and nearly of the apparent size of the moon.[*] There appeared at this time nothing like a tail, but the central part was much more luminous than the other portions of the comet, and presented something like the appearance of a star of the third or fourth magnitude surrounded with a haze. In some of the views I took of this object, the luminous part or nucleus appeared to be considerably nearer one side than another. At this period, and for a week or ten days afterward, the comet was altogether invisible to the naked eye. Many subsequent observations were made, and published in the provincial newspapers, but which my present limits prevent me from inserting.

After the comet became visible to the naked eye, the tail began to appear, and increased in length as it approached its perihelion, and at its utmost extent was estimated to be above thirty degrees in length. On the 13th of October, according to the observations of Arago, a luminous sector was visible in its head; on the day following, the sector had disappeared, and a more brilliant one and of greater longitudinal extent was formed in another place. This second sector was observed on the 17th, when it appeared less bright; and on the 18th its weakness had decidedly increased. The comet was concealed until the 21st, but on that day three distinct sectors were visible in the nebulosity. On the 23d, all traces of these sectors had disappeared, the nucleus, which had previously been brilliant and well-defined, having become so large and diffuse that the observer could scarcely believe in the reality of such a sudden and important alteration, until he satisfied himself that the appearance was not occasioned by the moisture on the glasses of his instrument. It appears, likewise, that one of these luminous fans or sectors was observed by Sir J. Herschel, at the Cape of Good Hope, after the comet had passed its perihelion. The nebulosity of this comet appears to have increased in magnitude as it approached the sun, but its changes were sometimes unaccountably rapid. On one occasion it was observed to become obscure and enlarged in the course of a few hours, though a little before, its nucleus was clear and well-defined. On the 11th of October, the Rev. T. W. Webb, and two other observers, observed *coruscations* in the tail. On that evening, at 7h. 30′, the tail was very conspicuous, extending between κ and γ Draconis, and evidently fluctuated, or rather coruscated, in length, being occasionally short, and then stretching, in the twinkling of an eye, to its full extent, which was at least equal to ten degrees. Its changes were extremely similar to the kindling and fading of a very faint streamer of the Aurora Borealis.

---

[*] Having referred, on various occasions, to the observations of that indefatigable astronomer, *Schroeter*, of Lilienthal, it may not be uninteresting to some readers to insert the account of the losses he sustained by the burning and plunder of his observatory, as expressed in his own pathetic language :

"At length, after the most touching afflictions of mortality, I once more awake in my temple consecrated to the Eternal Godhead, and am again able, after a total derangement of my affairs, to edit these collections concerning the great comet of 1811. Through the most barbarous fury, in consequence of an equally barbarous decision, the whole innocent soft vale of Lilies (the signification of the name of Lilienthal, where his observatory was situated) was burnt to the ground, without any previous examination. They likewise burnt down the royal government buildings. I lost my whole movable property, and, what was most sensibly felt by me, amongst it, with a considerable loss also to the booksellers of Europe, the sole copy of the whole of my works and writings deposited in the government house.—Even my observatory, preserved by Providence from the fire, was a few days afterward broken into, plundered, and shamefully thrown into confusion by demolishing the clocks, breaking off the finders from the instruments, and carrying off the smaller instruments. Previously, indeed, having been removed from my post, my income had gradually become so very straitened, I was obliged to forego all but the most necessary outlays, and to give myself up to a scientific slumber. Under the endurance of these troubles all my scientific patrons and friends will doubtless, as far as possible, excuse me, if through melancholy, and on account of the extraordinary high rate of postage, I have been compelled to put out of sight so many obligations of courtesy, for to the present time everything is so straitened with me that my observatory, from want of time and heavy expenses is for the most part a confusion.

"JOH. HIERONYM. SCHROETER."

"*Lilienthal*, Jan. 22, 1815."

Schroeter did not long survive the calamity alluded to above. He died on the 29th of August, 1816, in the 71st year of his age.

[*] In viewing comets, telescopes with large apertures and comparatively low magnifying powers should generally be used, as the faint light emitted by comets, whether it be inherent or reflected, will not permit the use of so high magnifying powers as may be applied to the planets.

"The influence of the ethereal medium on the motion of Halley's comet will be known after another revolution, and future astronomers will learn, by the accuracy of its returns, whether it has met with any unknown cause of disturbance in its distant journey. Undiscovered planets beyond the visible boundary of our system may change its path and the period of its revolution, and thus may indirectly reveal to us their existence, and even their physical nature and orbit. The secrets of the yet more distant heavens may be disclosed to future generations by comets which penetrate still farther into space, such as that of 1763, which, if any faith may be placed in the computation, goes nearly 43 times farther from the sun than Halley's does, and shows that the sun's attraction is powerful enough at the distance of 144,600 millions of miles to recall the comet to its perihelion. The periods of some comets are said to be many thousand years, and even the average time of the revolution of comets generally is about a thousand years; which proves that the sun's gravitating force extends very far. La Place estimates that the solar attraction is felt throughout a sphere whose radius is a hundred millions of times greater than the distance of the earth from the sun." "The orbit of Halley's comet is four times longer than it is broad; its length is about 3420 millions of miles, about 36 times the mean distance of the earth from the sun. At its perihelion it comes within 57 millions of miles of the sun, and at its aphelion it is 60 times more distant. On account of this extensive range, it must experience 3600 times more light when nearest to the sun than in the most remote point of its orbit. In the one position the sun will seem to be four times larger than he appears to us, and at the other he will not be apparently larger than a star.*

The appearance of this comet, so near the time predicted by astronomers, and in positions so nearly agreeing with those which were previously calculated, is a clear proof of the astonishing accuracy which has been introduced into astronomical calculations, and of the soundness of those principles on which the astronomy of comets is founded. It likewise shows, that comets, in general, are *permanent* bodies connected with the solar system, and that no very considerable change in their constitution takes place while traversing the distant parts of their orbits.†

From the preceding historical sketches and descriptions, the reader will learn something of the general phenomena of comets; and I shall now briefly inquire into the opinions which have been formed respecting the

PHYSICAL CONSTITUTION OF COMETS.

On this subject our knowledge is very imperfect; in fact, we may be said to know little or nothing of the physical construction of those mysterious bodies, or of the nature of the substances of which they are composed. In regard to the *nebulosity* of comets, where there appears no nucleus, it has been conjectured to be composed of something analogous to globular masses of vapor, slightly condensed toward the center, and shining either by inherent light or by the reflected rays of the sun. When there is a nucleus in the center of a comet, it seldom happens that the nebulosity extends to it with a gradually increasing intensity. On the contrary, the parts of the nebulosity near the nucleus are but slightly luminous, and seem to be extremely rarefied and transparent. At some distance from their center, their shining quality is suddenly increased, so that it looks like a ring of invariable size resting in equilibrium around the center. Sometimes two, and even three of these concentric rings have been perceived separated by intervals; but what appears to be a ring must in reality be a *spherical covering*, an idea of which may be formed by imagining, in our atmosphere, at three different hights, three continued layers of clouds entirely covering the globe. The matter of the nebulosity is so rare and transparent that the smallest stars may frequently be seen through it.

As to the *nucleus*, it is generally considered as the solid or densest part of the comet. The *nuclei* of comets are sometimes very similar to the discs of planets, both in form and brightness. They are generally small compared with the whole size of the comet; but in some cases they are of considerable magnitude, as we have already stated in respect to the comets of 1807 and 1811. Some suppose that the nuclei of comets are transparent as well as their nebulosities, and allege as a proof that stars have been seen through a nucleus. Thus, Montaigne is said to have seen a star of the sixth magnitude through the nucleus of a small comet, and Olbers saw a star of the seventh magnitude, although it was covered by a comet, and without its light being rendered less powerful; but the accuracy of such observations has been called in question. On the other hand, it has been concluded that the nucleus of a comet has on several occasions eclipsed a star which was in the same line of vision. Messier, when observing the small comet of 1774, perceived a star which was eclipsed by the opaque body of a comet, or at least, all the circumstances attending it led to that conclusion. On the 28th of Nov. 1828, at 10h. 30′, P. M., M. Wartmann, at Geneva, perceived a star of the eighth magnitude completely eclipsed by Encke's comet. Comets have likewise been observed to transit the disc of the sun like dark spots. M. Gambart, of Marseilles, calculated that a comet which he had observed would pass across the sun on the morning of the 18th of November, 1826, and both he and M. Flaucerques were successful in obtaining a sight of it during its transit. Mr. Capel Llofft, on the 6th June, 1818, at 11, A. M., saw a body passing over the sun's disc, which appears to have been a comet. It was likewise seen on the same day by Mr. Acton, at 2h. 30′, considerably advanced beyond the point in which it was seen at 11, A. M., and its progress over the disc seems to have exceeded that of Venus in transit. These observations seem evidently to indicate that some comets at least have nuclei composed of solid and opaque materials. From all the observations in relation to this point, collected by M. Arago, he deduces the following conclusions: 1. That there exist some comets destitute of the nucleus. 2. That there are other comets, the nuclei of which are transparent. 3. That there are also comets, which are more brilliant than the planets, the nuclei of which are probably solid and opaque.

---

* Mrs. Somerville's "Connection of the Physical Sciences," a work which, though written in a popular style, would do honor to the first philosophers of Europe. Of this lady's profound mathematical work on the "Mechanism of the Heavens," the Edinburgh Reviewers remark—"It is unquestionably one of the most remarkable works that female intellect ever produced in any age or country; and with respect to the present day, we hazard little in saying, that Mrs. Somerville is the only individual of her sex in the world who could have written it."

† The most particular observations on Halley's comet, during its appearance in 1835, which I have seen, are those which were made by the Rev. T. W. Webb, of Tretire, near Ross, an account of which, with deductions and remarks, was read to the Worcestershire Natural History Society. The observations were made with an excellent achromatic telescope by Tulley, of 5 feet 6 inches focal length, and 4 7-10 inches aperture. Through the kindness of this gentleman I was favored with a manuscript copy of these observations, and would have availed myself of many of his judicious remarks, had my limits permitted.

In respect to the *tail*, or luminous train which generally accompanies comets, it is found that it is *generally* in opposition to the sun, or on the prolongation of the line which would join the sun and the nucleus. But this is not always the case. Sometimes the direction of the tail has been found at right angles with this line; and in some extraordinary instances, the tails of comets have been observed to point directly toward the sun. This was the case with a comet that appeared in 1824, which for about eight days exhibited an additional luminous train in opposition to that which assumed the ordinary direction. This anomalous tail, according to Olbers, was 7° long, while the other was only 3½°, and it was bright enough to be seen with an opera-glass. In general, however, it is found that the tail inclines constantly toward the region last quitted by the comet, as if in its progress through an ethereal medium, the matter forming it experienced more resistance than that of the nucleus. The tail is generally enlarged in proportion to its distance from the head of the comet, and in certain cases it is divided into several branches, as already noticed of the comet of 1807. Some have supposed that the divided tail is nothing more than a perspective representation of the sides of a great hollow cone; but there are certain observations which seem to prove that, in some cases, they have a separate existence as independent branches. The most remarkable instance of a divided tail was in the comet of 1744. On the 6th and 7th of March, there were six branches in the tail, each of them about 4° in breadth, and from 30° to 40° long. Their edges were pretty well defined and tolerably bright; their middle emitted but a feeble light, and the intervening spaces were as dark as the rest of the firmament. The tails of comets, as already noticed, sometimes cover an immense space in the heavens. The comet of 1680 had a tail which extended to 68°, that of 1811 to 23°, and that of 1769 to 97° in length; so that some of these tails must have reached from the zenith to the horizon. The length of the tail of the comet of 1680, estimated in miles, was 112,750,000; that of 1769, 44,000,000; and that of 1744, 8,250,000 miles. A body moving at the rate of 20 miles every hour would not pass over the space occupied by the tail of the comet of 1680 in less than 643 years. It has been supposed by some astronomers that certain changes in the appearance of the tails of comets arise from the rotation of the cometary body; as some comets have been supposed to rotate about an axis passing through the center of the tail, such as that of 1825, which was concluded from certain appearances, to perform its rotation in 20 hours, 30 minutes.

As to the nature of the immense tails of comets, their origin, or the substances of which they are composed, we are entirely ignorant, and it would be wasting time to enter into any speculation on this subject, as nothing could be presented to the view of the reader but vague conjectures, gratuitous hypotheses, and unfounded theories.

MISCELLANEOUS REMARKS ON COMETS.

1. *Whether comets shine with their own native light, or derive their light from the sun?*—This is a question about which there have been different opinions, and at the present moment it may be considered as still undetermined, though the probability is, that in general, they derive their light from the same source as the planets. It appears to have been the opinion of both Schroeter and Herschel, that the comet of 1811 shone by inherent light; and the rapid variations which have been observed in the brightness of the nucleus, and the coruscations of the tail, are considered by some as inexplicable on any other hypothesis It is likewise supposed that certain phenomena which have been observed in the case of faint and rarefied comets tend to corroborate the same position. For example, Sir J. Herschel, on September 23, 1832, saw a small group of stars of the 16th and 17th magnitude through the comet of Biela. Though this group could have been effaced by the most trifling fog, yet they were visible through a thickness of more than 50,000 miles of cometary matter; and therefore it is supposed scarcely credible that so transparent a material, affording a free passage to the light of such minute stars, could be capable of arresting and reflecting to us the solar rays. On the other hand, it has been objected to this opinion, that comets have appeared as dark spots on the disc of the sun; that their light exhibits traces of *polarization:* and that they have been occasionally observed to exhibit *phases*. M. Arago remarks, that "on the very day that any comet shall appear with a distinct phase, all doubts on this subject will have ceased." But it is considered doubtful whether any *decided phase* has yet been perceived, although some observers were led, from certain phenomena to infer that something like a phase was presented to their view. It is found that all direct light constantly divides itself into two points of the same intensity when it traverses a crystal possessing the power of double refraction; reflected light gives, on the contrary, in certain portions of the crystal through which it is made to pass, two images of unequal intensity, provided the angle of reflection is not 90°; in other words, it is *polarized* in the act of reflection. On this principle, M. Arago pointed out a photometrical method of determining whether comets borrow their light from the sun, or are luminous in themselves. On the 23d of October, 1835, having applied his new apparatus to the observation of Halley's comet, he immediately saw two images presenting the complementary colors, one of them red, the other green. By turning the instrument half round, the red image became green, and *vice versa*. He concluded therefore that the light of the comet, at least the whole of it, is not composed of rays possessing the property of direct light, but consists of that which is *polarized* or reflected specularly: that is, of light derived from the sun. These experiments were repeated with the same result by three other observers in the Observatory of Paris.

2. It appears to be a remarkable fact in respect to comets, that *the real diameter of the nebulosity increases proportionably as the comet* BECOMES DISTANT *from the sun*. Hevelius appears to have been the first who made this observation; but it seems to have been overlooked, and even an opposite position maintained. As the tails of comets increase in length as they approach their perihelia, so it was generally considered that the

nebulosities followed the same law; but the observations which have lately been made on Biela's comet have confirmed the observations of Hevelius. On the 28th of October, 1828, this comet was found to be nearly three times farther from the sun than on the 24th of December, or in the proportion of 1.4617, to 0.5419, yet in October its diameter was about twenty-six times greater than in December, or in the proportion of 79.4 to 3.1; that is, its solid contents on the 28th of October were 16,800 times greater than on the 24th of December, and the *smallest* size of the comet corresponded to its *least* distance from the sun. M. Valz, of Nimes, and Sir John Herschel have attempted to account for this circumstance on very different principles, but neither hypothesis appears to be satisfactory.

3. *Whether a comet may ever come in contact with the earth, and produce a concussion?*—As comets move in orbits which form extremely elongated ellipses; as they move in all imaginable directions; as they traverse almost every part of the solar system in returning from the farthest verge of their excursions; as they penetrate within the interior of the planetary orbits—even within the orbit of Mercury, and cross the orbits of the earth, and the other planets, *it is not impossible* that a comet may come in contact with our globe. An apprehension of such an event produced a considerable degree of alarm on the continent at different periods, particularly in 1773 and 1832, as formerly stated. But when we consider the immense cubical space occupied by the planetary system in which the comets move, and compare it with the small capacities of these bodies; and when we take into view certain mathematical calculations in reference to the subject, the probability of a shock from a comet is extremely small. "Let us suppose," says Arago, "a comet of which we only know that at its perihelion it is nearer the sun than we are, and that its diameter is *one-fourth* of that of the earth, the calculation of probabilities shows that of 281,000,000 of chances there is only one unfavorable, there exists but one which can produce a collision between the two bodies. As for the *nebulosity*, in its most general dimensions; the unfavorable chances will be from ten to twenty in the same number of two hundred and eighty-one millions. Admitting then, for a moment, that the comets which may strike the earth with their nuclei would annihilate the whole human race, then the danger of death to each individual, resulting from the appearance of an *unknown* comet, would be exactly equal to the risk he would run if in an urn there was only one single white ball of a total number of 281,000,000 balls, and that his condemnation to death would be the inevitable consequence of the white ball being produced at the first drawing."

When we consider that a Wise and Almighty Ruler superintends and directs the movements of all the great bodies in the universe, and the erratic motions of comets among the rest; and that no event can befall our world without his sovereign permission and appointment, we may repose ourselves in perfect security that no catastrophe from the impulse of celestial agents shall ever take place but in unison with his will, and for the accomplishment of the plans of his universal providence. At the same time, the *possibility* of a shock from a large comet shows us that this earth and all its inhabitants are dependent for their present existence and comforts on the will of an Almighty Agent, "in whom we live, and move, and have our being;" and that were it conformable to his allwise and eternal designs he could easily disarrange the structure of our globe, and reduce its inhabitants either to misery or to complete destruction; and that, too, without altering a single physical law which now operates throughout the universe.

If we recognize the Scriptures as a revelation from God, we may rest assured that no danger from such a cause can happen to our world for ages yet to come; for there are many important predictions contained in Revelation which have not yet received their accomplishment, and must be fulfilled before any fatal catastrophe can happen to our globe. It is predicted that the Jews shall be brought into the Christian church "with the fullness of the Gentiles,"—that "the idols of the nations shall be abolished,"—that "wars shall cease to the ends of the earth,"—that the kingdom of Messiah shall extend over all nations,—that "the knowledge of Jehovah shall cover the earth, and that all shall know him from the least to the greatest,"—that "the earth shall yield its increase," and its desolate wastes be cultivated and inhabited,—that moral order shall prevail, and "righteousness and praise spring forth before all the nations,"—and that this happy era of the world shall continue during a lapse of ages. These events have not yet been accomplished, though at the present moment they appear either in a state of commencement or of progression; but they cannot be supposed to be fully realized until after a lapse of centuries. The believer in Divine revelation, therefore, has the fullest assurance that, whatever directions comets may take in their motions toward the center of our system, none of them shall be permitted to impinge upon our globe, or to effect its destruction, for at least a thousand years to come, or until the above and other predictions be completely accomplished.

4. Another question occurs on this subject—namely, *whether any comets have ever fallen into the sun?*—It was the opinion of Sir Isaac Newton that one purpose for which comets are destined is, to recruit the sun with fresh fuel, and repair the great consumption of his light by the streams continually emitted every way from that luminary; and that such comets as come very near the sun in their perihelions meet every time with so much resistance from his atmosphere as to abate their projectile force; by the constant diminution of which, the centripetal power, or gravitation toward the sun, would be so increased as to make them fall into his body. On a similar principle, Arago supposes that the comet of 1680, which approached so near the body of the sun, must have passed nearer to his surface at that time than at its preceding apparitions; that the decrease in the dimensions of the orbit will continue on each succeeding return to its point of perihelion; and that "*it will terminate its career by falling upon the sun.*" But he acknowledges that, "from our ignorance of the densities of the various strata of the sun's atmosphere, of that of the comet of 1680, and of the time of its revolution, it will be impossible to calculate after how many ages this extraordinary event is to happen;" and he likewise admits that, "the annals of astronomy do not afford any reason to suppose the previous occurrence of such an event since the origin of historical record;" so that we have no direct evidence that such an event has ever taken place, or that it ever will. We know too little of the physical constitution of the sun, and of the nature of comets, to be able to assert that the falling of a comet into the sun would actually recruit the luminous matter of which his outer surface is composed; for we have reason to believe that there

is little or no analogy between the mode in which we supply our fires by means of fagots, and that by which the solar light is recruited and preserved in its pristine vigor; and beside, it is found that bodies, particularly in certain electric states, may be rendered luminous without the addition of any extraneous body to their substances.

OF THE INFLUENCE OF COMETS ON THE EARTH.

In former times the appearance of comets was supposed to be the forerunner of wars, revolutions, famine, pestilence, the deaths of great men, earthquakes, inundations, and other calamities. When the splendid comet of 1456 appeared (supposed to be the same as Halley's comet), its tail extended at one time over more than 60 degrees. Three days before its perihelion, its nucleus was as bright as a fixed star, its tail of the color of gold, and it appears to have exhibited coruscations. Pope Calixtus, believing it to be at once the sign and instrument of Divine wrath, was so frightened at its appearance that he ordered public prayers to be offered up in every town, and the bells to be tolled at the noon of each day to warn the people to supplicate the mercy of Heaven. He at the same time excommunicated both the comet and the Turks, whose arms had lately proved victorious against the Christians, and established the custom, which still exists in Catholic countries, of ringing the church bells at noon. In modern times, certain natural effects have likewise been attributed to the influence of comets; such as tempests, hurricanes, volcanic eruptions, cold or hot seasons, overflowings of rivers, fogs, dense clouds of flies or locusts, the plague, the dysentery, the cholera, and other disorders.

Mr. T. Forster, a respectable writer on natural science, author of "Researches about Atmospherical Phenomena," &c., published in 1829 a work on the "Atmospherical Causes of Epidemic Diseases," in which he maintains that the most unhealthy periods are those during which some great comet has been seen; that the appearance of these bodies has been accompanied by earthquakes, eruptions of volcanoes, and atmospheric commotions; and that no comet has been seen during seasons of healthiness. For example, in the year 1665 a comet made its appearance, and soon after its disappearance, the city of London was ravaged by the plague. In 1680 one of the most splendid comets which have been observed in modern times made its appearance. The atmospheric effect produced by its influence, according to Mr. Forster, was "a cold winter, followed by a dry and hot summer," and "meteors in Germany."

As the influence of comets on our globe and its atmosphere (if such an influence exist) must have a respect to the whole earth, and not merely to any particular portion of it, we might ask in reference to the first example, why did not the comet of 1665, produce a similar effect in Amsterdam, Vienna, Paris, and Madrid, and in the principal cities of Asia, Africa, and America? But of such effects we never had the least intimation. In respect to the second example, we are warranted to inquire, whether the cold winter was followed by a hot summer in every other climate of the earth? whether meteors were as common in other countries as in Germany? and whether the comet produced opposite effects, at one time congealing the pools and rivers, and at another scorching the earth with heat? If such questions cannot be satisfactorily answered, we are not warranted in attributing such effects to the influence of comets.

We err egregiously, in this as well as in many other respects, when we infer, from two contemporaneous events, that the one is either the sign or the *cause* of the other. It is on a principle of this kind that some persons are led to attribute the events to which we have alluded to the influence of comets. Because an inundation, a war, a political convulsion, or a volcanic eruption has taken place at the time of the approach of a comet to this part of our system, therefore they conclude that there must be a certain connection between such events, and that the one is the cause, and the other the effect; while the two events, in point of fact, may not have the slightest relation to each other, except their casual occurrence at the same period. We might, on the same grounds, infer that the rising of the star *Sirius* along with the sun, which announced to the Egyptians the rise of the Nile, was the *cause* of the annual overflowing of that river. Before we can identify any event with the influence of a comet, we must not confine our views to an event or two in our immediate neighborhood, but must endeavor to ascertain whether similar events or phenomena have happened *on every part of the earth* at the same period. As comets, either large or small, either visible to the naked eye or through a telescope, make their appearance at an average almost every year, and as epidemics, political commotions, earthquakes, hurricanes and similar events are always to be found occurring in some particular portions of the globe, we should never be at a loss for a physical cause to account for everything that happens here below, if comets are to be supposed to have such an influence over terrestrial affairs. Whatever takes place in any country of an uncommon nature might then be attributed to a comet which is either approaching the center of our system or receding from it.

It is remarkable that the announcement of a comet has generally been received with melancholy anticipations, and the effects attributed to its influence have uniformly been of a calamitous nature. But why should it not be the precursor of prosperous events—of peace, plenty, social tranquillity, and genial seasons—as well as of wars, famines, revolutions, cold winters, and parched summers? It seems something like a reflection on the general benevolence of the Deity to imagine that he has created such a vast number of bodies, and directed their course through every part of the planetary regions, chiefly for the purpose of "shaking from their horrid hair" wars, famine, and pestilence; for if they produce such effects upon the earth, we might with equal reason believe that they produce similar effects on the other planets of our system as they pass along in their course toward the sun: and this would lead us to infer that the inhabitants of all the planetary orbs are liable to the same disasters and calamities as the inhabitants of the earth; a position which seems scarcely consistent with the boundless benevolence of the Divine mind.

But although I do not admit the conclusions and the cometary influences to which I have alluded, I am far from asserting that comets have no influence whatever over our globe or its surrounding atmosphere. The universe is one great whole, and all its parts, however remote, must be supposed to have a certain relation to one another; and they may produce an influence, however small and imperceptible, on each other at the greatest distances. The remotest star perceptible to the eye may produce a certain physical influence on our globe, though so small and insensible as to be beyond the limits of the nicest calculation; and therefore comets which sometimes approach pretty near the earth may produce a certain sensible effect upon our globe, particularly should a portion of their immense tails at any time sweep along the higher regions of our atmosphere. But what special influence or effects they may produce on the physical economy of our terrestrial system it is impossible for us, in the meantime, distinctly to ascertain, from our ignorance of the constitution of those mysterious bodies, and of the substances of which they are composed. While too much has doubtless been attributed to the influence of comets, it would be verging to an opposite extreme to maintain that they can produce no effect at all on our earth and atmosphere. We know that certain celestial bodies produce a powerful influence on our globe. The moon, in conjunction with the solar influence, rules the ocean and perpetuates the regular returns of ebb and flow. Its light not only cheers our winter nights, but produces a variety of other influences both on the human constitution, the atmosphere, and on the productions of the earth; and there may be many effects produced by its agency with which we are as yet unacquainted.[*] The sun not only diffuses light over every region of the earth for the purpose of vision, but rays or emanations invisible to our sight proceed from his body, which promote evaporation, the growth of vegetables, and the various degrees of temperature which prevail throughout the globe. These emanations are likewise found to produce certain chemical effects, to dissolve certain combinations of oxygen, and to give polarity to the magnetic needle; and many other effects, of which we are ignorant, may afterward be found to proceed from those invisible irradiations. The larger planets, Jupiter and Saturn, and those which are nearest to us, as Venus and Mars, may likewise produce certain effects on our globe, both in virtue of their attractive power and of the peculiar nature of the reflected rays they transmit to the regions we occupy.

We cannot therefore but conclude, that comets may exert a peculiar influence on our terrestrial system in addition to that of other celestial bodies, and different from it, particularly those whose bulk and masses are considerable, and which approach nearest to the earth. Their light, whether native or reflected, appears to be peculiar, and the margin of their immense tails may occasionally graze our atmosphere when we are not aware of it, and may produce a peculiar effect different from that produced by the other bodies of our system; but what that special effect is has not hitherto been determined; for the mere coincidences of certain events with the appearance of comets cannot be supposed to be owing to their peculiar influence, unless such events are found uniformly to happen on the apparition of a comet, and that too throughout a great portion of the earth. This subject is worthy of some attention; and perhaps future observers, by more accurate observations than have hitherto been made, may throw some light on an influence which, on the one hand, has been perhaps too rashly set aside, and on the other, carried to a pitch of extravagance beyond the line of sober reason and observation.

Let it not be supposed that, in admitting that comets may have an influence on our globe, I mean to give the least countenance to foolish superstitions, or to the absurdities of astrology, since all that I would be disposed to admit in the present case is purely a *physical* influence; an influence which may exist, although we have not yet been able to discriminate its specific effects. The most eminent philosophers have been disposed to admit such an influence. Sir Isaac Newton supposed that "the atmospheres and tails of comets may supply the planets with moisture, which is continually wasting by the growing of vegetables out of water and turning into earth;" and that from the same source may be derived "the purest part of our air, which is requisite for the existence of living beings." These opinions, indeed, cannot be proved, and they are evidently untenable; but they show that that great philosopher admitted the influence of comets. M. Arago, although he scouts the vulgar idea of comets being the cause of most calamitous events, yet he admits that, "not only cometary matter may fall into our atmosphere, but that this phenomenon is of a nature to occur frequently, and may possibly produce those epidemic diseases which have been attributed to it."

A variety of questions has been started respecting cometary action and influence, beside those to which we have now alluded. It has been a question whether we ought to have recourse to the action of a comet *to account for the rigor of the climate of North America?* It is found that in the northern regions of America, the climate in the same latitude is much colder than in Europe. To account for this, Dr. Halley supposed that a comet had formerly struck the earth obliquely, and changed the position of its axis of rotation. In consequence of that event, the North Pole, which had been originally very near to Hudson's Bay, was changed to a more easterly position; but the countries which it abandoned had been so long a time, and so deeply frozen, that vestiges still remain of its ancient polar rigor, and that a long series of years would be required for the solar action to impart to the northern parts of the new continent the climate of their present geographical position. But we have no proof that a comet has ever struck the earth, or that its concussion would have the effect to change the direction of the terrestrial axis. Beside, it is well known that the Asiatic coast is equally cold in the same latitudes as the Atlantic shores of North America.

It has likewise been a subject of inquiry *whether the depression of the soil of a great part of Asia* has been produced by the shock of a comet;

---

[*] It is stated by Mr. Martin, in his "Description of the Western Isles," that "peat dug in the increase of the moon continues moist and never burns clear, while the contrary is observed of that cut in the decrease; and that earthen dykes thrown up in the latter season are alone found to possess stability." It is also stated as a fact, that "if an animal fresh killed be exposed to the moon's rays, it will in a few hours become putrid, while another animal, only a few feet distant, protected from their influence, will not be in the least affected; that fruits exposed to moonlight have been known to ripen much more readily; that plants bleached in the dark recover their color from the beams of a full moon; and that in south America, trees cut at the full moon split almost immediately, as if torn asunder by great external force. Fish are said to be rapidly decomposed in the West Indies when taken by moonlight."—*Webb's MS. Treatise on Comets.* Unless such alleged facts can be *disproved*, we must admit that the moon may have a certain influence in such cases, though we may be unable to explain the mode by which it is effected. In Carne's "Letters from the East," we are told, that "the effect of the moonlight on the eyes in eastern countries is singularly injurious. The natives tell you always to cover your eyes when you sleep in the open air. The moon here really strikes or affects the sight, when you sleep exposed to it, much more than the sun; a fact of which I had a very unpleasant proof one night, and took care to guard against it afterward. Indeed, the sight of a person who should sleep with his face exposed to the moon at night would soon be utterly impaired or destroyed." This circumstance strikingly illustrates the expression of the Psalmist—"The sun shall not strike or smite thee by day, *nor the moon by night.*"

and *whether Siberia ever experienced a sudden change* by a similar event? This latter inquiry has been suggested by the circumstance of the bones of elephants, rhinoceroses, and other animals peculiar to the torrid zone, having been found imbedded in the strata of that country, which has led to the supposition that Siberia was, at some remote period, comprised within the tropics. But there is no proof, nor even probability, that the action of a comet was concerned in either case. It has also been supposed that the small planets, Vesta, Juno, Ceres, and Pallas, the supposed fragments of a large planet, may have been broken to pieces by the shock of a comet. The circumstance that two of these planets, Ceres and Pallas, are encompassed with an atmosphere of great density and elevation has been brought forward as a presumptive proof of the reality of such a concussion, and that the cometary atmosphere, not being liable to destruction by the percussion, was imparted to these planets. But when we consider the very small density of comets, it appears not at all probable that even a direct concussion from such a body would have produced such an effect, although it might have caused a considerable derangement of the physical constitution of the planet. Beside, this hypothesis does not account for the remarkable fact that Vesta and Juno exhibit no traces of an atmosphere which, in consistency with the supposition, ought to have been imparted to them by the comet, as well as to Ceres and Pallas. On the whole, we have no direct or satisfactory proofs that comets have ever come in direct contact with our globe, or that they have produced any considerable derangements throughout the planetary system; and whatever specific influence they may produce on our earth and atmosphere must be deduced from future observations.

ON THE INHABITABILITY OF COMETS.

Some philosophers have been disposed to doubt whether the constitution of comets be at all fitted for the abode of rational beings, especially when we take into consideration the extremes of heat and cold to which they would be subjected in their long and extensive career. Mr. Whiston supposed that on this account they could not be the abodes of happiness, and therefore was led to believe that they were the places of punishment for the wicked, who were alternately wheeled into regions of intolerable heat, and afterward exposed to all the rigors of the most intense cold. But when we consider the boundless beneficence of the Divine Being, and that "his tender mercies are displayed over all his works," we cannot for a moment suppose that so vast a number of these bodies would be created for such an end. The celebrated Lambert, on the other hand, considers comets as constituting some of the most splendid regions of the universe, and that their inhabitants are permitted to contemplate the scene of nature on a scale of grandeur far surpassing that which is presented to the population of the planets.

Many of the comets which exhibit no signs of a nucleus appear to be composed of very light, transparent, and gaseous substances; and therefore it is not very probable that such bodies are inhabited. Comets in this state are supposed by some philosophers, to be only approaching to a state of consolidation. But as to those which have a large and solid nucleus, there appears to be no physical impossibility, nor even improbability, of their being the abodes of sentient and intellectual beings, as well as the other moving bodies of our system. The extremes of heat and cold to which comets are supposed to be subjected form the principal argument against the opinion that these bodies are inhabited. But in reply to such an objection it may be stated, that we have no proof that heat or cold depend altogether on the distance of a body from the sun, but most probably on certain circumstances connected with the constitution of the body itself. Beside, it is a fact, that in the heating of bodies there is a certain point, beyond which their temperature can never be raised; as, for instance, in the case of water, which cannot be heated beyond the point of 212° of Fahrenheit's thermometer; and therefore the surface of a comet may have a certain point beyond which its temperature can never be elevated, even at its nearest approach to the sun. "When, by any means," says Mr. Milne, "the density of bodies is made to change by a process, whether of rarefaction, on the one hand, or of condensation on the other, they are always found to undergo a corresponding diminution or increase of temperature. When, therefore, in the approach of a comet to the sun, all the parts of its nebulous envelope and tail which in the remoter regions of its course had been gathered close about the head, become expanded and attenuated, a very large proportion of the solar heat, which would otherwise have passed into the nucleus, and contributed to raise its temperature to a certain point, is carried off by the envelope and tail, in order to preserve an equilibrium among the several parts." Mr. Milne proves that, if we assume that the nebulous matter is elevated about 30 times its former hight, the diminution of density corresponding with the increase of volume will amount to 27,000, and that a quantity of caloric will be extracted corresponding to 1,215,000° of Fahrenheit. He further shows that, "when the comet retires toward its aphelion, where the heat of the sun becomes so much weakened on account of the distance, the condensation of the nebulous matter forming the tail and envelope serves not only to furnish the nucleus with continual supplies from the heat acquired at the perihelion, but even to render the warming influence of the solar rays much more efficacious than at a less remote part of the comet's orbit."*

The extremes of heat and cold, therefore, in comets may not be so great as at first view we should be apt to imagine, and their constitution may be such as is not incompatible with the idea that they are inhabited by animated beings. We are not, however, to suppose that the constitution of beings like man would be adapted to the circumstances and changes to which comets are subjected, nor is such a supposition necessary in order to prove their inhabitability. For in the case of all worlds and beings, we must necessarily admit that the Creator has adapted the constitution of the inhabitants to the nature of the habitation. We find a striking variety in this respect in the constitution of the numerous orders of sentient beings that people the globe on which we live; and a similar variety doubtless exists in the peculiar constitutions of the inhabitants of the different planets, and of all the worlds in the universe. For anything we can prove to the contrary, some of the comets may be the abodes of greater happiness than is to be found in our sublunary world, and may be peopled with intelligences of a higher order than the race of man. In consequence of the extensive regions through which they move and the variety of objects which will successively burst upon their view, their prospects of the scenes of the universe will be far more diversified and expansive than those of the inhabitants of the planets.

---

* Milne, Prize Essay on Comets, Part IV.

At one period they will behold the stupendous globe of the sun filling a great portion of their celestial hemisphere, and be enabled to contemplate the august and splendid operations going on upon its surface and in its luminous atmosphere, a spectacle of grandeur which must be beyond conception sublime and overpowering. At another period they will be enabled to survey, at no great distance, the phenomenon and economy of some of the planetary worlds. The comet of 1744 passed within 180 terrestrial diameters, or 1,440,000 miles of the earth's surface, at which time its inhabitants (if any) would enjoy an interesting view of our earth and moon, with their diversified motions, and the general aspect of their surfaces. The same comet twice traversed the system of Jupiter's satellites, when the magnificent globe of Jupiter would appear at least 300 times larger than the moon appears to us, and when its satellites would likewise present a very large and splendid appearance. From such a position, even with eyes such as ours, assisted by telescopes, all the diversity of surface of this huge globe, as presented in its diurnal rotation, with the changes of its belts, and the peculiar scenery of its satellites, would be distinctly perceived. Above all, the system of Saturn will present a most magnificent spectacle to the inhabitants of a comet when it passes through the regions in its immediate vicinity. Its expansive rings, filling a considerable portion of the visible firmament, their rapid rotation round the planet, the vast globe of Saturn itself, and the numerous satellites which accompany it, in all their different phases and rapid motions, will present a scene at once diversified and sublime. To the inhabitants of comets, many vast bodies within the range of our system may be visible, which we have never yet discovered, and which may never be perceptible from the region we occupy. Traversing vast regions of space far beyond the orbit of Uranus, and perhaps approaching to the nearest stars, worlds may be presented to their view of which we have no conception, and the planets which revolve around other suns may be distinguishable in the remoter parts of their course. Enjoying such diversified and extensive prospects of the operations of Omnipotence, the intellectual beings who reside on those bodies will acquire more expansive views than the inhabitants of the earth of the vast scene of nature and of the perfections of that Allwise and Almighty Being whose power brought into existence, and whose incessant energy sustains in being, all the worlds in the universe.

The number of comets is supposed by some astronomers to amount to several millions; and if so, they must frequently pass near each other in their long eccentric courses, and consequently the beings connected with them will have their prospects of other worlds wonderfully diversified and continually expanding. It is likewise supposed that comets sometimes extend their excursions to other suns. On this point M. Lambert has the following remarks: "I shall suppose that a globe in our system begins to describe a parabola. If this curve closes and returns into itself, the globe will remain with us, and acquire a periodical motion round the sun. If, on the contrary, it extends its limits, so as to become a hyperbola, the globe will recede more and more from the sun, and leave us, never to return. Were we to pursue the fugitive in idea, we should see it perhaps at the end of some thousands of years flit along the frontiers of our system and dive into a neighboring world. The central body of this world would then exercise its attraction over the new visitor, and give a curvature to his orbit. From that moment one of two things would happen. Either its path would change into an ellipse, in which case its travels would be at an end, and it would proceed to make regular revolutions round the dominant star of that system; or, perhaps, after passing its perihelion, it would again resume its hyperbolic progress, and approaching the asymptote, withdraw in a straight line, and proceed to visit other worlds. Thus we can conceive comets which, being attached to no particular system, are in common to all, and which, roaming from one world to another, make the tour of the universe. I ask why, in the infinite variety which the Creator has introduced into his works, such globes should not have a place? Their destination may embrace the wisest purposes, concerning which we may be allowed to speculate."

This celebrated philosopher concludes his remarks on comets with the following reflections, which, although somewhat fanciful, may not be unworthy of the attention of the reader:

"I love to figure to myself those traveling globes, peopled with astronomers, who are stationed there for the express purpose of contemplating nature on a large, as we contemplate it on a small scale. Their movable observatory cruising from sun to sun, carries them in succession through every different point of view, places them in a situation to survey all, to determine the position and motion of each star, to measure the orbits of the planets and comets which revolve round them, to observe how particular, are resolved into general laws, in one word, to get acquainted with the whole as well as the detail. We may suppose that their year is measured by the length of their route from one sun to another. Winter falls in the middle of their journey; each passage of a perihelion is the return of summer; each introduction to a new world is the revival of spring; and the period of quitting it is the beginning of their autumn. The place of their abode is accommodated to all their distances from the fixed stars, and the different degrees of their heat make the fruits and vegetables designed for their use blossom and ripen. Happy intelligences, how excellent must be the frame of your nature! Myriads of ages pass away with you like so many days with the inhabitants of the earth. Our largest measurements are your infinitely small quantities; our millions the elements of your arithmetic; we breathe but a moment; our lot is error and death, yours science and immortality. All this is agreeable to the analogy of the works of creation. The frame of the universe furnishes matter of contemplation as a whole as well as in each of its parts. There is not a point that does not merit our observation; this magnificent fabric is portioned out in detached parts to created beings; but it is in the unity of the whole that sovereign perfection shines; and can we suppose that this whole has no observers? The imagination, indeed, after so sublime a flight, may be astonished at its own temerity; but, in short, here the cause is proportioned to the effect, and there is nothing great o small in immensity and eternity."

ON THE MOTIONS AND ORBITS OF COMETS.

When a comet comes within the limits of our view, its apparent motion is from east to west, and it generally appears to rise and set like most of the other heavenly bodies. This motion, however, like that of the diurnal motion of the sun and planets, is only *apparent*, and arises from the rotation of the earth upon its axis. Beside this apparent motion, it has a *real* and proper motion of its own, by which it is continually shifting its place in the heavens, in conformity to the nature of the orbit in which it moves. "The proper course of a comet may be found by observing every night its distance from two fixed stars whose longitudes and latitudes are known; or by finding its altitude when in the same azimuth with two known fixed stars; or by noting four fixed stars in the point of intersection of the two lines connecting which the comet is found. If the places of the comet as thus observed every night, be marked on the celestial globe, a line drawn through them will represent the comet's path among the stars; a great circle drawn through three distant places will nearly show the way it has to go. If it be continued until it intersect the ecliptic, it will show nearly the place of the node and the inclination of the orbit to the ecliptic.* There is, however, a practical difficulty which perplexes the observer in attempting to ascertain the true form of a cometary orbit. A comet remains so short a time in sight, and describes so small a part of its course within our view, that, from observation alone, without the assistance of hypothesis, we should not be able to determine the nature of its path. The only part of the course of a comet that can ever be visible is a portion throughout which the ellipse, the parabola, and hyperbola, so closely resemble each other that no observations can be obtained with sufficient accuracy to enable us to distinguish them. The hypothesis most conformable to analogy is, that the comet moves in an ellipse, having the sun in one of the foci, and that the *radius vector* from the sun to the comet describes areas proportional to the times, according to the law observed by the planets. If it be supposed that the comet describes an ellipse or a parabola, in conformity to the laws of Kepler, then from three geocentric places, known by observation, the orbit may be determined.

The orbits of the planets, although elliptical, approach very nearly to circles; but those of comets are extremely eccentric, and form very elongated ellipses. The orbit of Halley's comet is four times longer than it is broad, and the orbits of those comets whose periodical revolution exceeds a hundred or a thousand years must be still more elongated and eccentric. Fig. 82 represents the orbit of Halley's comet nearly in its exact proportions. *E C* represents the length of the ellipsis in which it performs its revolution: *E D*, the orbit of the earth, somewhat larger than it ought to be in proportion to the comet's orbit; *S*, the sun in one of the foci of the ellipse; *Sat.*, the proportional distance of the planet Saturn from the sun; and *U*, the proportional distance of Uranus. The orbit of this comet extends to nearly double the distance of Uranus.

Fig. 83 represents so much of the trajectory of the comet of 1680 as it passed through while visible to the inhabitants of our globe, as delineated in Newton's "*Principia.*" It shows also the tail as it appeared on the days mentioned in the figure. Like that of other comets, it increased in length and brightness as it came nearer to the sun, and grew shorter and fainter as it went farther from that luminary and from the earth, until the comet was too distant to be visible. This comet was observed in the morning from November 4, to Novemb. 25, 1680, in its descent toward its perihelion at *P;* and its positions on the 17th, 21st, and 25th of that month are here exhibited. It appears to have passed its perihelion sometime between the 25th of November and the 12th of December.

Fig. 82.

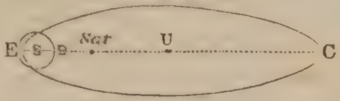


Fig. 83.

Its positions on the 12th, and 21st, and 29th of December, and on the 5th and 25th of January, 1681, after returning from its perihelion, as seen in the evening, are marked in the figure. The orbit of this comet must be extremely elongated, as its return is not expected for more than 400 years to come.

Fig. 84, taken from Arago's "Scientific Notices of Comets," exhibits a representation of the orbit of Biela's comet, with the relative position of the orbit to the earth. It shows both the space and the position it occupies in the solar system, and the points where its orbit intersects all the planetary orbits through which it passes. It exhibits its course at its return in November, 1832, and the path it describes until its subsequent return in 1839. From this figure it is seen that its perihelion lies between the orbits of the earth and Venus, and that its aphelion extends beyond the orbit of Jupiter. It would arrive at that point which is most distant from the earth, in the spring of 1836, and will probably return to it in January, 1843. The nearest approach to the earth of this comet was 51 millions of miles; its nearest approach to the sun, 83 millions; its mean distance from the sun, or half the longest axis of its orbit, 337 millions; and it is 507 millions of miles nearer the sun in its perihelion than in its aphelion. To be able to calculate and predict the future positions and appearances of such a body evinces an accuracy of observation, and a degree of perfection of astronomical *calculus*, which may justly challenge admiration, and which should lead those who are unacquainted with the minutiæ of astronomy to receive with confidence the results which have been deduced by those who have devoted themselves to celestial investigations.

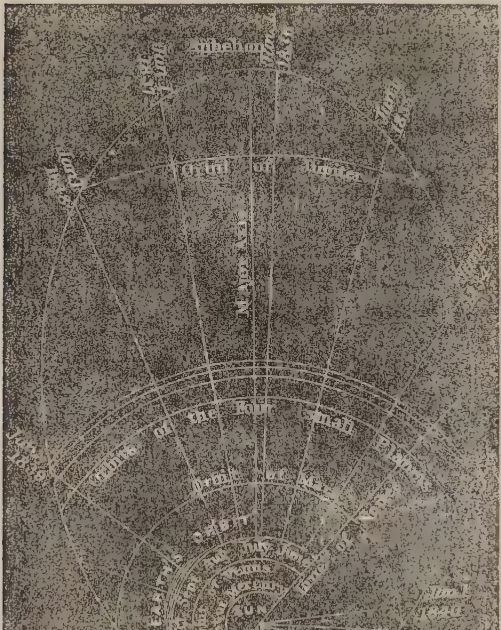
REPRESENTATION OF THE ORBIT OF THE COMET OF 1832, WITH THE RELATIVE POSITION OF THE ORBIT OF THE EARTH.



SUPPOSED NUMBER OF COMETS.

It is laid down as a principle by M. Lambert, that as the world is the expression of the perfections of God, we must believe that all the heavenly bodies are inhabited, and *"that universal space is replenished with as many globes as it can contain,"* so as to move with freedom and security within the circumference of the universe. Hence he infers, that the most perfect plan of our system will be that into which enters the greatest number of orbits, all separated from one another, and which in no one point intersects the other; and that the orbits of comets correspond to this end better than those of the planets, as an immensely greater number of elliptic or cometary orbits can be introduced into the system than of those which are circular. On the ground of the number of comets which have hitherto been observed, and on certain mathematical considerations, he instituted calculations which led to the conclusion that "at least five hundred millions of comets" might be contained within the limits of the solar system. On this point, M. Arago reasons in the following manner:—The number of comets really known, whose perihelion distance is less than the radius of the orbit of Mercury, amounts to thirty. This radius, and that of the orbit of Uranus, are in the ratio of 1 to 49; and the volumes of two spheres are to each other as the cubes of their radii. If, therefore, we adopt the hypothesis of the equal distribution of comets in all the regions of our system, and calculate the number of those luminaries whose perihelions are included in a sphere whose radius is the distance of Uranus from the sun, the following proposition would be supplied to us:—As the cube of 1 : to the cube of 49 : : so is 30 : to the number of comets sought;—or thus, $1^3 : 49^3 :: 30$; or, 1 : 117,649 : : 30 : 3,529,470. Thus within the orbit of Uranus, the solar system should contain more than three millions and a half of comets; or, we should rather find the double of that the true number, when we consider that in this calculation the term which represents the number of comets contained within the sphere of Mercury is certainly much too small, and that it ought to be conceded that the light of day, our clouded skies, and a too southerly declination, removes from our sight not fewer than every alternate one of these bodies. Taking these circumstances into consideration, there should, on the same hypothesis, be seven millions of comets.

The actual number of comets, however, which have been observed since the commencement of the Christian era, does not amount to above seven or eight hundred; but when we consider that in the earlier ages of astronomy, and likewise in more recent periods before the invention of the telescope, only large and conspicuous comets were noticed, and that the greater number, in all probability, had their visible courses in the southern regions of the heavens, and of whose appearance we have no records, it will easily be conceived that their actual number must amount to at least many thousands. Since particular attention has been directed to the astronomy of comets, and since the number of observers have increased, scarcely a year has passed without the observance of one or two of these bodies, and sometimes even two or three have appeared at once. In the year 1825, no less than *four* comets made their appearance within the space of three months. The first of these was discovered by M. Gambart, at Marseilles, on May 9, in the head of *Cassiopeia;* the second by M. Valtz, at Nismes, on July 13, in *Taurus;* the third by M. Pono, at Florence, on

August 9, in *Auriga;* the fourth, or Encke's comet, about the months of July or August. But it is evident that multitudes must escape all observation, by reason of their paths traversing only that portion of the heavens which is visible in the daytime.

The number of comets whose paths have been particularly observed during their visible course is about 137. Of these sixty-nine moved in a *direct* course, or according to the order of the signs, as the planets do, and sixty-eight in a retrograde direction. As to the *distances of their perihelions* from the sun and the earth, thirty were found to have their perihelions between the orbit of Mercury and the sun; forty-four, between the orbits of Mercury and Venus; thirty-four, between the orbits of Venus and the earth; twenty-three, between the orbits of the Earth and Mars; six, between the orbits of Mars and Jupiter. Beyond the orbit of Jupiter no comets have been perceived; and it is seldom they can be seen beyond the orbit of Mars. As to *the inclination of their orbits*, nine comets have been observed whose orbits incline to the ecliptic from 0° to 10°; thirteen, from 10° to 20°; ten, from 20° to 30°; seventeen, from 30° to 40°; fourteen, from 40° to 50°; twenty-three from 50° to 60°; seventeen, from 60° to 70°; nineteen, from 70° to 80°; fifteen, from 80° to 90°. It appears, then, that these 137 comets had their orbits inclined in almost every degree to the ecliptic; and it is probable that this is the case with all the other comets which belong to the system.

Although comets generally emit an obscure light, yet some have been seen whose splendor was so great as to be visible in daylight, even at noon, and while the sun was shining in all its brightness. Such, it is said, were the comets which appeared in 1402 and 1532, and that which appeared a little before the assassination of Cæsar, and which was supposed, after that event happened, to have been an omen or prelude of his death. It has likewise been stated, that comets have appeared of such a magnitude as to have eclipsed the sun. Seneca relates that such a coincidence happened sixty years before Christ, when a large comet was actually observed very near the sun.* The same author relates that a comet which appeared in the time of the Emperor Nero was not inferior in apparent magnitude to the sun himself;† and the comet which Hevelius observed in the year 1652 did not seem to be less than the moon, though it was deficient in splendor.

Comets traverse all parts of the heavens; and, as already noticed, their orbits have every possible inclination to the plane of the ecliptic. They are, however, governed in their motions by the same physical laws which regulate the motions of the planets. Their periodical times are to the periodical times of the planets, in the sesquiplicate ratio of their principal axes. Comets, therefore, being for the most part beyond the planetary regions, and on that account describing orbits with much larger major axes than the planets, revolve more slowly. Thus, if the major axis of a comet's orbit be four times as long as that of the orbit of Uranus, the time of the comet's period would be to that of the planet as 8 : 1; its periodic time would therefore be nearly 672 years; that is, $8 \times 84 =$ the period of Uranus $= 672$. Although comets move with great rapidity when near their perihelion, yet in the remote parts of their course their motion must be proportionally slow.

The motions of comets when approaching the sun are in certain cases extremely rapid. The comet which was observed by Regiomontanus, in 1472, was said to have passed through 40 degrees of a great circle in twenty-four hours. Brydone, in his "Tour through Sicily," relates that he observed a comet at Palermo, in June and July, 1770, which moved through 50 degrees of a great circle in twenty-four hours. At midnight, on the 30th of June, it passed the zenith of Palermo (latitude 38° 10′), and the next day, July 1, at 40 minutes past eight, P. M., it passed 4 degrees to the east of the polar star. He remarks that, "supposing it at the distance of the sun, at this rate of traveling, it would go round the earth's orbit in less than a week, which makes about eighty millions of miles a day,—a motion that vastly surpasses all human comprehension. And as this motion continues to be greatly accelerated, what must it be when the comet approaches still nearer to the body of the sun!" It is probable, however, that the comet was considerably nearer the earth than the distance of the sun; but still the velocity with which it was impelled must have been amazingly great.

Such is a brief summary of the most remarkable facts, interesting to the general readers, which have been ascertained in relation to comets. It is to be hoped that, in the progress of astronomical discovery, some additional light will be thrown on the nature and the destination of those mysterious bodies, whose number appears so far to surpass that of the primary and secondary planets of our system. It was long ago predicted by Seneca, a Roman philosopher who lived in the first century of the Christian era, "that the time will come when the nature of comets and their magnitude will be demonstrated, and the courses they take, so different from those of the planets; and that posterity will wonder that the preceding ages should be ignorant in matters so plain and easy to be known." In order that this prediction may be fully realized, it is requisite that we should become acquainted with all the observations that have hitherto been made, and the facts in relation to these bodies which have been ascertained; that we should compare the various observations with each other, and attend to the minutest circumstances and phenomena connected with comets; that numerous observers should be appointed to survey different portions of the firmament, both in the northern and southern hemispheres, that no comet that comes within the limits of our vision may pass unobserved; and that when a comet of large size approaches near the center of our system, every minute particular in reference to its motions, and the changes which take place in its nucleus, envelope, and tail, be carefully observed and delineated by accurate representations.

Whatever opinions we may adopt as to the physical constitution of comets, we must admit that they serve some grand and important purpose in the economy of the universe; for we cannot suppose that the Almighty has created such an immense number of bodies, and set them in rapid motion according to established laws, without an end worthy of his perfections, and, on the whole, beneficial to the inhabitants of the system through which they move.

They display the *wisdom* of their Creator *in the arrangements of their orbits and motions.* As we have every reason to conclude that at least thousands of those bodies traverse the solar system in all directions, and are certain that their orbits are inclined in every possible degree to one another, and to the orbit of the earth, so we find that they have been so admirably arranged by Divine Intelligence, that no one of them interferes with another, or with the courses of the planets, so as to produce concussion or disorder. The orbits of some comets indeed are found to approach very near, and even to cross the orbit of the earth and the orbits of several other planets, and consequently, there is a *possibility* that a comet might come into concussion with our globe; and this consideration shows us that we are dependent for our present security and comforts on the wise arrangements of the Almighty, in securing perfect harmony and order amidst apparent danger and confusion. But we have no evidence that such a catastrophe has ever happened, either in the case of the earth or of any of the other planets, or that one comet has ever impinged upon another. Believing that every object and event in the universe is arranged and directed by an Omnipotent Contriver, we must admit that when the Almighty formed the wondrous plan of creation, "foreseeing the end from the beginning," he arranged the periods and the velocities of comets in such a manner that, although occasionally crossing the planetary orbits, they should not pass these orbits at the time when the planets were in their immediate vicinity. And should such an event ever occur, we may rest assured that it is in perfect accordance with the plan and the will of Omnipotence, and that it is, on the whole, subservient to the happiness and order of the intelligent universe, and the ends intended by the Divine government. If there are thousands and perhaps millions of comets of all descriptions traversing every part of the planetary regions, in orbits of every degree of inclination, of extent, and of eccentricity, we are sure that none but a Being of infinite power and intelligence could have arranged such a vast and complicated system, so as to have prevented numerous interferences and disasters, and to make the whole move onward for ages in perfect harmony.

---

* Sir John Herschel's Astronomy.

† Dr. O. Gregory's Astronomy.

The system of comets likewise presents to us a display of *the omnipotence and grandeur of the Deity*. The number of these celestial visitors, the vast magnitude of their tails, envelopes, and nuclei, and the amazing velocity with which they wheel their courses through the ethereal regions, exhibit before us objects of astonishing grandeur, and evince the Almighty power of Him who at first impelled them in their rapid career. The diameter of the nucleus of the comet of 1807 was estimated by Schroeter at 4600 miles, and that of its coma 120,000 miles. Beside its principal tail, it shot forth coruscations to the extent of four millions, six hundred thousand miles. The nucleus of the comet of 1811 was, according to the same observer, 50,000 miles in diameter, its coma or envelope 947,000 miles, and its tail or train of light, sixty millions of miles in length, or more than half the distance between the earth and the sun. Let us conceive such a body, like the comet of 1680, traversing the immense spaces of creation with the velocity of ten hundred thousand miles an hour, and drawing after it a luminous train, a hundred millions of miles in length, approaching at one time so near the sun that his circumference would appear to fill the greater part of the firmament, and then rushing back through the depths of immeasurable space, thousands of millions of miles beyond the orbit of Uranus, and displaying its majestic train to the other planetary worlds of our system—and we have presented to our mental eye an object of peculiar grandeur and magnificence, different from everything else which the planetary system exhibits, and which displays in an eminent degree the power and magnificence of the Great Creator. Were such a body to sweep along the regions which lie in the immediate vicinity of our globe, at the distance of ten or twelve thousand miles, nothing that we have ever beheld or can well conceive could be compared to the majestic grandeur of the scene, which would overpower the mind both with astonishment and with terror. On the view of such an object, sweeping along with such velocity, we could scarcely refrain from exclaiming, in the language of inspiration, "Great and marvelous are thy works, Lord God Almighty!" What, then, shall we think of thousands of such mysterious orbs winding their flight in every direction, in perfect regularity and order, through the immensity of space! Surely these are the wonderful works of Him who is mighty in operation and perfect in knowledge.

In all the works of the Deity, we must likewise admit that his *goodness* is displayed, although we may not be able to trace the mode of its communication; for we may lay it down as an axiom, that wherever wisdom and omnipotence are exhibited throughout the Divine economy, there is also a display of *beneficence*, which appears to be one prominent design of all the works of God. Comets have long been considered as objects of terror, and as omens of impending calamities; but there can be no question that they are as intimately connected with a system of benevolence as are the solar radiations and their benign influence on our globe and on the other planets. It has been conjectured that comets may supply moisture to the planets, and invigorate the vital principle of our atmosphere; that they may recruit the sun with fresh fuel and repair the consumption of his light; or that they may be the agents for dispersing the electric fluid throughout the planetary regions; and although there is little probability that such conjectures are accordant with fact, yet it may be admitted that comets may produce a *physical* influence of a beneficial nature throughout the solar system. But what I conceive to be one of the main designs of the Creator in the formation of such a vast number of splendid bodies is, that they may serve as habitations for myriads of intellectual beings, to whom the Almighty bestows his perfections in a peculiar manner, and on whom he displays the riches of his beneficence. Whatever may be the intention of those comets which are destitute of a nucleus, this, in all probability, is the chief design of those which are large and which are invested with a solid nucleus; and the same arguments which we formerly brought forward to prove that the planets are inhabited might be adduced in proof of the inhabitability of comets. If this position be admitted, then we ought to contemplate the approach of a comet, not as an object of terror or a harbinger of evil, but as a splendid world, of a different construction from ours, conveying millions of happy beings to survey a new region of the Divine empire, to contemplate new scenes of creating power, and to celebrate in loftier strains the wonders of Omnipotence.* Viewing the comets in this light, what an immense population must be contained within the limits of the solar system, which gives room for the excursions of such a vast number of these bodies! and what an incalculable number of beings of all ranks must people the wide-extended universe!

---

* The most complete account of the phenomena, &c. of comets I have seen is a treatise on this subject in manuscript, by the Rev. Thomas W. Webb, of *Tretire*, near *Ross*.

APPENDIX.

GENERAL APPEARANCE OF THE STARRY HEAVENS AT DIFFERENT PERIODS OF THE YEAR.

The following descriptions are intended to point out to the young observer the principal stars and constellations in the beginning of every alternate month throughout the year, and the particular quarter of the heavens where they may be perceived. The time of observation is supposed to be *nine o'clock in the evening*, except on the 1st of July; but the general aspect of the heavens, and the relative positions of the different stars and constellations, will not be materially different when viewed an hour before or after the time specified.

ASPECT OF THE HEAVENS ON THE 1st OF JANUARY, AT NINE O'CLOCK IN THE EVENING.

At this time the *Pleiades*, or Seven Stars, are nearly on the meridian, at an elevation of more than 60 degrees above the southern horizon. The bright star *Aldebaran*, or the Bull's Eye, which is of a ruddy hue, appears to the left, in a direction nearly east by south, at the distance of 14°. About 15° east-north-east of Aldebaran is a bright star of the second magnitude, marked *Beta*, or El-nath; from this star to *Zeta*, in the tip of the southern horn of the Bull, is about 8° in a southern direction. This star forms a right angle with Aldebaran and Beta. North of Beta, at the distance of 17°, is the bright star Capella, in the constellation of Auriga, a star of the first magnitude, which appears at a high elevation a few degrees south-east of the zenith. In a direction south-east of Aldebaran and the Pleiades is the splendid constellation of *Orion*. *Bellatrix*, on the west shoulder of Orion, is about 16° south-east of Aldebaran, which is placed in the middle of the line which connects the Pleiades with Bellatrix; these three objects appearing nearly equidistant in a line N. W. and S. E. of each other. Nearly due east from Bellatrix, at the distance of 7½°, is Betelguese, a star of the first magnitude in the east shoulder of Orion. About 15° south by west of Bellatrix is *Rigel*, a star of the first magnitude in the left foot, and 8½° to the east is *Saiph*, a star of the third magnitude in the right knee of Orion. These four stars in the form of a parallelogram, with the three bright equidistant stars called the *Belt*, form the outlines of this constellation. There is a small triangle of three small stars in the head of Orion which forms a larger triangle with Bellatrix and Betelguese, the two in his shoulders. (See fig. of Orion, p. 26, and Plate I.)

North-east of Betelguese, at the distance of 14°, is the star *Alhena*, or γ Geminorum, the principal star in the feet of the Twins; and about 20° N. E., nearly in the same right line from Betelguese, are *Castor* and Pollux, Castor being the uppermost and the brightest, at the distance of only 4½° from Pollux. These and the other stars which lie adjacent to them form the constellation Gemini, one of the signs of the Zodiac. The small stars immediately to the east of Gemini are in the constellation *Cancer*, another zodiacal constellation through which the sun passes in July and August. In this constellation is a nebulous cluster of very small stars, called *Præsepi*, which may be distinguished as a faint cloudy speck by the naked eye. (See page 63.)

Immediately below Orion are the constellations of *Lepus*, or the Hare, and Noah's Dove, which are very near the horizon. South by east of Orion is *Canis Major*, or the Greater Dog, which is distinguished by its principal star *Sirius*, the brightest fixed star in the heavens. It is nearly straight south of Alhena, in the feet of the Twins, at 35° distant, and south by east of Betelguese at the distance of 27°. A line drawn through the three stars in the belt of Orion, and prolonged, meets Sirius at the distance of 23°. About 5½° west of Sirius is *Mirzam*, of the second magnitude, in the foot of the Dog. Nearly due east from Orion, but less elevated above the horizon, is *Canis Minor*, or the Lesser Dog. The center of this small constellation is situated about 5° north of the equinoctial, and midway between Gemini and Canis Major. It is distinguished by the bright

---

This treatise contains—1. A copious introduction, embodying a variety of interesting general remarks in relation to this subject. 2. A particular account of the comet of 1807, according to the observations of Sir William Herschel. 3. A description of the same comet from the observations of Dr. Johan. Hieronym. Schroeter. 4. An account of the great comet of 1811, according to the observations of Sir W. Herschel. 5. A particular description of the phenomena of the same comet, according to the observations of Schroeter. 6. A description of the second comet of 1811, according to the observations of Sir W. Herschel. These observations, particularly those of Schroeter, contain the most minute descriptions which have hitherto been given of the phenomena of this class of the celestial bodies, and will be found of essential service, not only to amateur observers, but to astronomers of every description. They have been extracted and arranged chiefly from the "Philosophical Transactions," and the works of Schroeter, which were published in the German language. The *Appendix*, or Second Part, which occupies nearly half the volume, comprises a lucid investigation of the following topics:—1. Comparison of observations. 2. Examination of hypotheses. 3. Nature, light, and solidity of comets. 4. Colors of Comets. 5. Brightness of Comets. 6. Divided tails of Comets. 7. Coruscations of Comets. 8. Miscellaneous notices concerning remarkable comets. 9. On the influence of comets. 10. Losses to science, containing an account of the disasters which befell Schroeter, Hevelius, &c. 11. Hints to amateur observers. This volume contains 230 quarto pages, beside a great number of copious notes, and forty-six figures of the different appearances of comets. It indicates a very great degree of labor and research, which the astronomer alone will be able fully to appreciate. The author appears to have consulted most of the works which have been published on the subject, in the English, Latin, French, and German languages, beside embodying a number of original observations and remarks. And what is not among the least important features of the work, the author takes every proper opportunity of introducing such moral reflections as the subject naturally suggests, and of directing the contemplations of his readers to Him who sits on the throne of the universe. The observations of Schroeter contained in the preceding pages, have been extracted from this volume. It is to be hoped that the worthy author, who is already known to a considerable portion of the scientific world by his communications to periodicals and scientific associations, will soon receive encouragement to lay this work before the public.

star named *Procyon*, which signifies "before the Dog." About 4° to the north-west is *Gomelza*, a star of the third magnitude. Procyon, at the time supposed, appears nearly due east from Betelguese, at the distance of about 26°. The head of *Hydra* lies immediately to the east of Procyon; but *Alphard*, or *Cor Hydræ*, the principal star of this constellation, is not risen at the time supposed. A little to the north of the eastern point of the compass, and at a very small elevation above the horizon, is *Regulus*, a star of the first magnitude, in the constellation Leo, which is the *fifth* sign, and the sixth constellation of the zodiac.

Turning our faces toward the north-east, *Ursa Major*, or the Great Bear, is the most striking constellation that meets the eye. The two pointers, *Dubhe* and *Merak*, appear uppermost, and point westward to the Pole-star; while the stars forming the tail seem to hang downward from the square of this constellation. As the night advances, this group of stars rises higher in the heavens, until, about three in the morning, they approach near the zenith. *Ursa Minor*, or the Lesser Bear, is seen *below* the pole, the square of which being a little to the eastward of the meridian. Directly below the Great Bear, at a very small elevation above the horizon, and in a direction N. E. by N., is *Cor Caroli*, a star of the second magnitude, in *Chara*, one of the Greyhounds. North by east of Aldebaran, at the distance of 30°, is the bright star *Capella* in *Auriga*.

Directing our view a little to the west of the meridian, we perceive the constellation *Aries*, which is immediately to the westward of the Pleiades, and nearly at the same altitude. Above 2000 years ago, in the days of Hipparchus, this constellation occupied the first sign in the zodiac, into which the sun entered about the 21st of March, but, as in consequence of the *precession of the equinoxes* the constellations gain about 50″ on the equinox every year, they have now advanced in the ecliptic nearly 31 degrees beyond it, or somewhat more than a whole sign; so that the constellation *Pisces* now occupies the same place in the zodiac that Aries did 2000 years ago, while the *constellation* Aries is now in the *sign* Taurus, Taurus in Gemini, &c., so that Aries, though the *first* sign, is the *second* constellation of the Zodiac. It is situated next east of Pisces, and midway between the *Triangles* and *Musca* on the north, and *Cetus*, or the Whale on the south. It is distinguished by two bright stars in the head, distant from each other about 4°, the brightest being a little to the east or north-east of the other, being about 25° west of the Pleiades, and 19° south of *Almaack*, in the foot of Andromeda. North by east from Aries is *Musca*, or the Fly, which consists of four or five stars, chiefly of the third and fourth magnitudes, very near to each other. It is situated between the first star of Aries and the Pleiades, but a little higher than either. North by east from the Fly, at the distance of about 15°, and at 20° north by west of the Pleiades, and at a higher elevation, is the head of *Medusa*, the principal star of which is Algol, which regularly varies in its luster. (See p. 41.) West by north from Medusa is *Andromeda*, one of the principal stars of which is *Almaack*, at the distance of 12° west by north of Algol. West of Almaack, at the distance of 12°, is *Mirach*, both of them stars of the second magnitude. If the line connecting Almaack and Mirach be prolonged 8° farther west or south-west, it will reach *Delta*, a star of the third magnitude, in the left breast.

West from Andromeda, and a little to the south, is *Pegasus*, or the Flying Horse, which is distinguished from the other constellations by four bright stars of the second magnitude, forming a square, which is generally termed *the square of Pegasus*. The northernmost star, which is the brightest of three that form a kind of triangle, is *Scheat*, whose N. declination is 26½°. *Markab* is situated 13° south of Scheat, and at the time supposed is nearly due west, and about 22° above the western point of the horizon. These two stars form the *western* side of the square. East from Markab, at the distance of 16½°, is *Algenib*, and 14° north of Algenib is *Alpheratz;* which two stars form the eastern side of the square. Scheat and Alpheratz form the *northern*, and Markab and Algenib the *southern* sides of the square. Alpheratz constitutes a part of the head of Andromeda, but it is also considered as connected with Pegasus. About 26° north of Andromeda is *Cassiopeia*, midway between it and the Pole-star. It passes the meridian nearly in the zenith about the 22d of November. At this time it is between 20° and 30° west of the meridian. (See pp. 16 and 37.) The star *Caph*, in this constellation, along with Alpheratz and Algenib, are situated on the *prime meridian* which passes through the first point of Aries, from which the right ascensions of all the heavenly bodies are measured. The line connecting these stars forms an arc of the *equinoctial colure*, which passes through the vernal equinox, and across which the sun passes on the 21st of March. When we say that the sun, or a star, or a planet is in so many degrees of right ascension, we mean that it is situated, or has moved *eastward* so many degrees from this great circle. North-west of Cassiopeia is *Cepheus*, at the distance of about 25°, the head of which is in the Milky Way, and may be known by three stars of the fourth magnitude in the crown, forming a small acute triangle about 9° from *Alderamin*, a star of the third magnitude in the left shoulder.

Next to Cepheus, on the west, is *Cygnus*, or the Swan; the principal stars of which are distinguished as forming the figure of a large *cross*, the upright piece of which lies along the Milky Way. The most brilliant star in this constellation is *Deneb* Cygni, of the first magnitude, which is at this time in a direction nearly north-west, and 25° above the horizon. West from Deneb, at the distance of 10° or 11°, is *Delta;* and the line prolonged about 15° farther leads to the bright star *Vega*, the principal star in *Lyra*, which is then about 6° above the horizon in a direction north-west by north. North by east of Lyra is the head of *Draco*, distinguished by four stars separated from each other by intervals of 3°, 4°, and 5°. The one to the south, or nearest Lyra, is *Etanim*, or γ Draconis, which Dr. Bradley fixed upon in his attempt to determine the annual parallax. At this time it is 16° above the horizon, in a direction N. N. W. About 4° to the north of it is *Rastuben*, both of them stars of the second magnitude. Turning our eyes again toward the southern part of the meridian, we behold the head of *Cetus*, or the Whale, about 20° S. E. of Aries, and about 24° S. by W. of the Pleiades. It is distinguished by five stars, 4° or 5° asunder, which form a figure resembling a regular *pentagon*. The brightest of these stars, which is the easternmost, and of the second magnitude, is *Menkar*, which makes an equilateral triangle with *Arictis* and the Pleiades, being distant from each about 23½°. About 14° south-west of Menkar is *Mira*, or the Wonderful Star, which is found to vary its apparent size from a star of the second or third, to one of the sixth or seventh magnitude. (See p. 41.) North-west of the head of Cetus, and west of Aries, is the constellation *Pisces*, or the Fishes, one of the signs of the Zodiac, in which there are no remarkable stars, most of them being of the third, fourth, and inferior magnitudes.

Such is the general outline of the heavens as they appear about the beginning of January.

GENERAL APPEARANCE OF THE HEAVENS ON THE 1ST OF MARCH, AT NINE O'CLOCK, P. M.

At this period of the year, at 9 P. M., several of the constellations which were seen in the beginning of January, have disappeared, such as Pegasus, Pisces, and others. Others, which are still visible, appear in other quarters of the heavens; and some stars and constellations which were then below the horizon have risen to a considerable elevation above it. Orion is now in the south-west quarter of the heavens; the Pleiades, instead of being on the meridian, are due west, at an elevation of 34° above the western point of the horizon; the bright star Sirius is to the west of the meridian, in a direction S. S. W.; Canis Minor and Procyon are a few degrees to the west of the meridian; Castor and Pollux, directly north of Procyon, have likewise passed the meridian; Capella is seen at a high elevation, 30° west of the zenith; Menkar, in the head of the Whale, is within a few degrees of the western horizon; Aries is likewise near the western horizon; and Cassiopeia is in a north-westerly direction, and at a lower altitude than in January; Deneb, in the Swan, is very near the horizon, a little to the west of the north point; Vega, in the Lyre, is just rising at a short distance to the east of it; the head of Draco is in a N. N. E. direction, about 18° above the horizon; the Great Bear is at a higher elevation than in January, and the Pointers in a direction N. N. E.; and Cor Caroli appears in a direction east by north, about midway between the zenith and the horizon.

The following constellations, among others, now appear, which were under the horizon in January:—*Hydra*, the largest star in which is *Alphard*, or Cor Hydræ. It is at this time in a direction S. S. E., about 28° above the horizon. It may be distinguished from this circumstance, that there is no other considerable star near it. It is 23° S. S. W. of Regulus. The constellation *Leo*, which was only partly visible in January, now appears in its splendor toward the eastern part of the sky. Regulus, one of its largest stars, situated within half a degree of the ecliptic, is distinguished as being the largest and lowest of a group of five or six stars which form a figure or curve somewhat resembling a *sickle*. East of Regulus, at the distance of 25°, is *Denebola*, in the Lion's tail, which appears nearly in an eastern direction 35° above the horizon. East from Leo is the constellation *Virgo;* but all the stars connected with it have not at this time risen above the horizon. It is situated midway between Coma Berenices, on the north, and Corvus on the south. *Coma Berenices*, which consists of a cluster of small stars, is in a direction nearly due east, and about midway between the zenith and the horizon. East by north of this cluster, at a low elevation, is Bootes, the principal star of which is *Arcturus*, of the first magnitude. It is at this time in a direction east by north, 14° above the horizon. Farther to the north, and at a lower elevation, is *Corona Borealis*, or the Northern Crown, the principal star in which is called *Alphacca*, of the third magnitude, and 11° east by north of *Mirac*, or ε Bootes. This constellation is distinguished by six principal stars, which are so placed as to form a circular figure, somewhat resembling a wreath or crown.

GENERAL APPEARANCE OF THE HEAVENS ON THE 1ST OF MAY, AT 9, P. M.

At this period several of the more splendid constellations which adorn our nocturnal sky during winter have disappeared. Orion is nearly hid beneath the western horizon, and only the bright star Betelguese can be faintly seen, as it is about to descend below the western point of the horizon. Aries has completely disappeared; Caput Medusæ, Taurus, the Pleiades, and Aldebaran, are just verging on the borders of the north-western horizon, and are scarcely visible; and the brilliant star Sirius has completely disappeared from the nocturnal sky. The head of Hydra, with Alphard, its principal star, are in a south-westerly direction; Canis Minor and Procyon are in a direction W. S. W., considerably to the west of Alphard, but nearly at the same altitude. North of Procyon, at a considerable distance, are Castor and Pollux, about midway between the zenith and the western point of the horizon. At a considerable distance to the north-west of these is Capella, considerably nearer the north-western horizon than the zenith. Cassiopeia appears very low in altitude, near the northern quarter of the heavens, and the Great Bear appears near its most elevated position, not far from the zenith, the two Pointers pointing nearly directly downward toward the Pole-star, while at the same hour in November, they point almost directly upward. Regulus is about 22° west of the meridian, at a considerable elevation; Denebola, in the same constellation (the Lion), is just on the meridian, at a little higher altitude than Regulus. Arcturus is seen in a direction E. S. E., at a very considerable elevation, and 26° north-west of it is Cor Caroli, not very far from the zenith. The stars in the Northern Crown appear due east, midway between the zenith and the horizon. The brilliant star α Lyræ appears near the north-east, about 23½° above the horizon. The Swan is near the N. N. E. quarter of the sky, and one of its principal stars, Deneb, is about 14° above the horizon. The principal stars in Draco appear elevated 20° above α Lyræ, and nearly in the same direction

The principal constellations which were formerly invisible are—the south-eastern portion of *Virgo*, *Libra*, *Taurus*, *Poniatowski*, *Serpentarius*, and *Hercules*. These constellations appear near the eastern and south-eastern portions of the sky. The bright star of the first magnitude, *Spica Virginis*, which was below the horizon in March, is now elevated 24°, and may be seen in a direction S. S. E. It is 35° south-east of Denebola, and about the same distance S. S. W. of Arcturus; three stars of the first magnitude, which form a large equilateral triangle, pointing to the south. A similar triangle, pointing to the north, is formed by Arcturus, Denebola, and Cor Caroli. The principal star in Hercules is *Ras Algethi;* and *Ras Alhague*, 5° from it, in the head of Ophiuchus, may be seen nearly due east, at a small elevation above the horizon, Ras Algethi being the brightest and the highest. Libra is situated to the south of the *Serpent*, and to the east of Virgo. Its two brightest stars are of the second magnitude; the one is named *Zubeneschamali*, 21° east of Spica Virginis, but at a much lower altitude; the other is called *Zubenelgemabi*, about 9½° above the other toward the north-east. At this time they appear in the south-east quarter of the heavens, at no great elevation above the horizon. The constellation *Serpens* lies between Corona Borealis and Libra. Its principal star is of the second magnitude, and named *Unuk;* it may be known by being nearly in the middle between two smaller stars, the lower one being 2½°, and the upper 5½° from it. It is in a direction E. S. E., at about 24° above the horizon.

ASPECT OF THE HEAVENS ON THE 1ST OF JULY, AT 10, P. M.

As the twilight at this season is too strong to admit of particular observations at 9 P. M., I have fixed the hour of *ten* as the most proper time for perceiving the principal stars. Most of the southern constellations which were visible in January, and which are the most brilliant, have now disappeared, and those in the north are in positions in the heavens very different from those on which they appeared in winter. The Northern Crown, the Serpent, and Libra, are now to the west of the meridian; Arcturus is now considerably to the west of the meridian, but at a high elevation; immediately below which, at a considerable distance, is Spica Virginis, very near the S.W. by W. point of the horizon. Cor Caroli appears north by west of Arcturus, at a considerable distance, and at a high altitude; immediately below which, at a considerable distance, and nearly due west, is Denebola. The Great Bear is now considerably west of the meridian, at a high altitude, the two pointers pointing *eastward* to the Pole-star. Castor and Pollux have just descended below the horizon near the north-west; and Capella, which never sets in this latitude, is very near the north point, only a few degrees above the horizon. Cassiopeia is near the north-eastern quarter, at no great elevation, and α Lyræ is at a very high altitude to the east of the meridian; east of which, at a lower altitude, is Deneb, one of the principal stars in the Swan. The four stars forming the *square of Pegasus* are now seen a little to the north of the E. point, in a position nearly opposite to that in which they appeared in January. The star *Antares*, in Scorpio, of the first magnitude, is past the meridian, at an altitude of only about 11°. Ras Algethi and Alhague are nearly on the meridian.

The constellation of *Aquila*, or the Eagle, which was formerly invisible, now makes its appearance in the south-east. *Altair*, its principal star, of between the first and second magnitude, is distinguished by being nearly in the middle between two stars of the third magnitude, each of them 2° distant from it in a line bearing S. E. and N. W. Altair is at this time about 37° above the south-eastern horizon. North-east of Aquila is the *Dolphin*, at the distance of 13° or 14°. It is a beautiful little cluster of stars, consisting of about 15 in number, including five of the third magnitude, but none larger, which are so arranged as to form the figure of a diamond, pointing N. E. and S. W. It is sometimes known by the name of *Job's Coffin*. North and north-west of the Dolphin are *Sagitta*, and *Vulpecula et Anser*, or the Fox and Goose; south of Aquila is *Capricornus*, and south-east of it, *Aquarius;* but these last are more distinctly seen in the month of September. The Milky Way runs along with considerable brightness in the neighborhood of Aquila, Vulpecula, Delphinus, and Cygnus.

APPEARANCES OF THE SIDEREAL HEAVENS ON THE 1ST OF SEPTEMBER, AT 9, P. M.

At this time *Altair* is nearly on the meridian at an altitude of 46½°, and *Vega*, or α Lyræ, is about 16° west of the meridian, in a direction north by west from Altair. Ras Algethi and Ras Alhague are west from Altair, nearly midway between that star and the south-western point of the horizon. To the north-west of Vega is the head of Draco, at the distance of nearly 20°. Arcturus is in a position west by north, within 19° of the horizon. The Northern Crown is in a higher elevation than Arcturus, nearly due west, rather nearer the horizon than the zenith. Cor Caroli appears nearly N. W. by W. at 23° of altitude; and the Great Bear, in a north-westerly direction, and at a lower altitude than formerly. To the east of the meridian Capella is seen in a direction nearly N. N. E., at an altitude of 15°. East of Capella, at a little lower elevation, is *Menkalina*, or β Aurigæ, a star of the second magnitude. Cassiopeia appears in the north-east, about midway between the zenith and the north-eastern horizon. The Square of Pegasus is in a direction east by south, and is in a much higher elevation than in July. The Dolphin is a few degrees east of the meridian, and N. E. of Altair, at an altitude of above 50°. Along the southern quarter of the heavens are the following constellations:—Aries, in a direction east by north; Pisces, due east, and next to Aries on the west; Aquarius, to the west of Pisces, in a direction S. S. E.; Capricornus, west from Aquarius, nearly in the south; Sagittarius and Sobieski's Shield, in a south-westerly direction, and Scorpio, which lies still farther to the west. Most of these constellations, except Aries and Pisces, are at a low altitude.

APPEARANCE OF THE HEAVENS ON THE 1ST OF NOVEMBER, AT 9, P. M.

About this time the winter constellations begin again to make their appearance in our hemisphere. The center of the Square of Pegasus is at this season and hour nearly on the meridian; the stars Scheat and Markab, of which Scheat is the uppermost, appear on the west of the meridian, and Alpheratz and Algenib on the east. Turning our eyes to the western part of the heavens, we see the *Southern Fish*, a little to the west of the south, and its principal star, Fomalhaut, several degrees to the west of the meridian, at a very low altitude. To the west is Capricornus, and to the north-west Aquarius. Aquila, with its principal star Altair, is in a direction west by south, at about 23° above the horizon. Deneb Cygni is at a very high elevation, about 30° degrees west from the zenith, and α Lyræ 26° north-west of it, in a direction W. N. W., at a much lower elevation. North by west of Lyra are the two stars in the head of Draco, *Etanim* and *Rastaben*, about 4° apart. Ras Algethi and Ras Alhague are nearly due west, at a very small elevation above the horizon. The center of the Great Bear is nearly due north, and at its lowest elevation, the stars in the tail being to the west, and the two pointers a little to the east of the northern part of the meridian, pointing upward. Turning our view to the eastern quarter of the sky, we behold Aries in a south-easterly direction, next to Pegasus, and at a pretty high elevation. South by east of the first star in Aries is Menkar, in the head of the Whale, in a direction S. E. by E., about 26° above the horizon. North-west of the first star in Aries is Mirach, and north by east Almaack, at a higher elevation, both of them in Andromeda. Near the north quarter is Capella, about midway between the zenith and the horizon. The Pleiades are seen nearly due east, followed by the ruddy star

Aldebaran, at a lower elevation. Below Aldebaran, and to the south-east, the head and shoulders of Orion begin to make their appearance, Bellatrix being 4° or 5° above the horizon, and Betelguese a little lower. Cassiopeia is near the zenith, a little to the east of the meridian, and Castor and Pollux, in Gemini, are in a direction north-east, just a little above the horizon. At this time the *equinoctial colure* is only a few degrees to the east of the meridian, and the three stars *Caph* in Cassiopeia, and *Alpheratz* and *Algenib*, in Pegasus, which lie in the line of its curve, may now be distinctly perceived. Caph is at the highest altitude of the three, and its distance from Alpheratz is about double the distance between Alpheratz and Algenib. If a line connecting these three stars be produced northward, it will terminate in the pole.

The above brief sketches may enable the young observer to trace the principal stars and constellations by a few observations at different seasons of the year. The altitudes here expressed are stated in reference to places about 52° north latitude; but by making certain allowances corresponding to the latitude of the observer, the relative positions of the stars will appear nearly the same as here represented, particularly if the difference of latitude does not much exceed 10 degrees. It should be carefully remarked that the *bearings* of one star from another, as here given, are strictly true only when the star from which the bearings are given is *on or near the meridian*. (See note, p. 70.)

As a further assistance to the astronomical tyro in distinguishing the stars, I have drawn up the following list of stars, chiefly of the first and second magnitudes, stating *the periods of the year* when they come to the meridian, or due south, *at nine o'clock in the evening*.

Caph, in Cassiopeia, and *Alpheratz* and *Algenib*, in Pegasus, come to the meridian on *the 10th of November*, at nine o'clock in the evening. Caph is near the zenith, and the other two at a considerably lower elevation. At this time Capella appears toward the north-east; the Pleiades, Aldebaran, and Orion, in the east; Deneb in Cygnus, in the north-west; Lyra, west-north-west; and Altair, in Aquila, west by south.

Arietis, or the first star of Aries, comes to the meridian on *the 5th of December*. The same stars noticed in the preceding instance are still visible, but those on the east of the meridian have risen to a higher altitude, and those on the west have descended to a lower elevation than on Nov. 10. Castor and Pollux are at this time seen toward the north-east, and Procyon, a very little above the eastern point of the horizon.

Menkar, in the head of the Whale, arrives at the meridian on *the 21st of December*, and at the same time the variable star *Algol*, in Medusa's head, which is 37° due north of Menkar. Altair has now disappeared from the west, and Sirius is seen at a small elevation in the south-east.

The *Pleiades* pass the meridian on *the 1st of January*, and *Aldebaran* on the 10th. When Aldebaran is due south, Capella is north by east of it, near the zenith; Cor Caroli, at a low altitude near the north-east; Lyra, near the horizon, N. by W.; Regulus in the east; and the head of Hydra, east by south.

Bellatrix, in Orion, passes the meridian on *the 21st of January*. Nearly at the same time Capella and β Aurigæ are on the meridian. These three stars are nearly equidistant in a line running north and south.

Castor and *Pollux* and *Procyon*. These three stars pass the meridian nearly at the same time, on the 24th of February. Pollux and Procyon culminate nearly at the same instant, and Castor about 11 minutes before them, at which time Procyon is 23° south of Pollux. Orion is then in a south-westerly direction; Aldebaran, midway between the meridian and the western horizon, Menkar, W. by S., at a small elevation; Sirius, S. by W.; and Capella to the west of the zenith On the east of the meridian, Regulus is S. E.; Denebola, E.; Cor Caroli, E. N. E.; immediately below which, near the horizon, is Arcturus.

Præsepe, in Cancer, a small cluster of stars just perceptible to the naked eye, like a nebula, approaches the meridian about the 3d of March, at an altitude of about 60°. They are N. E. of Procyon, and S. E. of Pollux. (See pp. 63, 64.)

Regulus, in Leo, passes the meridian on the 6th of April. At this time, Alphard, in Hydra, is past the meridian S. by E. from Regulus; Procyon. S. W.; Sirius, S. W. near the horizon; Orion, very low in the west; Algenib, in Perseus, Algol, Capella, &c., toward the N. W. On the east, Denebola appears E. from Regulus; Spica Virginis, S. E., at a low altitude; Cor Caroli, E., at a high altitude; Corona Borealis, E. by N.; and Lyra, at a low altitude, N. E. by N. The Great Bear, at a high altitude, approaching the zenith, and Cassiopeia, at a low altitude toward the north.

Denebola, in Leo, culminates on the 3d of May, at an altitude of 43°. Regulus is 25° west of it, and Phad, in the square of the Great Bear, is 39° N. of it. It forms with these two a large right-angled triangle, the right angle being at Denebola It is nearly on the meridian with Phad. Other stars then visible are — Procyon, W. by S.; Capella, N. W.; Arcturus, E.; Spica Virginis, S. S E.; Lyra, N. E., &c.

Coma Berenices, a beautiful cluster of small stars, but scarcely distinguishable by moonlight, is on the meridian on the 13th of May. (See p. 63.)

Spica Virginis comes to the meridian on the 23d of May. Stars visible on the west—Capella, Castor and Pollux, and Procyon, near the western point. On the east—Lyra, Arcturus, Ras Algethi, Ras Alhague, and Altair, near the eastern horizon. Near the meridian, to the west—Cor Caroli, Alioth and Mizar, in Ursa Major.

Arcturus is on the meridian on the 23d of June. The principal stars in Libra culminate at a lower altitude about the beginning of July.

Corona Borealis is on the meridian about the 1st of July. Its principal star is eleven degrees east of ε Bootes.

Antares, in Scorpio, passes the meridian on the 10th of July, at a very low altitude.

Ras Algethi, in Ophiuchus, and Ras Alhague, in Hercules, 5° apart, culminate about the 28th of July, nearly at the same time as the head of Draco.

Vega, or α Lyræ, culminates on the 13th of August. To the west of it, at a great distance, is Arcturus, and to the north-west, Cor Caroli. Capella is N. by E., at a low altitude; Altair, S. S. E.; and Deneb Cygni, E., at a high altitude.

Altair, in Aquila, is at the meridian about the 30th of August, at an altitude of about 46½°.

Arided or *Deneb Cygni*, is on the meridian on the 16th of September, at an altitude of 82½°. At this time Arcturus is W. S. W., near the horizon; Lyra and Etanim, in Draco, west from the meridian, but in a high elevation; Cor Caroli, N. W., at no great elevation; Hercules, S. W., midway between the meridian and the horizon; Altair, a little distance west of the S.; and the Dolphin on the meridian; the square of Pegasus in a south-eastern direction, Aries in the east, and Capella toward the north-east.

All the stars specified above, at the periods of the year stated, pass the meridian (or culminate) *at nine o'clock in the evening.* Therefore, if at any one of the periods of the year here specified, or a few days before or after it, an observer, at nine o'clock, P. M., observe the principal star or stars near the meridian, he can scarcely be at a loss to recognize them, as well as some of the other principal stars and constellations on the east and west of the meridian, which are also specified in the above descriptions. A person can never become familiar with the more prominent stars, the relative position of the different constellations, and the general aspect of the heavens, *without actual observations.* Even the delineations on the celestial globe will not convey an accurate and impressive conception of the scenery of the heavens, unless the study of these delineations be accompanied with frequent surveys of the heavens themselves. It is hoped the preceding descriptions will afford some assistance to those young observers and others who wish to contemplate the sublime objects of creation with their own eyes.

N. B. In the above and the following descriptions of celestial phenomena, *altitude* signifies the hight of the star or planet above the horizon; S. S. E., south-south-east; N. by E., north-by-east, &c. *Degrees* are marked thus °, *minutes* ′, *seconds* ″: thus, 54° 27′ 35″, expresses fifty-four degrees, twenty seven minutes of a degree, and thirty-five seconds Every degree contains 60 minutes, every minute 60 seconds, &c. When a heavenly body is said to *culminate*, the meaning is, that it has arrived at the highest point of its course, or its passage over the meridian. The term is derived from the Latin word *culmen*, the top or summit. An *occultation* signifies the obscuration of a star or planet by the interposition of the moon, or of another planet. *Conjunction* is when two or more stars or planets are in the same part of the heavens; and *opposition*, when they are 180° asunder, or in opposite parts of the heavens.

PHENOMENA OF THE PLANETS FOR THE YEARS 1840 AND 1841.

I. POSITIONS, ETC. OF THE PLANETS FOR 1840.

I. THE PLANET MERCURY.

This planet can be distinctly seen by the naked eye only about the time of its greatest elongation; and to those who reside in high northern latitudes it will scarcely be visible even at such periods, if it be near the utmost point of its southern declination.

The following are the periods of its greatest elongation for 1840: On the 8th of January it is at its western elongation, when it is 23° 19′ west of the sun, and will be seen in the morning near the south-eastern part of the horizon; but as it is then 21° 45′ in southern declination, and this declination every day on the increase, its position at that time will not be favorable for observation. Its next greatest elongation is on the 20th of March, when it will be 18½ degrees east of the sun, and be seen in the evening soon after sunset. This will form one of the most favorable opportunities of perceiving this planet by the naked eye, or by means of a small opera-glass. Its declination being above nine degrees north, and on the increase, it will be distinctly seen for about ten days—namely, from the 16th to the 26th of March, a little to the north of the western point of the horizon, not far from the point at which the sun sets at that period. On the 5th of May, it will again reach its greatest western elongation, when it will be seen in the morning before sunrise. Its declination is then 4½ degrees north, and western elongation from the sun, 26° 18′. At this period, about four o'clock in the morning, it may be seen for more than three weeks—namely, from about the 20th of April to the 25th of May. Its direction will be nearly due east. This would form the most favorable opportunity of viewing this planet, were it not that the strong twilight at this season has a tendency to overpower its light.

In the month of July, if the long twilight do not prevent, there will be another favorable opportunity of inspecting this planet. During the whole of this month, Mercury will be at a considerable distance from the sun; but the best time for observation will be from the middle until the end of the month, as the twilight will then be less intense. It arrives at the point of its greatest eastern elongation on the 18th, when it is nearly 27° from the sun, and will be seen in the evening a little to the north of the western point of the compass, about forty minutes after sunset, or nearly nine o'clock, P. M. Its next greatest western elongation will be on the 1st of September, when it is 18° 5′ west of the sun. At this period, it may be seen in the morning before five o'clock, in a direction nearly east-by-north, from the 27th of August to the 5th of September. On the 12th of November, it is at its next eastern elongation, when it will be seen after sunset near the south-western point of the horizon; but as its southern declination is at this time about 25 degrees, it will descend below the horizon nearly at the same time with the sun. The next elongation is on the 21st of December, when it is 21° 50′ west of the sun, and will be seen in the morning between seven and eight, near the south-east quarter of the horizon.

The periods most favorable for detecting this planet in the evenings are, March 20th and July 18th; and in the mornings, May 5th and September 1st. During the interval of a week or ten days, both before and after the time of its greatest elongation, and sometimes for three or four weeks in succession, when in high north declination, this planet may generally be seen in a clear sky when in such favorable positions as those now stated. In those regions of the globe which lie south of the equator, the planet will be in the most favorable position for observation when in south declination.

II. THE PLANET VENUS.

This planet, like Mercury, is seen alternately in the evening toward the western quarter of the heavens, and in the morning toward the eastern quarter. In its luster it exceeds all the other stars and planets, and its brilliancy is such that it can scarcely be mistaken by any observer when its position in the heavens is pointed out.

Venus will be seen only in the morning from the beginning of the year until the end of July. During the months of January, February, and March, it will be seen before sun-rise, chiefly in the *south-eastern* quarter of the heavens. Throughout April, May, June, and July, it will be seen in the eastern and *north-eastern* parts of the heavens. During the whole of this period, it will appear, when viewed with a telescope, either as a half-moon or with a gibbous phase. Its *superior* conjunction with the sun happens on the morning of the 25th of July, after which it becomes an *evening* star; but it will not be much noticed by common observers until about the beginning or middle of September, on account of its proximity to the sun. From this period it will continue to be seen in the evening chiefly in the *south-western* part of the sky, at a low elevation, until the end of the year. On the whole, this planet will not be very conspicuous during 1840, either to the eye of a common observer or for telescopic observation. From the beginning of September to the end of December, it will exhibit a gibbous phase, like the moon about three or four days before the full.

Venus will be in conjunction with Saturn on the 22d of January, at 2h. 8′, P. M., when it will be 57′ north of Saturn. It will be in conjunction with Mars on the 16th of June, at sixteen minutes past three in the morning, when Mars will be 46′ north of Venus; and it will be in conjunction with Jupiter on the 22d of October, at 8h. 34′, P. M., when it will be 1° 6′ south of that planet.

III. THE PLANET MARS.

This planet will not be very conspicuous during this year on account of its great distance from the earth, and its proximity to that part of the heavens in which the sun appears. It is in conjunction with the sun on the 4th of May, after which it will be a considerable time before it becomes conspicuous to the unassisted eye.—Throughout the months of August and September, and the latter part of July, it will be seen early in the morning, before sun-rise, near the north-eastern quarter of the heavens. From September until the end of the year, it will appear somewhat more conspicuous, but not exceeding in apparent size a star of the third magnitude. On the 1st of October it comes to the meridian at six minutes past nine in the morning, at an altitude of $52\frac{2}{3}^\circ$ above the southern horizon. On the first of November, it passes the meridian at fourteen minutes past eight in the morning, at an altitude of about 46°; and on the 1st of December, it transits the meridian at nineteen minutes past seven in the morning, at an altitude of $39\frac{2}{3}^\circ$. At this time (1st of December), it rises nearly due east about one in the morning, and will be pretty distinguishable on account of its ruddy aspect about an hour before sunrise.

IV. THE PLANETS VESTA, JUNO, CERES, AND PALLAS.

These planets are not perceptible by the naked eye. The best time for observing them with telescopes is when they are at or near the period of opposition to the sun, when they are nearest the earth. Even then it will be sometimes difficult to detect them without the assistance of transit or equatorial instruments.

Vesta will be in opposition on the 18th of May, when it will pass the meridian at midnight, at an elevation above the horizon of $27^\circ\ 34\frac{1}{2}'$. Its right ascension is then 15h. $51'\ 55\frac{1}{2}''$, and its declination, $10^\circ\ 25\frac{1}{2}'$ south. This planet will be in conjunction with the star ξ Libræ on the first of March, at twenty-seven minutes past five in the morning, the star being 55′ north of Vesta; it will likewise be in conjunction with the same star on the 15th of May, at noon, when the star will be 29′ south of the planet. On the 19th of July, at six in the morning, it will be in conjunction with γ1 Libræ, when the star will be only one minute south of the planet, so that they will both appear in the same field of the telescope. On the 26th of August, at nineteen minutes past eight, A. M., it will be in conjunction with ν Scorpio, when the star will be only 11′ south of Vesta. On September 3d, at eight in the evening, it will be in conjunction with ψ Ophiuchi, the star 11′ north of the planet. On the 2d of October, at half-past one in the morning, it is in conjunction with Saturn, being 1° 2′ south of that planet; and on the 6th of December, at ten minutes past one in the morning, it is in conjunction with Venus, Vesta being only 11′ north of Venus.

Pallas will be in opposition to the sun on the 5th of July, at thirty minutes past nine in the evening. Right ascension, 18° 44′ 52″; north declination, 22° 11′ 37″. It will pass the meridian about midnight, at an altitude of about $60^\circ\ 11\frac{1}{2}'$

Ceres will be in opposition July 17th, at six in the morning. Right ascension, 19° 51′; south declination, 30° 8′. It will pass the meridian at an elevation somewhat less than 8°.

Juno will not be in opposition to the sun during 1840.

That the best time for observing these bodies is at the period of their opposition will appear from the following consideration:—that they are between two and three times nearer the earth at the time of opposition than when near the period of their conjunction with the sun; for example, Vesta is 225 millions of miles distant from the sun, and consequently only 130 millions distant from the earth at the time of opposition; but at the conjunction, it is the whole diameter of the earth's orbit=190 millions of miles, farther distant,—that is 320 millions of miles, which is a distance about two and a half times greater than when it is in opposition.

V. THE PLANET JUPITER.

During the months of January, February, March, and April, this planet will be seen chiefly in the morning. About the beginning of February, it will rise in a direction south-east by east, about half-past one in the morning, and will come to the meridian at a quarter past six in the morning, at an elevation of about 22° above the southern horizon. On the 1st of March, it will rise about eight minutes before midnight, and pass the meridian about half-past four in the morning. On the 1st of April, it will rise at forty-three minutes past nine in the evening, and pass the meridian at a quarter past two in the morning. It will be in opposition to the sun, and consequently nearest the earth, on the 4th of May, when it will rise between seven and eight in the evening. From this period until the middle of November, when it is nearly in conjunction with the sun, it will be visible as an *evening* star, when it will be seen at different periods, chiefly in the south-eastern, the southern, and south-western parts of the heavens, at a comparatively low altitude; but it will not be much noticed by the naked eye after the end of September on account of its southern declination, which, for a considerable time, will be gradually increasing. Toward the end of December, it will again be seen in the morning near the south-eastern quarter of the horizon. The best time for telescopic observations on this planet will be from the beginning of April until the beginning of September

Jupiter will be in conjunction with the star

α^2 Libræ on the 15th of May, at forty-three minutes past three in the morning, when the star will appear one degree south of Jupiter; and on the 27th of August, at a quarter past two in the morning, it will be in conjunction with the same star, when it will be 34′ below Jupiter. On the 21st of November, at 4h. 34′, P. M., it is in conjunction with the sun. On March 5th, at three in the morning, all the satellites of Jupiter will be on the *east* of that planet, when viewed with a telescope having an erect eye-piece, and *in the order of their distances from Jupiter.* The same phenomenon will happen on the 8th of June, at thirty minutes past eleven in the evening; on the 1st of August, at half-past eight in the evening; on the 27th of August, at the same hour, but on the *west* of Jupiter; on the 20th of September, at seven, P. M., on the *east* of Jupiter; and on the 16th of October, at six, P. M., on the *west* of Jupiter.

This planet can scarcely be mistaken, even by a common observer, when the quarter of the heavens in which it is visible is known, as it is next to Venus in apparent magnitude and splendor. It will appear most brilliant about the end of April and the beginning of May.

VI. THE PLANET SATURN.

This planet was in conjunction with the sun on the 6th of December, 1839; and therefore it will not be before the month of February this year that it will be in a favorable position for telescopic observation. During the months of February, March, and April, it will be seen only in the morning before sunrise, in the south-eastern quarter of the heavens, at a comparatively low altitude. On the 1st of February, it rises at half-past four in the morning, and comes to the meridian about half-past eight, at an elevation of about 16½°. On the first of March, it rises at forty minutes past two in the morning; on the 1st of April, at forty-two minutes past twelve, midnight; and on the first of May, it rises at forty minutes past ten in the evening. It is in opposition to the sun on the 8th of June; after which it will be seen in the evening. During the greater part of the month of May, it will likewise be seen between ten in the evening and midnight, but at a low altitude. It will continue to be visible until the month of December, but it will be difficult to distinguish it after the month of October, on account of its low altitude and its proximity to the sun. It arrives at the point of its conjunction with the sun on the 15th of December. The most favorable times and positions for taking telescopic views of this planet will be during the months of May, June, July, August, and September, especially when it is on or near the meridian. During the latter part of August and the months of October and November, about an hour after sunset, it will be seen toward the south-western quarter of the heavens, at a comparatively small elevation above the horizon.

This planet is not distinguished for its brilliancy to the naked eye; but it exhibits a most striking and beautiful appearance through a good telescope; more so than any other planet of our system. It appears of a dull leaden color when viewed by the naked eye, and is not easily distinguished from a fixed star except by the steadiness of its light, never presenting a *twinkling* appearance as the stars do; and from which circumstance it may be distinguished from neighboring stars. It will be in conjunction with the star *Rho* Ophiuchi on the 5th of June, at 51 minutes past 8, P. M., when the star will be about half a degree north of the planet. It will likewise be in conjunction with the same star on the 27th of October, at 9h. 36′, P. M., when the star will be fifty-four minutes of a degree north of the planet. During this year the rings of Saturn will appear to the greatest advantage, the openings of these rings being then at their utmost extent. In the beginning of October, the proportion of the longer axis to the transverse axis of the rings is nearly as 35 to 16.

VII. THE PLANET URANUS.

This planet is for the most part invisible to the naked eye. The best time for detecting it by means of a telescope is when it is at or near the period of its opposition to the sun, which happens this year on the morning of the 11th of September. At that time it passes the meridian about midnight, at an elevation of about 32⅔° above the horizon. On the 1st of August, it passes the meridian at forty minutes past two in the morning; on the 1st of October, at thirty-two minutes past ten in the evening; on the 1st of November, at twenty-seven minutes past eight; and on the 1st of December, at twenty-eight minutes past six, in the evening. Its right ascension, or distance from the first point of Aries at its opposition, September 11, is 23h. 18′; and its south declination 5° 20′ 26″. It rises during the year at points a little to the southward of the eastern point of the compass. It is in conjunction with the moon on the 9th of January, at 2h. 17′, P. M., when it is 1° 27′ south of the moon. It is in conjunction with Mars on the 16th of February, at 11h. 33′, P. M., when Uranus is only nine minutes of a degree to the north of Mars; so that the two planets would be seen at the same time in the field of the telescope, were not both these bodies rather too near the sun at that time for distinct observation. It is in conjunction with the sun on the 6th of March, and with the moon on the 31st, when it is 2° 1′ south of the moon. It is in conjunction with Venus on the 6th of April, at seven in the morning, when it is 49′ north of Venus. On the 25th of May, at forty-five minutes past nine in the evening, it is in conjunction with the moon, when it is 2° 39′ south of that luminary. On the 15th of August, at 3h. 15′, P. M., it is again in conjunction with the moon, when it is 3° 9′ south of that luminary. On the 11th of September, at 8h. 42′, P. M.; and on the 9th of October, at four in the morning, it is in conjunction with the moon, and in both cases it is then about 3° south of the moon.

N. B. In the preceding statements, the observer is supposed to be in 52° north latitude. In places a few degrees to the north or south of this latitude, a certain allowance must be made for the times of rising and the altitudes which are here specified. To those who reside in lower latitudes than 52° the altitudes of the different bodies will be *higher*, and to those in higher latitudes the altitudes will be *lower* than those which are here specified. For example; when it is stated that Saturn comes to the meridian at an altitude of 16½°, this planet will pass the meridian of a place in 42° N. latitude, at an altitude of 26½°, and the meridian of a place in 62° N. latitude, at an altitude of only 6½°. There being 10° of difference in the latitude of the supposed places, the altitude of the heavenly body will be 10° higher in the one case, and 10° lower in the other.

II POSITIONS OF THE PLANETS FOR 1841.

I. MERCURY.

This planet is at its superior conjunction with the sun on the 5th of February, and at its greatest elongation on the 4th of March, when it is 18° 8′ east of that luminary; it will therefore appear as an evening star, in a direction nearly due west, a little above the horizon, after sunset, between six and seven in the evening. It arrives at its inferior conjunction with the sun on the 20th March. Its next greatest western elongation happens on the 17th of April, when it is 27° 21′ west of that luminary. The planet will be seen about ten or twelve days before and after this time in an easterly direction, between three and four in the morning. Its next superior conjunction is on the 26th of May; and its next greatest eastern elongation, on the 30th June, when it is 25° 49′ east of the sun, and consequently will be visible in the evening, in a north-westerly direction, after sunset. This would form one of the most favorable opportunities of seeing this planet, as it is then in a high north declination, were it not that the strong twilight at this season prevents small objects in the heavens from being easily distinguished. Its next greatest elongation is on August 15th, when it is 18° 37′ west of the sun, when it will be seen in a north-easterly direction, about four in the morning. It is again at its greatest eastern elongation on the 25th of October, when it is nearly 24° east of the sun. It will be near the south-western part of the sky about sunset; but its great southern declination, at that period, will prevent it from being easily distinguishable. On the 3d of December, it will reach the point of its greatest western elongation, when it is 20½° west of the sun, when it may be seen for a week before and after this time, about seven in the morning, in a direction a little to the north of the south-east point of the compass, at low altitude.

II. VENUS.

Venus will this year exhibit a more frequent and brilliant appearance to common observers than in 1840. It will be an evening star, first in the south-western, next in the western, and afterward in the north-western quarter of the heavens, during the months of January, February, March, April, and the beginning of May. During the greater part of January, it will appear nearly in a south-westerly direction, and W. S. W. Throughout February, it will appear nearly west, and west-by-north. Throughout March, April, and the beginning of May, it will be seen in a north-westerly direction, will be visible in a pretty high elevation above the western horizon, and will continue for the most part nearly three hours above the horizon after sunset. Its greatest brilliancy is about the 8th of April, when it appears in a crescent form. When viewed by the telescope in January, it will present a *gibbous* phase, like the moon four or five days before or after the full. In February and March it will be in the form of a half moon; in April and the beginning of May, it will assume the figure of a crescent; this crescent will appear more and more slender, but more expansive, until within a few days of its inferior conjunction with the sun, which takes place on the 15th of May, about one in the morning. After this period, this planet will be seen by the naked eye only in the morning before sunrise, in an easterly and north-easterly direction, until the end of the year; but with an equatorial telescope it may be distinctly seen every clear day, even at noon, during its whole course from one conjunction to another, with the exception of only two or three weeks in the course of nineteen months. Its greatest brilliancy after passing its inferior conjunction, is about the 29th of June; previous to which it will appear as a crescent, and will afterward gradually assume a half moon and a gibbous phase.

Venus, in its course throughout this year, will pass very near some of the other planets and some of the fixed stars. The following table exhibits the times and circumstances of those conjunctions in which Venus makes the nearest approach to some of these bodies.

In the following table, the first column states the time of conjunction of the star or planet with Venus; the second column contains the same star or planet; and the third, the distance and position of the star or planet from Venus. N. denotes that the star is north of Venus; and S., that it is south A. M. denotes before twelve at noon; and P. M., afternoon. In those conjunctions marked Nos. 1, 2, 3, 4, 8, 9, 12, 15, 17, 18, 20, 22, the star and

the planet will be seen in the same field of view of the telescope; and although the observation should require to be made in the day-time, the star may probably be distinguished if the telescope have a great magnifying power. The conjunction of Venus with *Uranus* on the 25th of January, at twenty-five minutes past one in the morning, will afford an opportunity to amateur observers of observing this latter planet, which is invisible to the naked eye. Although both these bodies will be set to the inhabitants of Britain before the conjunction takes place, yet they will be both seen in the same field of the telescope between six and eight o'clock on the preceding evening, and they will not be far distant on the evening immediately succeeding the conjunction. At New York, Philadelphia, Boston, and other parts of the United States, these planets will be seen about an hour or an hour and a half before the time of conjunction, Uranus appearing very near Venus, and uppermost, when viewed with a telescope having an erect eye-piece.

N. B. All the above and the preceding and following statements are calculated for the meridian of Greenwich, and are expressed, not in *astronomical*, but in *civil* time.

III. MARS.

During this year this planet will make a conspicuous appearance, and be seen in its brightest luster; but its declination being *south* throughout the year, it will not rise to so high an altitude, nor remain so long above the horizon, as in some former years. During the months of January, February, and March, it will be seen only or chiefly in the morning, in a south-easterly direction. In the beginning of January, it will appear nearly in a direction east by south, soon after the time of its rising. On February the first, it comes to the meridian about five in the morning, at an altitude of about 29°; and on March the first, at thirty-seven minutes past three in the morning, at an altitude of 27°. About the middle of March, it will rise about half-past nine in the evening, and may be seen about an hour or two afterward near the south-west quarter of the heavens. From this period, it will be seen in the evening, until the end of the year; but as its distance from the earth will rapidly increase after the months of August and September, and as it is then in a high degree of south declination, it will not be much noticed by common observers during October, November, and December. On the 18th of April, about two in the morning, it arrives at the point of its *opposition* to the sun, when it is nearest the earth, when it appears with a full enlightened hemisphere, and when it affords the best opportunities for telescopic observation. It will be most conspicuous this year in the evening, during March, April, May, June, July, and August, and will be distinguished from surrounding stars by its *ruddy* appearance. During the months of July, August, and September, it will be seen chiefly near the south-western portion of the sky. On the 11th of March it is *stationary;* that is, appears without any apparent motion; after which, its motion is *retrograde,* or contrary to the order of the signs of the Zodiac, and so continues until the 29th of May, when it is again stationary; after which its motion is *direct* or according to the order of the signs.

The planet Mars will be in conjunction with θ Virginis on the 1st of January, at thirty-two minutes past four, P. M., when the star will be 17″ south of the planet. It will be in conjunction with χ Virginis on the 4th of April, at eight o'clock in the morning, when the star will be 49′ north of Mars. It will be in conjunction with α 2 Libræ on the 10th of August, at nineteen minutes past two, P. M., the star 1° 58′ north. On the 16th of September, at fifty-three minutes past three in the morning, the star *g* Ophiuchi will be in conjunction, at the distance of only 1′ to the south; so that the two bodies will seem almost to touch each other. On the 27th of September, about six o'clock in the evening, this planet will be in conjunction with Jupiter, when Mars will appear 2° 4′ to the south of Jupiter. On the 4th of October, at thirty-five minutes past ten, P. M., it will be in conjunction with θ Ophiuchi, when the star will appear only 6′ south of the planet. On December 18th, it will be in conjunction with ι Capricorni, at 8h. 47′, P. M., when the star will be only eight minutes of a degree south of Mars.

IV. VESTA, JUNO, CERES, AND PALLAS.

These planets will all be in opposition to the sun this year. *Vesta* will be in opposition on the 22d of October, at twenty-one minutes past three in the morning. It will transit the meridian about midnight, at an altitude of 38° 20′. Right ascension, 2h. 2′ 27″; north declination, 20′ 23″. On the 20th of April, at 1h. 25″, P. M., it is in conjunction with the star ρ Piscium, the star 1° 34′ north of the planet. On the 22d of April, at 10h. 56′, A. M., it is in conjunction with *r* Piscium, the star 1° 11′ south of Vesta. On the 24th of August, at 1h. 44′, A. M., the star ν Ceti will be in conjunction, the star 14′ north of Vesta; both these bodies will therefore be seen in the same field of a telescope.

Juno will be in opposition on the 19th of March, at 2h. 45′, P. M., and will come to the meridian about midnight, at an altitude of 41° 3′. Right ascension, 11h. 59′ 55″; north declination, 3° 3′ 15″. Juno will be in conjunction with η Virginis on the 4th of March, at 3h. 24′, P. M., the star 28′ south of Juno. On the 25th of April, at noon, it will be in conjunction with ν Virginis, when the star will be only 7′ north of the planet. This conjunction will afford a favorable opportunity for detecting Juno. On the 24th of May, at 7h. 12′, A. M., it will again be in conjunction with ν Virginis, when the star will be 36′ south of the planet. On the 22d of June, at 8h. 36′, A. M., it will be in conjunction with π Virginis, the star 45′ north of the planet.

Pallas is in opposition to the sun on the 4th of September, at 5h. 34′, P. M., when it will come to the meridian at an altitude of 40° 41⅓′. Right ascension, 22h. 37′; north declination, 2° 41′ 20″. Pallas will be in conjunction with the star κ Aquarii on the 20th of September, about one in the morning, when the star will be 22′ south of Pallas.

Ceres is in opposition on October 13th, at twenty-two minutes past eleven, A. M., and comes to the meridian at that time at an elevation above the southern horizon of 32° 45½′. Right ascension, 1h. 35′ 20″; north declination, 5° 14 30

V. JUPITER.

This planet passed its conjunction with the sun on the 21st of November, 1840, and will appear as a *morning* star during the months of January, February, March, and April. On the 1st of January, it will rise near the south, at thirty-four minutes past five in the morning, and will pass the meridian at forty minutes past nine, at an altitude of nearly 17°. On the 1st of February, it will rise in the same quarter, at fifty-six minutes past three, and come to the meridian about eight. On the 1st of March, it will rise at twenty-two minutes past two in the morning, and pass the meridian at twenty-eight minutes past six. On the 1st of April, it rises at twenty-eight minutes past twelve, midnight; and on the 1st of May, at thirty-two minutes past ten in the evening; after which it will continue to be seen in the evening until about the middle of November. It will be in conjunction with the sun on the morning of the 23d of December, after which, it will be a morning star. The declination of Jupiter on January 1st is 21° 3½′ *south*, and on the 1st of December, 23° 13½′ south. On account, therefore, of its great southern declination, its altitude will be low, and its duration above the horizon comparatively short. Its altitude, when passing the meridian about the beginning of December, is only 14° 46′. Its opposition to the sun happens on the 5th of June, at 10h. 16′, P. M. It will appear chiefly in a southerly and south-westerly direction in the evenings of July, August and September. The best time for telescopic observations on this planet, in the evening, will be from April until the end of August.

On the 20th of April, at a quarter-past three in the morning all the satellites of Jupiter will appear on the west side of the planet, when viewed with a telescope having an erect eye-piece, and *in the order of their distances from Jupiter*. The same phenomenon will happen on the 8th of June, at thirty minutes past eleven in the evening. On the 5th and 18th of July (on the *east* of Jupiter), at forty-five minutes past nine in the evening; on the 27th of September, at 7h. 30′, P. M.; and on the 17th of November, at 5h., P. M.

VI. SATURN.

This planet will be seen only in the morning from the beginning of January until the beginning of May. On the 1st of February, it will rise at 5h. 8′, A. M., in a direction nearly south-east, and will come to the meridian at 9h. 8′, A. M., at an altitude of 15° 35′; on the 1st of March, it rises at twenty-eight minutes past three in the morning; on the 1st of April, at thirty-one minutes past one; and on the 1st of May, at thirty-two minutes past eleven in the evening. From January until May the planet will be seen chiefly in a *south-easterly* direction in the morning, at a small elevation above the horizon. From July until October it will be seen in the evening, chiefly in a southerly and south-by-west direction. It is in opposition to the sun on the 21st of June, when it rises about eight in the evening, and passes the meridian about midnight. It will be in conjunction with the sun on the 27th of December. Its right ascension on the 1st of January is 17h. 43′, and its south declination, 22° 21′. On the 31st of December, its right ascension is 18h. 26′, and south declination, 22° 40′. On account of its great southern declination and its vicinity to the sun, it will not be much noticed during the latter part of October and the months of November and December.

During this year the ring of Saturn will be in a very favorable position for telescopic observation, the elliptical figure of the ring appearing nearly at its utmost width, so that it will appear very nearly to encompass the planet. The best periods for telescopic observations in the evening will be from the month of May, until the end of September.

VII. URANUS.

Uranus will be in opposition to the sun on the 15th of September, at 10h. 17′, A. M., when it will pass the meridian about midnight, at an altitude of 34° 15′. Right ascension at this period, 23h. 33½′; south declination, 3° 45′. It is in conjunction with Venus on the 25th of January, at twenty-five minutes past one in the morning, and is distant from Venus only four minutes of a degree. It is in conjunction with Vesta on the 9th of April, at nine in the evening, being 3° 54′ to the north of Vesta. On the 1st of September, it passes the meridian at fifty-one minutes past twelve, midnight; on the 1st of October, at forty-nine minutes past ten in the evening; on the 1st of November, at forty-three minutes past eight; on the 1st of December, at forty-four minutes past six; and on the 1st of January, 1842, at forty-four minutes past four in the afternoon. The most eligible periods for detecting this planet by means of the telescope are the months of August, September, October, and November.

N. B. The preceding descriptions of planetary phenomena are chiefly intended to inform common observers as to the seasons of the year when the different planets may be seen, and the quarters of the heavens to which they are to direct their attention in order to distinguish them. It may be proper to observe, that the planets in general cannot be distinguished by the naked eye for about a month before and after their conjunctions with the sun, except *Venus*, which may frequently be seen within a week before and after its *inferior* conjunction; but this planet will sometimes be invisible to the naked eye for a month or two before and after its *superior* conjunction with the sun.

For a particular description of the motions, distances, magnitudes, and other phenomena in relation to the primary planets and their satellites, the reader is respectfully referred to the volume entitled "CELESTIAL SCENERY; or the Wonders of the Planetary System Displayed," where all the most interesting facts connected with the solar system, and the scenery it displays, are particularly detailed.

ECLIPSES AND OCCULTATIONS.

ECLIPSES IN 1840.

There will be four eclipses this year, two of the sun and two of the moon; but none of them will be visible within the limits of the British isles, nor in the United States of America, except a partial eclipse of the moon, August 13th, at 7h. 23′, A. M., Greenwich time. This eclipse will be visible at Philadelphia, New York, Boston, and most parts of North America, but not in Britain. On March 4th, there will be an *annular* eclipse of the sun, the middle of which will happen at 7h. 23′, A. M.; and on August 27th there will be a total eclipse of the sun; middle of the eclipse about 7h., A. M. These two interesting eclipses will be visible chiefly in the eastern parts of the globe, in the eastern parts of Africa, the East Indies, the Indian Ocean, Australia, &c. At the Cape of Good Hope, there will be a *partial* eclipse of the sun on August 27th; but both eclipses will be invisible both in Britain and America.

ECLIPSES in 1841.

This year there will be six eclipses, four of the *sun* and two of the *moon*, at the following times:

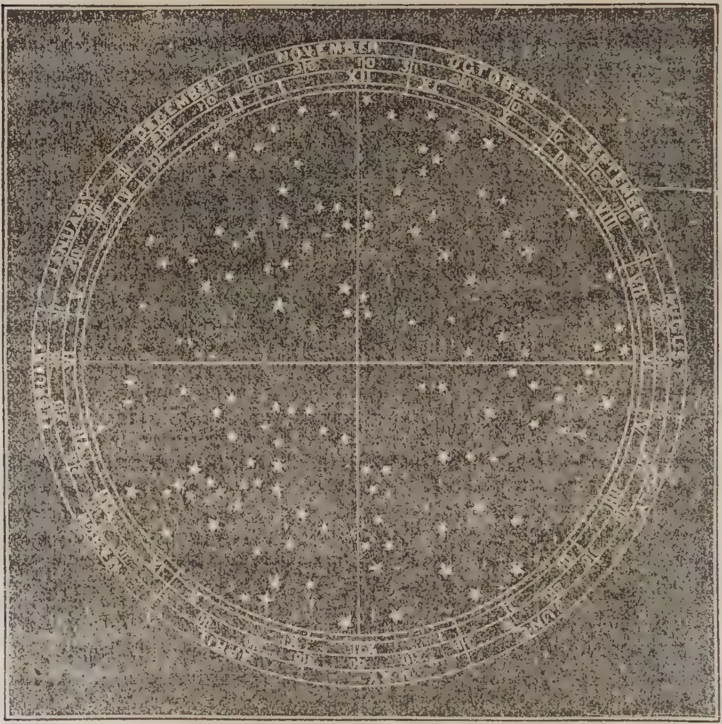
Of the *sun*, January 22d, at 5h. 23′, a partial eclipse, visible only in a small portion of the southern ocean; of the *moon*, February 6th, at 2h. 6′, A. M., visible in Great Britain; of the *sun*, a partial eclipse, February 21st, at 11h. 4′, A. M., visible chiefly in the North Atlantic Ocean, Iceland, and East Greenland; of the *sun*, a partial eclipse, July 18, at 2h. 24′, P. M., visible in Baffin's Bay, Iceland, Norway, Sweden, Russia in Europe, Prussia, Germany, Scotland, &c., but invisible at Greenwich; of the *moon*, a *total* eclipse, August 2d, at 10h. 1′, A. M.; of the *sun*, a partial eclipse, August 16th, at 9h. 19′, P. M., visible chiefly in the South Pacific Ocean. The times here specified denote the *middle* of the eclipse.

All the above eclipses are invisible at Greenwich, and in most parts of Britain, except the total eclipse of the moon on February 5th and 6th, of which the following is a more particular detail in mean time at Greenwich:

	h. m.	
First contact with penumbra of the earth's shadow, Feb. 5	11 24	P. M
First contact with dark shadow, Feb. 6	0 20	A. M
First total immersion in dark shadow, Feb. 6	1 17	A. M
Middle of the eclipse, Feb. 6	2 6½	A. M
Last total immersion in dark shadow, Feb. 6	2 55⅓	A. M
Last contact with dark shadow, Feb. 6	3 52⅔	A. M
Last contact with penumbra, Feb. 6,	4 49	A. M
Digits eclipsed,	20½	

PLATE IV.

THE SOUTH CIRCUMPOLAR STARS.



A large *solar* eclipse will be visible on July 8, 1842; and no eclipse of the sun will be visible in Britain until that time. That eclipse will be *total* in the southern parts of France, and large even in and near London. At Greenwich, it will begin at 4h. 52½′, A. M., and end at 6h. 43′. Digits eclipsed 9° 42½′. Of course this eclipse will not be visible in the United States, nor throughout any part of America, as the sun will not at that time be risen to those places.

OCCULTATIONS OF VENUS BY THE MOON IN 1841.

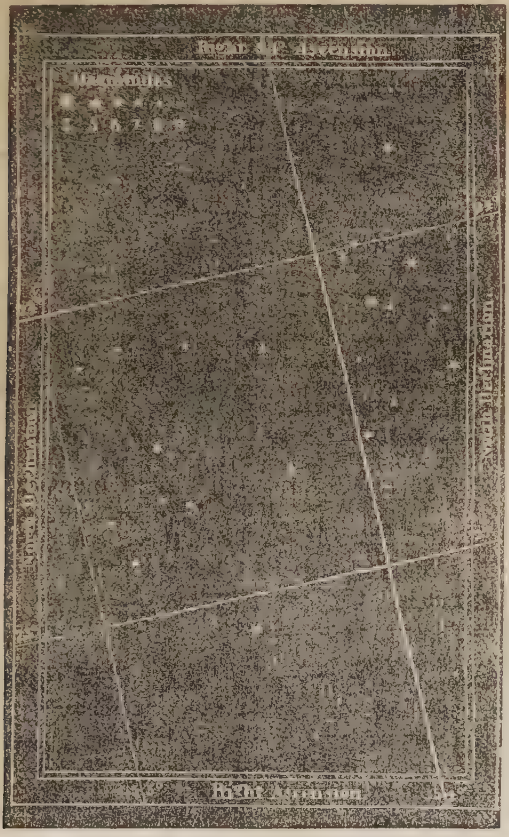
On the 26th of March, 1841, the planet Venus will suffer an occultation by the moon. It will begin to be immersed behind the moon at forty minutes past two o'clock in the afternoon, of Greenwich mean time, and will emerge from behind the opposite limb of the moon at twenty-three minutes past 3, P. M. Another occultation of Venus will happen on the 12th of September, 1841; immersion, thirty minutes past six in the morning; emersion, forty-two minutes past 7, A. M. In the occultation of March 26, Venus will be nearly in the form of a half moon, and the moon in the form of a crescent. Venus will be immerged at the dark (or eastern) limb of the moon, and will emerge from the enlightened crescent. They will be then nearly on the meridian, at an altitude of about 60°, and nearly three hours of right ascension east of the sun. A short time after sunset, Venus will be seen a little west from the lunar crescent, but very near it, shining with considerable splendor. Although this occultation will happen while the sun is above the horizon, yet both the moon and Venus will be easily perceived with a common telescope of very moderate magnifying power. In the occultation which takes place on the morning of September 12, Venus will, as in the former case, be nearly in the shape of a half moon, and the moon a slender crescent, being only 2½ days from the period of conjunction or new moon. In this case Venus will be immerged at the enlightened limb of the moon, and emerge from the dark limb. Both bodies will be then in an easterly or north-easterly direction, and the immersion will take place a little after sunrise; about half an hour before which, Venus will be seen a very little to the east of the moon.

EXPLANATIONS OF SOME OF THE ENGRAVINGS OF THE STARS.

Plates I and II, which represent portions of the heavens as seen about the middle of January and the 1st of September, have been explained pp. 13–16; and Plate III, which represents the north circumpolar stars has been explained pp. 16–19.

Plate IV represents some of the larger stars and principal constellations around the *South Pole*, to the distance of 45° from that pole. It also shows a portion of the Milky Way which traverses that region of the heavens, and which is said to appear there with peculiar brilliancy. One of the principal constellations which is frequently noticed, and which appears peculiarly striking to sea-faring people and others, is called *Crux*, or the *Cross*, from the resemblance it bears to that figure It consists of five stars, one of the first magnitude, two of the second, one of the third, and one of the fourth magnitude. Four of these are in the position of the cross; the northernmost and southernmost of which are always in a line with the south pole, and therefore serve for a direction in south latitude to discover that pole, as the Two Pointers in the Great Bear serve to direct the eye to the *North* Polar-star. There is no large or prominent star at or near the South Pole. This constellation is represented near the line, or meridian, which points at XII, opposite to the month of *May.* All its stars, except the lowermost, appear within the limits of the Milky Way. The stars immediately below the Cross belong to the *Centaur;* those on the left, opposite *April*, belong to *Robur Caroli*, or King Charles's Oak, which contains a star of the first magnitude. Farther to the left, opposite *March*, is *Argo Navis* or the *Ship.* Still farther to the left, opposite *February*, is *Pisces Volans*, the Flying Fish, which contains a star of the first magnitude, named *Canopus*. This star is marked near the left side of the map, opposite the middle of February. To the *right* from the Cross are the two fore legs of the Centaur distinguished by two stars of the first magnitude, named *Agena* and *Bungula*, Agena being the one next to the Cross. They are in the Milky Way,

Fig. 85.



and appear opposite the month of *June*. Next to the Cross and the Centaur, on the right, are *Circinus*, or the Compasses; the Southern *Triangle*, which contains three stars of the second magnitude in the form of a triangle; and *Ara*, or the Altar, which lies adjacent to the right-hand side of the map, opposite the space between *July* and *August*.

Directing our attention to the upper part of the map, on the left, there is the constellation *Equuleus Pictoria*, or the Painter's Easel, which consists of a number of small stars. Next to this, and a little above it, is *Dorado*, or the Sword-Fish, which contains two or three stars of the second and third magnitudes. To the right of Dorado is *Hydrus*, or the Water Snake; above which is *Achernar*, a star of the first magnitude in *Eridanus*, which appears opposite the 1st of *December*. Next to Achernar on the right is *Toucana*, or the American Goose; above which, opposite *November*, is the *Phœnix;* to the right of which is the *Crane*, which contains two stars of the second magnitude; below which is *Pavo*, or the Peacock, which contains several stars of the second and third magnitudes; below Pavo, opposite to August, is *Telescopium*, or the Telescope, which contains no remarkable stars. Within eleven degrees of the South Pole, represented by the central point of the map, are two of those whitish or nebulous spaces called the *Magellanic Clouds*, which are found by the telescope to consist of small stars and nebulous appearances. The other Magellanic cloud, which is the largest, is at a considerable distance from the South Pole. In specifying the names of some of the above stated constellations, the *incongruity* of the animals and figures by which these groups of stars are represented will at once be apparent to the reader.

Fig. 86.

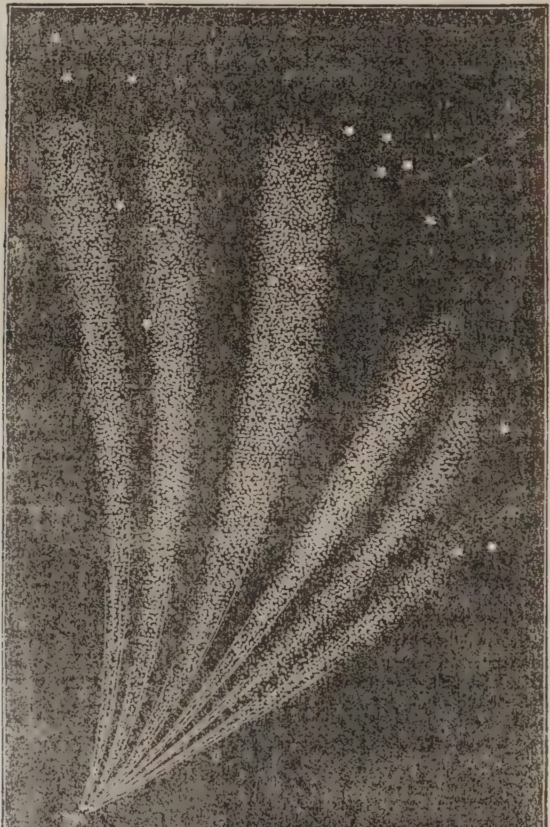


PLATE V. contains a condensed representation of some of the principal constellations in the northern and southern hemispheres on *Mercator's Projection*, chiefly for the purpose of exhibiting THE COURSE OF THE MILKY WAY, and the relative positions of the constellations. Some of the larger stars may be here traced as α Lyræ, Capella, &c., but they are more easily distinguished in the other maps. (See the description given of the Milky Way p. 57.)

Fig. 80 (p. 124) represents the comet of 1661, as seen by Hevelius; the atmosphere, or nebulosity, surrounding the nucleus, when viewed at different times, varied in its extent, as likewise the tail in its length and breadth.

Fig. 81 (p. 124) represents a class of comets which have their tails somewhat bent, which some suppose to be owing to the resistance of the ethereal fluid through which they move.

Fig. 85 represents a telescopic view of the *Pleia-*

des, a group of stars in the constellation Taurus. About forty stars are here represented, but with powerful telescopes many more may be discovered. *Rheita* affirms that he counted 200 stars within this cluster, and yet telescopes, at the period when he lived, had not arrived at the point of perfection they have now attained. The principal star in the Pleiades is *Alcione*, of the third magnitude, which is here represented near the center of the cluster. The names of the others visible to the naked eye are Merope, Maia, Electra, Tayeta, Sterope, and Celine. Merope is the one which some suppose to have been lost. In fabulous history, these stars were the seven daughters of Atlas and the nymph Pleione, who were turned into stars with their sisters the Hyades, on account of their mutual affection and amiable virtues.

The other five stars, beside Alcione, are of the fifth magnitude, as represented in the plate; and the rest are telescopic stars of the sixth, seventh, eighth, and ninth magnitudes. The lines from right to left are portions of circles of declination which run parallel with the equinoctial, as the parallels of latitude on the terrestrial globe do with respect to the equator; and on these the *declination*, or distance of the body from the equinoctial, is marked. The other lines, from top to bottom, are portions of circles of right ascension corresponding with meridians on the terrestrial globe. On these are marked the right ascensions of the heavenly bodies or their distance, reckoned on the equinoctial from the first point of Aries. One of these lines, at the top and bottom, is marked 54°, showing that the stars in that line are 54° east from the first point of Aries; and the number 23, marked at the right and left hand sides, shows that the star or stars in that line are 23° north of the equinoctial.

Fig. 86 represents the tail of the splendid comet of 1744, which was divided into six branches, as described p. 127. See also the description given of this comet, pp. 122, 123.

THE

PRACTICAL ASTRONOMER,

COMPRISING

ILLUSTRATIONS OF LIGHT AND COLORS—PRACTICAL DESCRIPTIONS OF ALL
KINDS OF TELESCOPES—THE USE OF THE EQUATORIAL-TRANSIT—
CIRCULAR, AND OTHER ASTRONOMICAL OBSERVATIONS;

A PARTICULAR ACCOUNT OF THE

EARL OF ROSSE'S LARGE TELESCOPES;

AND OTHER TOPICS CONNECTED WITH ASTRONOMY.

PREFACE.

THE following work was announced several years ago in the preface to the volume on "The Sidereal Heavens," since which time numerous inquiries have been made after it by correspondents in England, the West Indies, and America. It was nearly ready for publication three years ago, but circumstances over which the author had no control prevented its appearance at that period. This delay, however, has enabled him to introduce descriptions of certain instruments and inventions which were partly unknown at the time to which he refers.

The term "Practical Astronomer" has been fixed upon as the shortest that could be selected, although the volume does not comprise a variety of topics and discussions generally comprehended in this department of astronomy. The work is intended for the information of general readers, especially for those who have acquired a relish for astronomical pursuits, and who wish to become acquainted with the instruments by which celestial observations are made, and to apply their mechanical skill to the construction of some of those which they may wish to possess. With this view, the author has entered into a variety of minute details, in reference to the construction and practical application of all kinds of telescopes, &c., which are not to be found in general treatises on Optics and Astronomy.

As *Light* is the foundation of astronomical science, and of all the instruments used for celestial observation, a brief description is given of the general properties of light—of the laws by which it is refracted and reflected when passing through different mediums, and of the effects it produces in the system of nature—in order to prepare the way for a clear understanding of the principles on which optical instruments are constructed, and the effects they produce.

As this, as well as every other physical subject, forms a part of the arrangements of the Creator throughout the material system, the author has occasionally taken an opportunity of directing the attention of the reader to the Wisdom and Beneficence of the Great First Cause, and of introducing those moral reflections which naturally flow from the subject.

The present is the ninth volume which the author has presented to the public, and he indulges the hope that it will meet with the same favorable reception which his former publications have uniformly experienced. It was originally intended to conclude the volume with a few remarks on the *utility* of astronomical studies, and their *moral* and *religious* tendency, but this has been prevented, for the present, in consequence of the work having swelled to a greater size than was anticipated. Should he again appear before the public as an author, the subject of discussion and illustration will have a more direct bearing than the present on the great objects of religion and a future world.

BROUGHTY FERRY, NEAR DUNDEE.

CONTENTS.

PART I.

ON LIGHT.

INTRODUCTION.

Page

Necessity of light to the knowledge and happiness of all Sentient Beings. Its beautiful and enlivening effects. An emblem of the Deity. Provision made for its universal diffusion ... 11

CHAPTER I.

GENERAL PROPERTIES OF LIGHT.

Interesting nature of this study. Different Hypotheses which have been formed respecting the nature of light. It radiates in straight lines—moves with amazing velocity—flows in all directions from luminous bodies. Duration of its impressions on the eye. Supposed to have a certain degree of force or momentum. Experiments in relation to this point. Its intensity diminished in proportion to the square of the distance. Its reflection from opaque bodies renders objects visible. Intensity of reflected light. Subject to the law of attraction. Forms a constituent part of certain bodies. *Solar Phosphori*, and the phenomena they exhibit. Produces certain effects on plants and flowers, exemplified in a variety of instances Supposed to have an influence on the *propagation of sound*.......................... 13

Reflections on the nature of light, and the multifarious effects it produces throughout the universe. A representation of the Divinity. Wisdom and goodness of God displayed in its formation 19

CHAPTER II.

ON THE REFRACTION OF LIGHT.

Nature of refraction—illustrated by experiments. Angle of refraction. Familiar experiments illustrative of refraction. Refraction explains the causes of many curious and interesting phenomena. Its effect on the heavenly bodies—on the twilight. Illustrated by figures...... 21

EXTRAORDINARY CASES OF REFRACTION IN RELATION TO TERRESTRIAL OBJECTS.

Extraordinary appearance of the Coast of France from Hastings. Appearance of a ship seen by Captain Colby, beyond the Coast of Caithness. Scoresby's view of his father's ship when beyond the horizon. Phenomenon near the Himalaya Mountains. Bell Rock Light-House. Summary statement of the diversified effects of refraction. Reflections on the beneficent and diversified effects produced by the law of refraction. It increases the length of the day, particularly in the Polar regions—is the cause of that splendor which appears in the objects around us. Quantity of refraction in respect to terrestrial objects, and its utility. Its effects may be more diversified in other worlds.. 24

CHAPTER III.

ON THE REFRACTION OF LIGHT THROUGH SPHERICAL TRANSPARENT SUBSTANCES, OR LENSES.

Refraction the foundation of optical instruments. Various forms of lenses. *Parallel, converging,* and *diverging* rays—illustrated by diagrams. *Concave* lenses—their effects, and how to find their focal distances. Images formed by convex lenses—illustrated by experiments. Principles in relation to images formed by lenses. Their magnifying powers, &c..................... 26

REFLECTIONS DEDUCED FROM THE PRECEDING SUBJECT.

Property of the rays of light in forming *images* of objects. Wonderful results and discoveries which have flowed from this property in relation to our knowledge of the scenery of the heavens and the minute parts of nature, and of our views of the attributes of Deity....... 29

CHAPTER IV.

ON THE REFLECTION OF LIGHT.

Nature of reflection. Plane, convex, and concave speculums. Angle of reflection. Reflection of objects from plane mirrors, illustrated by figures. *Reflection by convex* and *concave mirrors.* Properties of *convex* mirrors, and the purposes to which they are applied. Properties of concave speculums, and their utility. Of the *images* formed by concave speculums—illustrated by a variety of figures and experiments—their power of magnifying and burning. Amusing deceptions produced by. Resemblance between the properties of convex lenses and concave mirrors. Quantity of light reflected by polished surfaces........................ 31

UNCOMMON APPEARANCES OF NATURE PRODUCED BY THE COMBINED INFLUENCE OF REFLECTION AND REFRACTION.

Fata Morgana. The Mirage. Inverted images of ships seen in the horizon. Appearance of Dover Castle at Ramsgate. Specter of the Brocken. Scenes in the Highlands of Scotland. Large cross seen at Migne in France. Dr. Wollaston's illustrations of such phenomena. Utility of science in dissipating superstitious fears.. 37

REMARKS AND REFLECTIONS IN REFERENCE TO THE PHENOMENA DESCRIBED ABOVE.

Light, the beauty of the universe, and a symbol of the divinity. In other worlds it may produce an infinite variety of sublime Scenery.. 40

CHAPTER V.

SECTION I

ON THE COLORS OF LIGHT.

Colors, the beauty of nature. Opinions which were formerly entertained respecting their cause. Sir I. Newton's experiments with the prism. Colors and phenomena produced by the prism. Imperfection of optic lenses. Various illustrations. Differently colored rays have not the same illuminating power. Heating and chemical properties of some of the rays of the solar spectrum. Property of communicating the magnetic power. Fraunhofer, and his discoveries in reference to the spectrum. Experiments on white and colored light..................... 41

SECTION II.

ON THE COLORS OF NATURAL OBJECTS.

Colors not in the objects themselves, but in the light which falls upon them. Illustrations of this position. Atmosphere the source of a variety of colors. Various natural phenomena, in relation to color, explained.. 44

SECTION III.

PHENOMENA OF THE RAINBOW.

Rainbow described Experiments to illustrate its cause. Descriptions of its various phenomena, and optical explanations of their causes. Rainbows exhibiting *complete circles.* Their appearance in different countries. Summary view of the principal facts respecting the rainbow. *Lunar* rainbows. Scriptural allusions to the rainbow. Whether there was any rainbow before the Deluge.. 46

SECTION IV.

REFLECTIONS ON THE BEAUTY AND UTILITY OF COLORS.

Beauty and variety derived from colors in the scenery of nature. Colors produced by the atmosphere in different countries. What would be the aspect of nature, in heaven and on earth, were there only one color. How it would affect the common intercourse and employments of society. Wisdom and beneficence of the Creator displayed in the diversity of colors. Throughout all the systems of the universe a diversity of colors prevails. This subject has a tendency to inspire us with gratitude................................... 49

PART II.

ON TELESCOPES.

CHAPTER I.

HISTORY OF THE INVENTION OF TELESCOPES.

The telescope a noble instrument. Effects it produces. Whether known to the ancients. Friar Bacon's ideas respecting telescopes. First constructed in Holland. The invention claimed by different persons. Galileo's account of the construction of his telescope. Discoveries which he made with this instrument. How his discoveries were received by the learned. Specimens of learned nonsense brought forward by pretended philosophers. Supposed length of Galileo's telescope. Various claimants to the invention of this instrument........................ 52

CHAPTER II.

ON THE CAMERA OBSCURA.

Appearance of objects in a camera obscura. The dark chamber. This instrument serves to explain the nature of a refracting telescope. Particulars to be attended to in exhibiting objects with the camera. It illustrates the nature of vision. Revolving camera obscura. *Portable* camera.. 56

THE DAGUERREOTYPE.

An important discovery for fixing the images produced by the camera. Description of the Daguerreotype process—preparation of the plate, fixing the impression, &c. Preparation of photogenic paper. Beneficial effects which this art may produce. Representations of objects in the heavens, &c.. 59

CHAPTER III.

ON THE OPTICAL ANGLE, AND THE APPARENT MAGNITUDE OF OBJECTS.

Various illustrations of the apparent magnitude of objects. Fallacies in relation to apparent magnitudes. Apparent magnitudes in the heavens. Difference between *absolute* and apparent magnitudes.. 61

CHAPTER IV.

ON THE DIFFERENT KINDS OF REFRACTING TELESCOPES

SECTION I.

THE GALILEAN TELESCOPE.

Construction and peculiar properties of this instrument.................................. 63

SECTION II.

THE COMMON ASTRONOMICAL REFRACTING TELESCOPE.

Description of its nature and construction. How its magnifying power is determined. Table of the linear aperture, magnifying powers, &c., of astronomical telescopes from 1 to 120 feet in length. Summary view of the properties of this telescope.............................. 64

SECTION III.

THE AERIAL TELESCOPE.

This telescope is used without a tube. Description of the apparatus connected with it, illustrated with figures. Huygen's, Hartsocker's, and Cassini's large telescopes........... 66

SECTION IV.

THE COMMON REFRACTING TELESCOPE FOR TERRESTRIAL OBJECTS.

Arrangement of its lenses. Magnifying power. Manner in which the rays of light are refracted through the telescope now described.. 67

SECTION V

TELESCOPE FORMED BY A SINGLE LENS.

Various experiments in relation to this point. Experiments with a lens 26-feet focal distance, and 11½ inches diameter........ 63

SECTION VI.

THE ACHROMATIC TELESCOPE.

Imperfections of common refracting telescopes. Dollond's discovery. Newton's err Explanation of the principle of achromatic telescopes. Combination of lenses. Difficulti in the construction of such instruments. Difficulty in procuring large discs of flint glass. Guinaud's experiments........ 68

NOTICES OF SOME LARGE ACHROMATIC TELESCOPES ON THE CONTINENT, AND IN GREAT BRITAIN.

The Dorpat telescope—Sir J. South's telescope—Captain Smyth's—Rev. Dr. Pearson's—Mr Lawson's—Mr. Cooper's—Mr. Bridges', &c. Achromatics in Cambridge and Paris Observatories........ 72

ACHROMATIC TELESCOPES OF A MODERATE SIZE, WITH THEIR PRICES, AS SOLD BY LONDON OPTICIANS.

The 2½-feet achromatic—the 3½-feet. The powers applied to it, and the views it gives of the heavenly bodies. The 5-feet achromatic. *Stands* for telescopes, illustrated by engravings... 73

PROPORTIONS OF CURVATURE OF THE LENSES WHICH FORM AN ACHROMATIC OBJECT-GLASS.

Various tables and explanations........ 76

ACHROMATIC TELESCOPES COMPOSED OF FLUID LENSES.

Blair's fluid telescope, with an account of its performance. Barlow's large refracting telescope, with a fluid concave lens—its construction, and the effect it produces on double stars, &c. Rodger's achromatic telescope on a new plan. Wilson's telescope, &c........ 77

CHAPTER V.

ON REFLECTING TELESCOPES.

SECTION I.

HISTORY OF THE INVENTION, AND A GENERAL DESCRIPTION OF THE CONSTRUCTION OF THESE INSTRUMENTS.

Gregory's reflector—Newtonian reflector—Cassegrainian reflector. Magnifying powers of reflectors. Short's reflectors—their powers and prices. *General remarks on Gregorian reflectors.* Apertures and magnifying powers of Newtonian telescopes. *Prices* of reflecting telescopes........ 81

SECTION II.

THE HERSCHELIAN TELESCOPE.

Description of Sir W. Herschel's 40-feet telescope, with its machinery, apparatus, and the discoveries made by it. Sir J. Herschel's 20-feet reflector........ 86

SECTION III.

Ramage's large reflecting telescope........ 88

SECTION IV.

THE AERIAL REFLECTOR—CONSTRUCTED BY THE AUTHOR.

Construction of this telescope, and the manner of using it—illustrated by figures—its proprieties and advantages. Tube not necessary in reflecting telescopes. How a large reflector may be constructed without a tube. How the form of a telescope may be used for viewing perspectives. 88

SECTION V.

EARL OF ROSSE'S REFLECTING TELESCOPES.

His mode of forming a large speculum, &c.—see also Appendix........ 92

SECTION VI.

REFLECTING TELESCOPES WITH GLASS SPECULA.

Various experiments on this subject, with their results.................................. 93

SECTION VII.

A REFLECTING TELESCOPE WITH A SINGLE MIRROR AND NO EYEPIECE.

Experiments illustrative of this construction.................................. 93

ON THE EYEPIECES OF TELESCOPES. ASTRONOMICAL EYEPIECES.

Huygenian eyepieces—Ramsden's eyepiece. Aberration of lenses. Celestial eyepieces without variable powers. *Diagonal* eyepieces. Various forms of them described. Various aspects in which objects may be viewed by them.................................. 95

SECTION VIII.

TERRESTRIAL EYEPIECES.

Eyepieces with four lenses. Proportions of the focal lengths of these lenses. Dimensions and powers of several eyepieces stated.................................. 98

DESCRIPTION OF AN EYEPIECE, ETC., OF AN OLD DUTCH ACHROMATIC TELESCOPE.

This telescope supposed to have been *invented* in Holland before Dollond's discovery was known. Peculiarity of its eyepiece.................................. 99

SECTION IX.

Description of the Pancratic Eyetube.................................. 100

CHAPTER VI.

MISCELLANEOUS REMARKS IN RELATION TO TELESCOPES.

I Adjustments requisite to be attended to in the use of telescopes. II. State of the atmosphere most proper for observing terrestrial and celestial objects. Average number of hours in the year fit for celestial observations. III. On the magnifying powers requisite for observing (the phenomena of the different planets—comets—double stars, &c)—illustrated at large from pp. 103–107. IV. Mode of exhibiting the solar spots. Eyepieces best adapted for this purpose. How they may be exhibited to a large company. Mode in which their dimensions may be determined. V. On the *space-penetrating* power of telescopes. Herschel's observations on space-penetrating powers. Comparison of Achromatic and Gregorian reflectors. VI. On choosing telescopes, and ascertaining their properties—various modes of ascertaining the goodness of telescopes—general remarks and cautions on this point. A circumstance which requires to be attended to in using achromatics. VII. On the mode of determining the magnifying power of telescopes. Various experiments in relation to this point. VIII. On cleaning the lenses of telescopes.................................. 101

ON MEGALASCOPES, OR TELESCOPES FOR VIEWING VERY NEAR OBJECTS.

Mode of adapting a telescope for this purpose. Objects to which they may be applied........ 112

REFLECTIONS ON LIGHT AND VISION, AND ON THE NATURE AND UTILITY OF TELESCOPES.

Wonderful and mysterious nature of light. The organ of vision, and its expansive range. Wonderful nature of the telescope, and the objects it has disclosed to view. No boundaries should be set to the discoveries of Science and the improvement of art. The telescope is a machine which virtually transports us to the distant regions of space. It enlarges our views of the sublime scenes of creation. It has tended to amplify our conceptions of the empire and the attributes of the Deity. Various uses of this instrument in relation to science and common life.................................. 113

CHAPTER VII.

ON THE METHOD OF GRINDING AND POLISHING OPTICAL LENSES AND SPECULA.

I. Directions for grinding lenses for eyeglasses, microscopes, &c. II. Method of casting and grinding the specula of reflecting telescopes. Compositions for speculum metal. To try the figure of the metal. To adjust the eyehole of Gregorian reflectors—to center the specula—to center lenses.................................. 119

PART III.

ON VARIOUS ASTRONOMICAL INSTRUMENTS.

CHAPTER I.

ON MICROMETERS.

Various descriptions of micrometers. *Cavallo's* micrometer described. To ascertain the value of its divisions. Practical uses of this micrometer. Problems which may be solved by it. Tables for facilitating its use.......... 122

CHAPTER II.

ON THE EQUATORIAL TELESCOPE, OR PORTABLE OBSERVATORY.

History of Equatorials. Description of one of the simplest construction of these instruments. To adjust the equatorial for observation—to adjust the line of sight. Description of the *Nonius*. To find the meridian line by one observation. Manner of observing stars and planets in the day-time.......... 124

OBSERVATIONS, BY THE AUTHOR, ON THE FIXED STARS AND PLANETS, MADE IN THE DAY-TIME, BY THE EQUATORIAL.

Object of these observations. Stars of the first and second magnitudes. General deductions from these observations.......... 127

OBSERVATIONS ON THE PLANETS IN THE DAY-TIME.

Series of observations on *Venus*, when near the sun—seen at the time of her superior conjunction in 1843. Conclusions deduced from these observations. Phenomena observed during these observations. Remarkable phenomena during an eclipse of the sun.......... 128

OBSERVATIONS ON JUPITER AND OTHER PLANETS.

General conclusions, &c.......... 131

Utility of celestial day observations.......... 132

On the astronomical quadrant.......... 134

The astronomical circle.......... 135

The transit instrument.......... 136

CHAPTER III.

ON OBSERVATORIES.

Leading features of a spot adapted for celestial observations. Public and private Observatories. Greenwich Observatory. Instruments with which an Observatory should be furnished. The author's private Observatory. Revolving domes for Observatories. Cautions to be attended to in celestial observations.......... 138

CHAPTER IV.

ON ORRERIES OR PLANETARIUMS.

History of such machines. Sphere of Archimedes and Posidonius. Dr. Long's *Uranium*. Wheel-work of the common planetarium. Figure representing this machine. Problems which may be performed by it.......... 140

DR. HENDERSON'S PLANETARIUM.

Section of its wheel-work. Number of teeth in the wheels and pinions which move the different planets. Extreme accuracy of these movements.......... 143

ON THE VARIOUS OPINIONS WHICH WERE ORIGINALLY FORMED OF SATURN'S RING, ILLUSTRATED WITH THIRTEEN VIEWS.

When and by whom its true figure was discovered.......... 146

ON THE SUPPOSED DIVISION OF THE EXTERIOR RING OF SATURN.

Kater's, Short's, Quetelet's, and Decuppis's observations.......... 147

APPENDIX.

I. DESCRIPTION OF THE EARL OF ROSSE'S LARGEST TELESCOPE.

Composition of the speculum, and the process of casting it. Mode of grinding and polishing it. Manner in which it is filled up. Expenses incurred in its construction. Results of observations which have been made with it. Two views representing this instrument and the buildings connected with it. Sir J. South's remarks and anticipations.......... 148

II. HINTS TO AMATEURS IN ASTRONOMY RESPECTING THE CONSTRUCTION OF TELESCOPES. 152

THE

PRACTICAL ASTRONOMER.

PART I.

ON LIGHT.

INTRODUCTION.

LIGHT is that invisible ethereal matter which renders objects perceptible by the visual organs. It appears to be distributed throughout the immensity of the universe, and is essentially requisite to the enjoyment of every rank of perceptive existence. It is by the agency of this mysterious substance that we become acquainted with the beauties and sublimities of the universe, and the wonderful operations of the Almighty Creator. Without its universal influence, an impenetrable vail would be thrown over the distant scenes of creation; the sun, the moon, the planets, and the starry orbs would be shrouded in the deepest darkness, and the variegated surface of the globe on which we dwell would be almost unnoticed and unknown. Creation would disappear, a mysterious gloom would surround the mind of every intelligence, all around would appear a dismal waste and an undistinguished chaos. To whatever quarter we might turn, no form nor comeliness would be seen, and scarcely a trace of the perfections and agency of an All-wise and Almighty Being could be perceived throughout the universal gloom. In short, without the influence of light, no world could be inhabited, no animated being could subsist in the manner it now does, no knowledge could be acquired of the works of God, and happiness, even in the lowest degree, could scarcely be enjoyed by any organized intelligence.

We have never yet known what it is to live in a world deprived of this delightful visitant; for in the darkest night we enjoy a share of its beneficial agency, and even in the deepest dungeon its influence is not altogether unfelt.* The blind, indeed, do not directly enjoy the advantages of light, but its influence is reflected upon them, and their knowledge is promoted through the medium of those who enjoy the use of their visual organs. Were all the inhabitants of the world deprived of their eyesight, neither knowledge nor happiness, such as we now possess, could possibly be enjoyed.

There is nothing which so strikingly displays the beneficial and enlivening effects of light as the dawn of a mild morning after a night of darkness and tempest. All appears gloom and desolation in our terrestrial abode until a faint light begins to whiten the eastern horizon. Every succeeding moment brings along with it something new and enlivening. The crescent of light toward the east now expands its dimensions, and rises upward toward the cope of heaven; and objects, which a little before were immersed in the deepest gloom, begin to be clearly distinguished. At length the sun arises, and all nature is animated by his appearance; the magnificent scene of creation, which a little before was involved in obscurity, opens gradually to view, and every object around excites sentiments of wonder, delight, and adoration. The radiance which emanates from this luminary displays before us a world strewed with blessings, and embellished with the most beautiful attire. It unvails the lofty mountains and the forests with which they are crowned; the fruitful fields, with the crops that cover them; the meadows, with the rivers which water and refresh them; the plains, adorned with verdure; the placid lake, and the expansive ocean. It removes the curtain of darkness from the abodes of men, and shows us the cities, towns, and villages, the lofty domes, the glittering spires, and the palaces and temples with which the landscape is adorned. The flowers expand their buds and put forth their colors, the birds awake to melody, man goes forth to his labor, the sounds of human voices are heard, and all appears life and activity, as if a new world had emerged from the darkness of chaos.

The whole of this splendid scene, which light produces, may be considered as a new creation, no less grand and beneficent than the first creation, when the command was issued, "Let there be light, and light was." The aurora and the rising sun cause the earth, and all the objects which adorn its surface, to arise out of that profound darkness and apparent desolation which deprived us of the view of them as if they had been no more. It may be affirmed, in full accordance with truth, that the efflux of light in the dawn of the morning, after a dark and cloudy night, is even more magnificent and exhilarating than at the first moment of its creation. At that moment there were no spectators on earth to admire its glorious effects; and no objects, such as we now behold, to be embellished with its radiance. The earth was a shapeless chaos, where no beauty or order could be perceived; the mountains had not reared their heads; the seas were not collected into their channels; no rivers rolled through the valleys; no verdure adorned the plains; the atmosphere was not raised on high to reflect the radiance, and no animated beings existed to diversify and enliven the scene. But now, when the dawning of the morning scatters the darkness of the night, it opens to view a scene of beauty and magnificence. The heavens are adorned with azure, the clouds are tinged with the most lively colors, the mountains and plains are clothed with verdure, and the whole of this lower creation stands forth arrayed with diversified scenes of beneficence and grandeur, while the contemplative eye looks round and wonders.

---

* Those unfortunate individuals who have been confined in the darkest dungeons have declared, that though, on their first entrance, no object could be perceived, perhaps for a day or two, yet, in the course of time, as the pupils of their eyes expanded, they could readily perceive mice, rats, and other animals that infested their cells, and likewise the walls of their apartments; which shows that, even in such situations, light is present, and produces a certain degree of influence.

Such, then, are the important and beneficent effects of that *light* which every moment diffuses its blessings around us. It may justly be considered as one of the most essential substances connected with the system of the material universe, and which gives efficiency to all the other principles and arrangements of nature. Hence we are informed, in the sacred history, that light was the first production of the Almighty Creator, and the first-born of created beings; for without it the universe would have presented nothing but an immense blank to all sentient existences. Hence, likewise, the Divine Being is metaphorically represented under the idea of *light*, as being the source of knowledge and felicity to all subordinate intelligences: "God is light, and in Him is no darkness at all;" and he is exhibited as "dwelling in light unapproachable and full of glory, whom no man hath seen or can see." In allusion to these circumstances, Milton, in his Paradise Lost, introduces the following beautiful apostrophe:

> "Hail holy light! offspring of heaven first born,
> Or of the eternal, coeternal beam!
> May I express thee unblamed? since God is light
> And never but in unapproached light
> Dwelt from eternity; dwelt then in thee,
> Bright effluence of bright essence increate.
> ——————Before the sun,
> Before the heavens thou wert, and at the voice
> Of God, as with a mantle, didst invest
> The rising world of waters dark and deep,
> Won from the void and formless infinite."

As light is an element of so much importance and utility in the system of nature, so we find that arrangements have been made for its universal diffusion throughout all the worlds in the universe. The sun is one of the principal sources of light to this earth on which we dwell, and to all the other planetary bodies; and, in order that it may be *equally* distributed over every portion of the surfaces of these globes, to suit the exigencies of their inhabitants, they are endowed with a motion of rotation, by which every part of their surfaces is alternately turned toward the source of light; and when one hemisphere is deprived of the direct influence of the solar rays, its inhabitants derive a portion of light from luminaries in more distant regions, and have their views directed to other suns and systems, dispersed, in countless numbers, throughout the remote spaces of the universe. Around several of the planets, satellites or moons have been arranged for the purpose of throwing light on their surfaces in the absence of the sun, while, at the same time, the primary planets themselves reflect an effulgence of light upon their satellites. All the stars which our unassisted vision can discern in the midnight sky, and the millions more which the telescope alone enables us to descry, must be considered as so many fountains of light, not merely to illuminate the voids of immensity, but to irradiate with their beams surrounding worlds with which they are more immediately connected, and to diffuse a general luster throughout the amplitudes of infinite space; and, therefore, we have every reason to believe that, could we fly, for thousands of years, with the swiftness of a seraph, through the spaces of immensity, we should never approach a region of absolute darkness, but should find ourselves every moment encompassed with the emanations of light, and cheered with its benign influences. That Almighty Being who inhabiteth immensity and "dwells in light inaccessible," evidently appears to have diffused light over the remotest spaces of his creation, and to have thrown a radiance upon all the provinces of his wide and eternal empire, so that every intellectual being, wherever existing, may feel its beneficent effects, and be enabled, through its agency, to trace his wonderful operations, and the glorious attributes with which he is invested.

As the science of astronomy depends solely on the influence of light upon the organ of vision, which is the most noble and extensive of all our senses; and as the construction of telescopes and other astronomical instruments is founded upon our knowledge of the nature of light and the laws by which operates, it is essentially requisite, before proceeding to a description of such instruments, to take a cursory view of its nature and properties, in so far as they have been ascertained, and the effects it produces when obstructed by certain bodies, or when passing through different mediums

CHAPTER I.

GENERAL PROPERTIES OF LIGHT.

It is not my intention to discuss the subject of light in minute detail, a subject which is of considerable extent, and which would require a separate treatise to illustrate it in all its aspects and bearings. All that I propose is to offer a few illustrations of its general properties, and the laws by which it is refracted and reflected, so as to prepare the way for explaining the nature and construction of telescopes and other optical instruments.

There is no branch of natural science more deserving of our study and investigation than that which relates to light, whether we consider its beautiful and extensive effects, the magnificence and grandeur of the objects it unfolds to view, the numerous and diversified phenomena it exhibits, the optical instruments which a knowledge of its properties has enabled us to construct, or the daily advantages we derive, as social beings, from its universal diffusion. If air, which serves as the medium of sound and the vehicle of speech, enables us to carry on an interchange of thought and affection with our fellow-men, how much more extensively is that intercourse increased by light, which presents the images of our friends and other objects as it were immediately before us, in all their interesting forms and aspects—the speaking eye, the rosy cheeks, the benevolent smile, and the intellectual forehead. The eye, more susceptible of multifarious impressions than the other senses, "takes in at once the landscape of the world," and enables us to distinguish, in a moment, the shapes and forms of all its objects, their relative positions, the colors that adorn them, their diversified aspect, and the motions by which they are transported from one portion of space to another. Light, through the medium of the eye, not only unfolds to us the presence of others, in all their minute modifications and peculiarities, but exhibits us to ourselves. It presents to our own vision a faithful portrait of peculiar features behind reflecting substances, without which property we should remain entirely ignorant of those traits of countenance which characterize us in the eyes of others.

But what is the nature of this substance we call *light*, which thus unfolds to us the scenes of creation? On this subject two leading opinions have prevailed in the philosophical world. One of these opinions is, that the whole sphere of the universe is filled with a subtile matter, which receives from luminous bodies an agitation which is incessantly continued, and which, by its vibratory motions, enables us to perceive luminous bodies. According to this opinion, light may be considered as analogous to sound, which is conveyed to the ear by the vibratory motions of the air. This was the hypothesis of Descartes, which was adopted, with some modifications, by the celebrated Euler, Huygens, Franklin, and other philosophers, and has been admitted by several scientific gentlemen of the present day. The other opinion is, that light consists of the emission or emanation of the particles of luminous bodies, thrown out incessantly on all sides, in consequence of the continued agitation it experiences. This is the hypothesis of the illustrious Newton, and has been most generally adopted by British philosophers.

To the first hypothesis it is objected that, if true, "light would not only spread itself in a direct line, but its motion would be transmitted in every direction like that of sound, and would convey the impression of luminous bodies in the regions of space beyond the obstacles that intervene to stop its progress." No wall or other opaque body could obstruct its course, if it undulated in every direction like sound; and it would be a necessary consequence, that we should have no night, nor any such phenomena as eclipses of the sun or moon, or the satellites of Jupiter and Saturn. This objection has never been very satisfactorily answered. On the other hand, Euler brings forward the following objections against the Newtonian doctrine of emanation. 1. That, were the sun emitting continually, and in all directions, such floods of luminous matter, with a velocity so prodigious, he must speedily be exhausted, or at least some alteration must, after the lapse of so many ages, be perceptible. 2. That the sun is not the only body that emits rays, but that all the stars have the same quality; and as everywhere the rays of the sun must be crossing the rays of the stars, their collision must be violent in the extreme, and that their direction must be changed by such a collision.*

To the first of these objections it is answered, that so vast is the tenuity of light, that it utterly exceeds the power of conception; the most delicate instrument having never been certainly put in motion by the impulse of the accumulated sunbeams. It has been calculated that in the space of 385,130,000 Egyptian years (of 360 days), the sun would lose only the 1-1,217,420th of his bulk from the continual efflux of his light. And, therefore, if in 385 *millions* of years t sun's diminution would be so extremely small, would be altogether insensible during the comparatively short period of five or six thousand years. To the second objection it is replied, that the particles of light are so extremely rare that their distance from one to another is incomparably greater than their diameters; that all objections of this kind vanish when we attend to the continuation of the impression upon the retina, and to the small number of luminous particles which are on that account necessary for producing constant vision. For it appears, from the accurate experiments of M. D'Arcy, that the impression of light upon the retina continues *eight-thirds* and as a particle of light would move through 26,000 miles in that time, constant vision would be maintained by a succession of luminous particles twenty-six thousand miles distant from each other.

Without attempting to decide on the merits of these two hypotheses, I shall leave the reader to adopt that opinion which he may judge to be attended with the fewest difficulties, and proceed to illustrate some of the *properties of light;* and in the discussion of this subject I shall generally adhere to the terms employed by those who have adopted the hypothesis of the *emanation* of light.

---

* Letters to a German Princess, vol. i., p. 68, &c.

1. *Light emanates or radiates from luminous bodies in a straight line.* This property is proved by the impossibility of seeing light through bent tubes, or small holes pierced in metallic plates placed one behind another, except the holes be placed in a straight line. If we endeavor to look at the sun or a candle through the bore of a bended pipe, we cannot perceive the object, nor any light proceeding from it, but through a straight pipe the object may be perceived. This is likewise evident from the form of the rays of light that penetrate a dark room, which proceed straight forward in lines proceeding from the luminous body; and from the form of the *shadows* which bodies project that are bounded by right lines passing from the luminous body, and meeting the lines which terminate the interposing body. This property may be demonstrated to the eye by causing light to pass through small holes into a dark room filled with smoke or dust. It is to be understood, however, that in this case the rays of light are considered as passing through the same medium; for when they pass from air into water, glass, or other media, they are bent at the point where they enter a different medium, as we shall afterward have occasion to explain.

2. *Light moves with amazing velocity.* The ancients believed that it was propagated from the sun and other luminous bodies *instantaneously;* but the observations of modern astronomers have demonstrated that this is an erroneous hypothesis, and that light, like other projectiles, occupies a certain time in passing from one part of space to another. Its velocity, however, is prodigious, and exceeds that of any other body with which we are acquainted. It flies across the earth's orbit, a space of 190 millions of miles in extent, in the course of sixteen and a half minutes, which is at the rate of 192,000 miles every second, and more than a million of times swifter than a cannon ball flying with its greatest velocity. It appears from the discoveries of Dr. Bradley, respecting the aberration of the stars, that light flies from these bodies with a velocity similar, if not exactly the same; so that the light of the sun, the planets, the stars, and every luminous body in the universe is propagated with uniform velocity.* But, if the velocity of light be so very great, it may be asked, how does it not strike against all objects with a force equal to its velocity? If the finest sand were thrown against our bodies with the hundredth part of this velocity, each grain would pierce us as certainly as the sharpest and swiftest arrows from a bow. It is a principle in mechanics that the force with which all bodies strike is in proportion to the size of these bodies, or the quantity of matter they contain, multiplied by the velocity with which they move. Therefore, if the particles of light were not almost infinitely small, they would, of necessity, prove destructive in the highest degree. If a particle of light were equal in size to the twelve hundred thousandth part of a small grain of sand—supposing light to be material—we should be no more able to withstand its force than we should that of sand shot point blank from the mouth of a cannon. Every object would be battered and perforated by such celestial artillery, until our world were laid in ruins, and every living being destroyed. And herein are the wisdom and benevolence of the Creator displayed in making the particles of light so extremely small as to render them in some degree proportionate to the greatness of the force with which they are impelled; otherwise, all nature would have been thrown into ruin and confusion, and the great globes of the universe shattered to atoms.

We have many proofs, beside the above, that the particles of light are next to infinitely small. We find that they penetrate with facility the hardest substances, such as crystal, glass, various kinds of precious stones, and even the diamond itself, though among the hardest of stones; for such bodies could not be transparent, unless light found an easy passage through their pores. When a candle is lighted in an elevated situation, in the space of a second or two it will fill a cubical space (if there be no interruption) of two miles around it, in every direction, with luminous particles, before the least sensible part of its substance is lost by the candle: that is, it will in a short instant fill a sphere four miles in diameter, twelve and a half miles in circumference, and containing thirty-three and a half cubical miles, with particles of light; for an eye placed in any part of this cubical space would perceive the light emitted by the candle. It has been calculated that the number of particles of light contained in such a space cannot be less than *four hundred septillions*—a number which is *six billions* of times greater than the number of grains of sand which could be contained in the whole earth considered as a solid globe, and supposing each cubic inch of it to contain ten hundred thousand grains. Such is the inconceivable tenuity of that substance which emanates from all luminous bodies, and which gives beauty and splendor to the universe. This may also be evinced by the following experiment: Make a small pin-hole in a piece of black paper, and hold the paper upright facing a row of candles placed near each other, and at a little distance behind the black paper place a piece of white pasteboard. On this pasteboard the rays which flow from all the candles through the small hole in the black paper, will form as many specks of light as there are candles, each speck being as clear and distinct as if there were only one speck from a single candle. This experiment shows that the streams of light from the different candles pass through the small hole without confusion, and, consequently, that the particles of light are exceedingly small. For the same reason we can easily see through a small hole not more than 1-100th of an inch in diameter, the sky, the trees, houses, and nearly all the objects in an extensive landscape, occupying nearly an entire hemisphere, the light of all which may pass through this small aperture.

3. *Light is sent forth in all directions from every visible point of luminous bodies.* If we hold a sheet of paper before a candle, or the sun, or any other source of light, we shall find that the paper is illuminated in whatever position we hold it, provided the light is not obstructed by its edge or by any other body. Hence, wherever a spectator is placed with regard to a luminous body, every point of that part of its surface which is toward him will be visible, when no intervening object intercepts the passage of the light. Hence, likewise, it follows that the sun illuminates not only an immense plane extending along the paths of the planets, from the one side of the orbit of Uranus to the other, but the whole of that sphere,

---

* The manner in which the motion of light was discovered is explained in the author's work, entitled, "Celestial Scenery;" and the circumstances which led to the discovery of the aberration of light are stated and illustrated in his volume on the "Sidereal Heavens."

or solid space, of which the distance of Uranus is the radius. The diameter of this sphere is three thousand six hundred *millions* of miles, and it consequently contains about 24,000,000,000,000,000,000,000,000,000, or twenty-four thousand *quartillions* of cubical miles, every point of which immense space is filled with the solar beams. Not only so, but the whole cubical space which intervenes between the sun and the nearest fixed stars is more or less illuminated by his rays. For, at the distance of Sirius, or any other of the nearest stars, the sun would be visible, though only as a small, twinkling orb; and, consequently, his rays must be diffused, however faint, throughout the most distant spaces whence he is visible. The diameter of this immense sphere of light cannot be less than *forty billions* of miles, and its solid contents 33,500,000,000,000,000,000,000,000,000,000,000,000, or thirty-three thousand five hundred *sextillions* of cubical miles. All this immense and incomprehensible space is filled with the radiations of the solar orb; for were an eye placed in any one point of it, where no extraneous body interposed, the sun would be visible either as a large luminous orb, or as a small twinkling star. But he can be visible only by the rays he emits, and which enter the organs of vision. How inconceivably immense, then, must be the quantity of rays which are thrown off in all directions from that luminary which is the source of our day! Every star must likewise be considered as emitting innumerable streams of radiance over a space equally extensive; so that no point in the universe can be conceived where absolute darkness prevails, unless in the interior regions of planetary bodies.

4. *The effect of light upon the eye is not instantaneous, but continues for a short space of time.* This may be proved and illustrated by the following examples: if a stick, or a ball connected with a string, be whirled round in a circle, and a certain degree of velocity given it, the object will appear to fill the whole circle it describes. If a lighted firebrand be whirled round in the same rapid manner, a complete circle of light will be exhibited. This experiment obviously shows that the impression made on the eye by the light from the ball or the firebrand, when in any given point of the circle, is sufficiently lasting to remain until it has described the whole circle, and again renews its effect as often as the circular motion is continued. The same is proved by the following considerations: we are continually shutting our eyes, or winking; and, during the time our eyes are shut on such occasions, we should lose the view of surrounding objects if the impression of light did not continue a certain time while the eyelid covers the pupil; but experience proves that during such vibrations of the eyelids the light from surrounding objects is not sensibly intercepted. If we look for some time steadily at the light of a candle, and particularly if we look directly at the sun, without any interposing medium, or if we look for any considerable time at this luminary through a telescope with a colored glass interposed —in all these cases, if we shut our eyes immediately after viewing such objects, we shall still perceive a faint image of the object by the impression which its light has made upon our eyes.

"With respect to the duration of the impression of light, it has been observed that the teeth of a cogwheel in a clock were still visible in succession, when the velocity of rotation brought 246 teeth through a given fixed point in a second. In this case it is clear that if the impression made on the eye by the light reflected from any tooth had lasted without sensible diminution for the 246th part of a second, the teeth would have formed one unbroken line, because a new tooth would have continually arrived in the place of the anterior one before its image could have disappeared. If a live coal be whirled round, it is observed that the luminous circle is complete when the rotation is performed in the 81-60th part of a second. In this instance we see that the impression was much more durable than the former. Lastly, if an observer sitting in a room, direct his sight, through a window, to any particular object out of doors, for about half a minute, and then shut his eyes and cover them with his hands, he will still continue to see the window, together with the outline of the terrestrial objects bordering on the sky. This appearance will remain for near a minute, though occasionally vanishing and changing color in a manner that brevity forbids our minutely describing. From these facts we are authorized to conclude that all impressions of light on the eye last a considerable time; that the brightest objects make the most lasting impressions; and that, if the object be very bright, or the eye weak, the impression may remain for a time so strong as to mix with and confuse the subsequent impressions made by other objects. In the last case the eye is said to be dazzled by the light."*

The following experiment has likewise been suggested as a proof of the impression which light makes upon the eye: If a card, on both sides of which a figure is drawn, for example, a bird and a cage, be made to revolve rapidly on the straight line which divides it symmetrically, the eye will perceive both figures at the same time, provided they return successively at the same place. M. D'Arcy found by various experiments that, in general, the impression which light produces on the eye lasts about the *eighth of a second.* M. Plateau, of Brussels, found that the impression of different colors lasted the following periods, the numbers here stated being the decimal parts of a second: flame, 0.242, or nearly one-fourth of a second; burning coal, 0.229; white, 0.182, or a little more than one-sixth of a second; blue, 0.186; yellow, 0.173; red, 0.184.

5. *Light*, though extremely minute, *is supposed to have a certain degree of force or momentum.* In order to prove this, the late ingenious Mr. Mitchell contrived the following experiment: He constructed a small vane in the form of a common weathercock, of a very thin plate of copper, about an inch square, and attached to one of the finest harpsichord wires about ten inches long, and nicely balanced at the other end of the wire by a grain of very small shot. The instrument had also fixed to it, in the middle, at right angles to the length of the wire, and in a horizontal direction, a small bit of a very slender sewing needle, about half an inch long, which was made magnetical. In this state the whole instrument might weigh about ten grains. The vane was supported in the manner of the needle in the mariner's compass, so that it could turn with the greatest ease; and to prevent its being affected by the vibrations of the air, it was inclosed in a glass case or box. The rays of the sun were then thrown upon the broad part of the vane, or copper plate, from a concave mirror of about two feet diameter, which, passing through the front glass of the box, were collected into the focus of the mirror upon the copper plate. In consequence of this, the plate began to move with a slow motion of about

---

* Nicholson's Introduction to Natural Philosophy, vol 1.

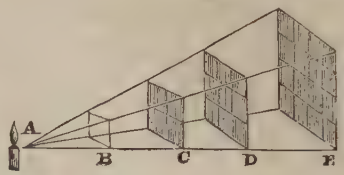
an inch in a second of time, until it had moved through a space of about two inches and a half, when it struck against the back of the box. The mirror being removed, the instrument returned to its former situation, and the rays of the sun being again thrown upon it, it again began to move, and struck against the back of the box as before. This was repeated three or four times with the same success.

On the above experiment the following calculation has been founded: if we impute the motion produced in this experiment to the impulse of the rays of light, and suppose that the instrument weighed ten grains, and acquired a velocity of one inch in a second, we shall find that the quantity of matter contained in the rays falling upon the instrument in that time amounted to no more than one twelve hundredth-millionth part of a grain, the velocity of light exceeding the velocity of one inch in a second in the proportion of about 12,000,000,000 to 1. The light, in this experiment, was collected from a surface of about three square feet, which, reflecting only about half what falls upon it, the quantity of matter contained in the rays of the sun incident upon a foot and a half of surface in one second of time, ought to be no more than the twelve hundredth-millionth part of a grain. But the density of the rays of light at the surface of the sun is greater than that at the earth in the proportion of 45,000 to 1; there ought, therefore, to issue from one square foot of the sun's surface in one second of time, in order to supply the waste of light, $\frac{1}{45,000}$th part of a grain of matter, that is, a little more than two grains a day, or about 4,752,000 grains, or 670 pounds avoirdupois, nearly, in 6,000 years; a quantity which would have shortened the sun's diameter no more than about ten feet, if it were formed of the density of water only.

If the above experiment be considered as having been accurately performed, and if the calculations founded upon it be correct, it appears that there can be no grounds for apprehension that the sun can ever be sensibly diminished by the immense and incessant radiations proceeding from his body on the supposition that light is a material emanation. For the diameter of the sun is no less than 880,000 miles; and, before this diameter could be shortened, by the emission of light, one English mile, it would require three millions one hundred and sixty-eight thousand years, at the rate now stated; and, before it could be shortened ten miles, it would require a period of above thirty-one millions of years. And although the sun were thus actually diminished, it would produce no sensible effect or derangement throughout the planetary system. We have no reason to believe that the system, *in its present state and arrangements*, was intended to endure forever; and before that luminary could be so far reduced, during the revolutions of eternity, as to produce any irregularities in the system, new arrangements and modifications might be introduced by the hand of the All-wise and Omnipotent Creator. Beside, it is not improbable that a system of means is established by which the sun and all the luminaries in the universe receive back again a portion of the light which they are continually emitting, either from the planets from whose surfaces it is reflected, or from the millions of stars whose rays are continually traversing the immense spaces of creation, or from some other sources to us unknown.

6. *The intensity of light is diminished in proportion to the square of the distance from the luminous body.* Thus, a person at two feet distance from a candle, has only the fourth part of the light he would have at one foot; at three feet distance, the ninth part; at four feet, the sixteenth part; at five feet, the twenty-fifth part; and so on for other distances. Hence the light received by the planets of the solar system decreases in proportion to the squares of the distances of these bodies from the sun. This may be illustrated by the following figure:

Fig. 1.



Suppose the light which flows from a point *A*, and passes through a square hole, *B*, is received upon a plane, *C*, parallel to the plane of the hole—or let the figure *C* be considered as the shadow of the plane *B*. When the distance of *C* is double of *B*, the length and breadth of the shadow, *C*, will be each double of the length and breadth of the plane *B*, and treble when *A D* is treble of *A B*, and so on, which may be easily examined by the light of a candle placed at *A*. Therefore the surface of the shadow *C*, at the distance *A C*—double of *A B*, is divisible into four squares, and, at a treble distance, into nine squares, severally equal to the square *B*, as represented in the figure. The light, then, which falls upon the plane *B* being suffered to pass to double that distance, will be uniformly spread over four times the space, and, consequently, will be four times thinner in every part of that space. And, at a treble distance, it will be nine times thinner, and, at a quadruple distance, sixteen times thinner than it was at first. Consequently, the quantities of this rarefied light received upon a surface of any given size and shape, when removed successively to their several distances, will be but one-fourth, one-ninth, one-sixteenth of the whole quantity received by it at the first distance, *A B*.

In conformity with this law, the relative quantities of light on the surfaces of the planets may be easily determined when their distances from the sun are known. Thus, the distance of Uranus from the sun is 1,800,000,000 miles, which is about nineteen times greater than the distance of the earth from the same luminary. The square of 19 is 361; consequently, the earth enjoys 361 times the intensity of light, when compared with that of Uranus; in other words, this distant planet enjoys only the $\frac{1}{361}$ part of the quantity of light which falls upon the earth. This quantity, however, is equivalent to the light we should enjoy from the combined effulgence of 348 full moons, and if the pupils of the eyes of the inhabitants of this planet be much larger than ours, and the *retina* of the eye be indued with a much greater degree of nervous sensibility, they may perceive objects with as great a degree of splendor as we perceive on the objects which surround us in this world. Following out the same principle, we find that the quantity of light enjoyed by the planet Mercury is nearly *seven* times greater than that of the Earth, and that of Venus nearly *double* of what we enjoy; that Mars has less than the one-half; Jupiter the one-*twenty-seventh* part; and Saturn only the *one-ninetieth* part of the light which falls upon the Earth. That the light of these distant planets, however, is not so weak as we might first imagine, appears from the brilliancy they exhibit, when viewed in our nocturnal sky, either with the telescope or with the unassisted eye; and likewise from the circumstance that a very small portion of the Sun—such as the one-fortieth or one-fiftieth part—diffuses a quantity of light sufficient for most of the purposes of life, as is found in the case of total eclipses of the Sun, when his western limb begins to be visible, only like a fine luminous thread, for his light is then sufficient to render distinctly visible all the parts of the surrounding landscape.

7. *It is by light reflected from opaque bodies that most of the objects around us are rendered visible.*—When a lighted candle is brought into a dark room, not only the candle, but all other bodies in the room become visible. Rays of the sun, passing into a dark room, render luminous a sheet of paper on which they fall, and this sheet, in its turn, enlightens, to a certain extent, the whole apartment, and renders objects in it visible so long as it receives the rays of the sun. In like manner, the moon and the planets are opaque bodies, but the light of the sun falling upon them, and being reflected from their surfaces, renders them visible. Were no light to fall on them from the sun, or were they not indued with a power of reflecting it, they would be altogether invisible to our sight. When the moon comes between us and the sun, as in a total eclipse of that luminary, as no solar light is reflected from the surface next the earth, she is invisible, only the curve or outline of her figure being distinguished by her shadow. In this case, however, there is a certain portion of reflected light on the lunar hemisphere next the earth, though not distinguishable during a solar eclipse. The earth is enlightened by the sun, and a portion of the rays which fall upon it is reflected upon the dark hemisphere of the moon which is then toward the earth. This reflected light from the earth is distinctly perceptible, when the moon appears as a slender crescent, two or three days after new moon—when the earth reflects its light back on the moon, in the same manner as the full moon reflects her light on the earth. Hence, even at this period of the moon, her whole face becomes visible to us, but its light is not uniform or of equal intensity. The thin crescent on which the full blaze of the solar light falls, is very brilliant and distinctly seen, while the other part, on which falls only a comparatively feeble light from the earth, appears very faint, and is little more than visible to the naked eye, but with a telescope of moderate power—if the atmosphere be very clear—it appears beautifully distinct, so that the relative positions of many of the lunar spots may be distinguished.

The intensity of reflected light is very small, when compared with that which proceeds directly from luminous bodies. M. Bouguer, a French philosopher, who made a variety of experiments to ascertain the proportion of light emitted by the heavenly bodies, concluded from these experiments, that the light transmitted from the sun to the earth is at least 300,000 times as great as that which descends to us from the full moon, and that, of 300,000 rays which the moon receives, from 170,000 to 200,000 are absorbed. Hence we find that, however brilliant the moon may appear at night, in the day-time she appears as obscure as a small portion of dusky cloud to which she happens to be adjacent, and reflects no more light than a portion of whitish cloud of the same size. And as the full moon fills only the ninety-thousandth part of the sky, it would require at least ninety thousand moons to produce as much light as we enjoy in the day-time under a cloudy sky.

As the moon and the planets are rendered visible to us only by light reflected from their surfaces, so it is in the same way that the images of most of the objects around us are conveyed to our organs of vision. We behold all the objects which compose an extensive landscape—the hills and vales, the woods and lawns, the lakes and rivers, and the habitations of man—in consequence of the capacity with which they are indued of sending forth reflected rays to the eye, from every point of their surfaces and in all directions. In connection with the reflection of light, the following curious observation may be stated: Baron Funk, visiting some silver mines in Sweden, observed, that, "in a clear day, it was as dark as pitch under ground in the eye of a pit, at sixty or seventy fathoms deep; whereas, in a cloudy or rainy day, he could see to read even at 106 fathoms deep. Inquiring of the miners, he was informed that this is always the case; and reflecting upon it, he imagined it arose from this circumstance, that, when the atmosphere is full of clouds, light is reflected from them into the pit in all directions, and that thereby a considerable proportion of the rays are reflected perpendicularly upon the earth: whereas, when the atmosphere is clear, there are no opaque bodies to reflect the light in this manner, at least in a sufficient quantity; and rays from the sun himself can never fall perpendicularly in that country." The reason here assigned is, in all probability, the true cause of the phenomenon now described.

8. It is supposed by some philosophers that *light is subject to the same laws of attraction that govern all other material substances*, and that *it is imbibed and forms a constituent part of certain bodies.* This has been inferred from the phenomena of the *Bolognian stone*, and what are generally called the *solar phosphori.* The Bolognian stone was first discovered about the year 1630, by Leascariolo, a shoemaker of Bologna. Having collected together some stones of a shining appearance at the bottom of Monte Paterno, and being in quest of some alchemical secret, he put them into a crucible to calcine them; that is, to reduce them to the state of cinders. Having taken them out of the crucible, and exposed them to the light of the sun, he afterward happened to carry them into a dark place, when, to his surprise, he observed that they possessed a self-illuminating power, and continued to emit faint rays of light for some hours afterward. In consequence of this discovery, the Bolognian spar came into considerable demand among natural philosophers, and the curious in general; and the best way of preparing it seems to have been hit upon by the family of Zagoni, who supplied all Europe with Bolognian phosphorus until the discovery of more powerful phosphoric substances put an end to their monopoly. In the year 1677, Baldwin, a native of Misnia, observed that chalk, dissolved in aquafortis, exactly resembled the Bolognian stone in its property of imbibing light, and emitting it after it was brought into the dark; and hence it has obtained the name of Baldwin's phosphorus.

In 1730 M. Du Fay directed his attention to this subject, and observed that all earthy substances susceptible of calcination, either by mere fire, or when assisted by the previous action of nitrous acid, possessed the property of becoming more or less luminous, when calcined and exposed for a short time in the light; that the most perfect of these phosphori were limestones, and other kinds of carbonated lime, gypsum, and particularly the topaz, and that some diamonds were also observed to be luminous by simple exposure to the sun's rays. Some time afterward Beccaria discovered that a great variety of other bodies were convertible into phosphori by exposure to the mere light of the sun, such as organic animal remains, most compound salts, niter and borax—all the farinaceous and oily seeds of vegetable substances, all the gums and several of the resins—the white woods and vegetable fiber, either in the form of paper or linen; also starch and loaf-sugar proved to be good phosphori, after being made thoroughly dry, and exposed to the direct rays of the sun. Certain animal substances, by a similar treatment, were also converted into phosphori; particularly bone, sinew, glue, hair, horn, hoof, feathers, and fish-shells. The same property was communicated to rock-crystal and some other of the gems, by rubbing them against each other so as to roughen their surfaces, and then placing them for some minutes in the focus of a lens, by which the rays of light were concentrated upon them at the same time that they were also moderately heated.

In the year 1768, Mr. Canton contributed some important facts in relation to solar phosphori, and communicated a method of preparing a very powerful one, which, after the inventor, is usually called *Canton's phosphorus.* He affirms that his phosphorus, inclosed in a glass flask, and hermetically sealed, retains its property of becoming luminous for at least four years, without any apparent decrease of activity. It has also been found that, if a common box smoothing-iron, heated in the usual manner, be placed for half a minute on a sheet of dry, white paper, and the paper be then exposed to the light, and afterward examined in a dark closet, it will be found that the whole paper will be luminous, that part, however, on which the iron had stood being much more shining than the rest.

From the above facts it would seem that certain bodies have the power of imbibing light and again emitting it, in certain circumstances, and that this power may remain for a considerable length of time. It is observed that the light which such bodies emit, bears an analogy to that which they have imbibed. In general, the illuminated phosphorus is reddish; but when a weak light only has been admitted to it, or when it has been received through pieces of white paper, the emitted light is pale or whitish. Mr. Morgan, in the seventy-fifth volume of the Philosophical Transactions, treats the subject of light at considerable length; and as a foundation for his reasoning, he assumes the following data: 1. That light is a body, and, like all others, subject to the laws of attraction. 2. That light is a heterogeneous body, and that the same attractive power operates with different degrees of force on its different parts. To the principle of attraction, likewise, Sir Isaac Newton has referred the most extraordinary phenomena of light, Refraction and Inflection. He has also endeavored to show that light is not only subject to the law of attraction, but of repulsion also, since it is repelled or reflected from certain bodies. If such principles be admitted, then it is highly probable that the phosphorescent bodies to which we have adverted have a power of attracting or imbibing the substance of light, and of retaining or giving it out under certain circumstances, and that the matter of light is incorporated, at least, with the surface of such bodies; but on this subject, as on many others, there is a difference of opinion among philosophers.*

9. *Light is found to produce a remarkable effect on plants and flowers, and other vegetable productions.* Of all the phenomena which living vegetables exhibit, there are few that appear more extraordinary than the energy and constancy with which their stems incline toward the light. Most of the discous flowers follow the sun in his course. They attend him to his evening retreat, and meet his rising luster in the morning with the same unerring law. They unfold their flowers on the approach of this luminary; they follow his course by turning on their stems, and close them as soon as he disappears. If a plant, also, is shut up in a dark room, and a small hole afterward opened by which the light of the sun may enter, the plant will turn toward that hole, and even alter its own shape in order to get near it; so that though it was straight before, it will in time become crooked, that it may get near the light. Vegetables placed in rooms where they receive light only in one direction, always extend themselves in that direction. If they receive light in two directions, they direct their course toward that which is strongest. It is not the *heat,* but the *light* of the sun which the plant thus covets; for, though a fire be kept in the room, capable of giving a much stronger heat than the sun, the plant will turn away from the fire in order to enjoy the solar light. Trees growing in thick forests, where they only receive light from above, direct their shoots almost invariably upward, and therefore become much taller and less spreading than such as stand single.

The *green* color of plants is likewise found to depend on the sun's light being allowed to shine on them; for without the influence of the solar light they are always of a *white* color. It is found by experiment that, if a plant which has been reared in darkness be exposed to the light of day, in two or three days it will acquire a green color perceptibly similar to that of plants which have grown in open daylight. If we expose to the light one part of the plant, whether leaf or branch, this part alone will become green. If we cover any part of a leaf with an opaque substance, this place will remain white, while the rest becomes green. The whiteness of the inner leaves of cabbages is a partial effect of the same cause, and many other examples of the same kind might easily be produced. M. Decandolle, who seems to have paid particular attention to this subject, has the following remarks: "It is certain, that between the white state of plants vegetating in darkness, and complete verdure, every possible intermediate degree exists, determined by the intensity of the light. Of this any one may easily satisfy himself by attending to the color of a plant exposed to the full daylight; it exhibits in succession all the degrees of verdure. I had already seen the same phenomenon, in a particular manner, by exposing plants reared in darkness to the light of lamps. In these experiments, I not only saw the color come on gradually, according to the continuance of the exposure to light, but I satisfied myself that a certain intensity of permanent light never gives to a plant more than a certain degree of color. The same fact readily shows itself in nature, when we examine the plants that grow under shelter or in forests, or when we examine in succession the state of the leaves that form the heads of cabbages."*

---

* Light of a phosphoric nature is frequently emitted from various putrescent animal substances, which, in the ages of superstition, served to astonish and affright the timorous.—We learn from Fabricius, an Italian, that three young men, residing at Padua, having bought a lamb, and eaten part of it on Easter day, 1592, several pieces of the remainder, which they kept until the following day, shone like so many candles when they were casually viewed in the dark. The astonishment of the whole city was excited by this phenomenon, and a part of the flesh was sent to Fabricius, who was professor of anatomy, to be examined by him. He observed that those parts which were soft to the touch and transparent in candle-light were the most resplendent; and also that some pieces of kid's flesh which had happened to have laid in contact with them were luminous, as well as the fingers and other parts of the bodies of those persons who touched them. Bartholin gives an account of a similar phenomenon, which happened in Montpelier, in 1641.—A poor woman had bought a piece of flesh in the market, intending to make use of it on the following day; but happening not to be able to sleep well that night, and her bed and pantry being in the same room, she observed so much light come from the flesh as to illuminate all the place where it hung. We may judge of the terror and astonishment of the woman herself, when we find that a part of this luminous flesh was carried as a very extraordinary curiosity to Henry, duke of Conde, the governor of the place, who viewed it several hours with the greatest astonishment. The light was as if gems had been scattered over the surface, and continued until the flesh began to putrefy, when it vanished, which it was believed to do in the form of a cross. Hence the propriety of instructing the mass of the community in the knowledge of the facts connected with the material system, and the physical causes of the various phenomena of nature.

It is likewise found that the *perspiration* of vegetables is increased or diminished in a certain measure by the degree of *light* which falls upon them. The experiments of Mr. P. Miller, and others, prove that plants uniformly perspire most in the forenoon, though the temperature of the air in which they are placed should be unvaried. M. Guettard likewise informs us that a plant exposed to the rays of the sun has its perspiration increased to a much greater degree than if it had been exposed to the same heat under the shade. Vegetables are likewise found to be indebted to light for their smell, taste, combustibility, maturity, and the resinous principle, which equally depend upon this fluid. The aromatic substances, resins, and volatile oils, are the productions of southern climates, where the light is more pure, constant, and intense. In fine, another remarkable property of light on the vegetable kingdom is, that, when vegetables are exposed to open daylight, or to the sun's rays, they emit oxygen gas, or vital air. It has been proved that, in the production of this effect, the sun does not act as a body that heats. The emission of the gas is determined by the light: pure air is therefore separated by the action of light, and the operation is stronger as the light is more vivid. By this continual emission of vital air, the Almighty incessantly purifies the atmosphere, and repairs the loss of pure air occasioned by respiration, combustion, fermentation, putrefaction, and numerous other processes which have a tendency to contaminate this fluid, so essential to the vigor and comfort of animal life; so that, in this way, by the agency of light, a due equilibrium is always maintained between the constituent parts of the atmosphere.

In connection with this subject the following curious phenomenon may be stated, as related by M. Haggern, a lecturer on Natural History in Sweden. One evening he perceived a faint flash of light repeatedly dart from a marigold. Surprised at such an uncommon appearance, he resolved to examine it with attention; and, to be assured it was no deception of the eye, he placed a man near him, with orders to make a signal at the moment when he observed the light. They both saw it constantly at the same moment. The light was most brilliant on marigolds of an orange or flame color, but scarcely visible on pale ones. The flash was frequently seen on the same flower two or three times in quick succession, but more commonly at intervals of several minutes; and when several flowers in the same place emitted their light together, it could be observed at a considerable distance. The phenomenon was remarked in the months of July and August at sunset, and for half an hour when the atmosphere was clear; but after a rainy day, or when the air was loaded with vapors, nothing of it was seen. The following flowers emitted flashes more or less vivid, in this order: 1. The Marigold. 2. Monk's Hood. 3. The Orange Lily. 4. The Indian Pink. As to the *cause* of this phenomenon, different opinions may be entertained. From the rapidity of the flash and other circumstances, it may be conjectured that electricity is concerned in producing this appearance. M. Haggern, after having observed the flash from the orange lily, the antheræ of which are at considerable distance from the petals, found that the light proceeded from the petals only; whence he concludes that this electrical light is caused by the pollen, which, in flying off, is scattered on the petals. But, perhaps, the true cause of it still remains to be ascertained.

10. *Light has been supposed to produce a certain degree of influence on the* PROPAGATION OF SOUND. M. Parolette, in a long paper in the "Journal de Physique," vol. 68, which is copied into "Nicholson's Philosophical Journal," vol. 25, pp. 25–39, has offered a variety of remarks, and detailed a number of experiments on this subject. The author states the following circumstances as having suggested the connection between light and sound: "In 1803 I lived in Paris, and being accustomed to rise before day to finish a work on which I had long been employed, I found myself frequently disturbed by the sound of carriages, as my windows looked into one of the most frequented streets in that city. This circumstance, which disturbed me in my studies every morning, led me to remark that the appearance of daybreak peculiarly affected the propagation of the sound; from dull and deep, which it was before day, it seemed to me to acquire a more sonorous sharpness in the period that succeeded the dissipation of darkness. The rolling of the wheels seemed to announce the friction of some substances grown more elastic; and my ear, on attending to it, perceived this difference diminish in proportion as the sound of wheels was confounded with those excited by the tumult of objects quitting their nocturnal silence. Struck with this observation, I attempted to discover whether any particular causes had deceived my ears. I rose several times before day for this purpose alone, and was every time confirmed in my suspicion that light must have a peculiar influence on the propagation of sound. This variation, however, in the manner in which the air gave sounds, might be the effect of the agitation of the atmosphere produced by the rarefaction the presence of the sun occasioned; but the situation of my windows, and the usual direction of the morning breeze, militated against this argument."

The author then proceeds to give a description of a very delicate instrument, and various apparatus for measuring the propagation and intensity of sound, and the various experiments both in the dark and in daylight, and likewise under different changes of the atmosphere, which were made with his apparatus, all of which tended to prove that light had a sensible influence in the propagation of sound. But the detail of these experiments, and their several results, would be too tedious to be here transcribed. The night has generally been considered as more favorable than the day for the transmission of sound. "That this is the case," says Parolette, "with respect to our ears cannot be doubted: but this argues nothing against my opinion. We hear farther by night on account of the silence, and this always contributes to it, while the noise of a wind favorable to the propagation of a sound may prevent the sound from being heard." In reference to the cause which produces the effect now stated, he proposes the following queries: "Is the atmospheric air more dense on the appearance of light than in darkness? Is this greater density of the air, or of the elastic fluid that is subservient to the propagation of sound, the effect of aeriform substances kept in this state through the medium of light?" He is disposed, on the whole, to conclude that the effect in question is owing to the action of light upon the oxygen of the atmosphere, since oxygen gas is found by experiment to be best adapted to the transmission of sound.

---

* Memoires de la Soc. d Aroncil, vol. ii.

Our author concludes his communication with the following remarks: "Light has a velocity 900,000 times as rapid as that of sound. Whether it emanate from the sun and reach to our earth, or act by means of vibrations agitating the particles of a fluid of a peculiar nature, the particles of this fluid must be extremely light, elastic, and active. Nor does it appear to me unreasonable to ascribe to the mechanical action of these particles set in motion by the sun, the effects its presence occasions in the vibrations that proceed from sonorous bodies. The more deeply we investigate the theory of light, the more we must perceive that the powers by which the universe is moved reside in the imperceptible particles of bodies; and that the grand results of nature are but an assemblage of an order of actions that take place in its infinitely small parts; consequently, we cannot institute a series of experiments more interesting than those which tend to develop the properties of light. Our organs of sense are so immediately connected with the fluid that enlightens us, that a notion of having acquired an idea of the mode of action of this fluid presents itself to our minds, as the hope of a striking advance in the knowledge of what composes the organic mechanism of our life, and of that of beings which closely follow the rank assigned to the human species."

Such is a brief description of some of the leading properties of light. Of all the objects that present themselves to the philosophic and contemplative mind, light is one of the noblest and most interesting. The action it exerts on all the combinations of matter, its extreme divisibility, the rapidity of its propagation, the sublime wonders it reveals, and the office it performs in what constitutes the life of organic beings, lead us to consider it as a substance acting the first part in the economy of nature. The magic power which this emanation from the heavens exerts on our organs of vision, in exhibiting to our view the sublime spectacle of the universe, cannot be sufficiently admired. Nor is its power confined to the organs of sight; all our senses, are, in a greater or less degree, subjected to the action of light, and all the objects in this lower creation—whether in the animal, the vegetable, or the mineral kingdoms—are, to a certain extent, susceptible of its influence. Our globe appears to be little more than an accumulation of terrestrial materials introduced into the boundless ocean of the *solar light*, as a theater on which it may display its exhaustless power and energy, and give animation, beauty, and sublimity to every surrounding scene, and to regulate all the powers of nature, and render them subservient to the purposes for which they were ordained. This elementary substance appears to be universal in its movements and in its influence. It descends to us from the solar orb. It wings its way through the voids of space, along a course of ninety-five millions of miles, until it arrives at the outskirts of our globe; it passes freely through the surrounding atmosphere; it strikes upon the clouds, and is reflected by them; it irradiates the mountains, the vales, the forests, the rivers, the seas, and all the productions of the vegetable kingdom, and adorns them with a countless assemblage of colors. It scatters and disperses its rays from one end of creation to another, diffusing itself throughout every sphere of the universe. It flies without intermission from star to star, and from suns to planets, throughout the boundless sphere of immensity, forming a connecting chain and a medium of communication among all the worlds and beings within the wide empire of Omnipotence.

When the sun is said "to rule over the day," it is intimated that he acts as the vicegerent of the Almighty, who has invested him with a mechanical power of giving light, life, and motion to all the beings susceptible of receiving impressions from his radiance. As the servant of his Creator, he distributes blessings without number among all the tribes of sentient and intelligent existence. When his rays illumine the eastern sky in the morning, all nature is enlivened with his presence. When he sinks beneath the western horizon, the flowers droop, the birds retire to their nests, and a mantle of darkness is spread over the landscape of the world. When he approaches the equinox in spring, the animal and vegetable tribes revive and nature puts on a new and a smiling aspect. When he declines toward the winter solstice, dreariness and desolation ensue, and a temporary death takes place among the tribes of the vegetable world. This splendid luminary, whose light embellishes the whole of this lower creation, forms the most lively representation of Him who is the source and the center of all beauty and perfection. "God is a sun," the sun of the moral and spiritual universe, from whom all the emanations of knowledge, love, and felicity descend. "He covereth himself with light as with a garment," and "dwells in light inaccessible and full of glory." The felicity and enjoyments of the future world are adumbrated under the ideas of *light* and *glory*. "The glory of God enlightens the celestial city;" its inhabitants are represented as "the saints *in light;*" it is declared that "their *sun* shall no more go down," and that "the Lord God is their *everlasting light*." So that light not only cheers and enlivens all beings throughout the material creation, but is the emblem of the Eternal Mind, and of all that is delightful and transporting in the scenes of a blessed immortality.

In the formation of light, and the beneficent effects it produces, the wisdom and goodness of the Almighty are conspicuously displayed. Without the beams of the sun and the influence of light, what were all the realms of this world but an undistinguished chaos and so many dungeons of darkness? In vain should we roll our eyes around to behold, amid the universal gloom, the flowery fields, the verdant plains, the flowing streams, the expansive ocean, the moon walking in brightness, the planets in their courses, or the innumerable host of stars. All would be lost to the eye of man, and the "blackness of darkness" would surround him forever. And with how much wisdom has everything been arranged in relation to the motions and minuteness of light? Were it capable of being transformed into a solid substance, and retain its present velocity, it would form the most dreadful and appalling element in nature, and produce universal terror and destruction throughout the universe. That this is not impossible, and could easily be effected by the hand of Omnipotence, appears from such substances as *phosphorus*, where light is supposed to be concentrated in a solid state. But in all its operations and effects, as it is now directed by unerring wisdom and beneficence, it exhibits itself as the most benign and delightful element connected with the constitution of the material system, diffusing splendor and felicity wherever its influence extends.

CHAPTER V.

ON THE REFRACTION OF LIGHT.

Refraction is the turning or bending of the rays of light out of their natural course.

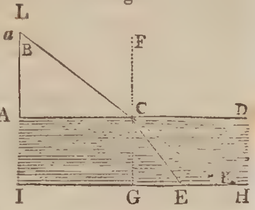
Light, when proceeding from a luminous body—without being reflected from any opaque substance or inflected by passing near one—is invariably found to proceed in straight lines without the least deviation. But if it happens to pass obliquely from one medium to another, it always leaves the direction it had before and assumes a new one. This change of direction, or *bending* of the rays of light is what is called *Refraction*—a term which probably had its origin from the broken appearance which a staff or a long pole exhibits when a portion of it is immersed in water—the word, derived from the Latin *frango*, literally signifying *breaking* or bending.

When light is thus refracted, or has taken a new direction, it then proceeds invariably in a straight line until it meets with a different medium,* when it is again turned out of its course. It must be observed, however, that though we may by this means cause the rays of light to make any number of angles in their course, it is impossible for us to make them describe a curve, except in one single case, namely, where they pass through a medium, the density of which either uniformly increases or diminishes. This is the case with the light of the celestial bodies, which passes downward through our atmosphere, and likewise with that which is reflected upward through it by terrestrial objects. In both these cases it describes a curve of the hyperbolic kind; but at all other times it proceeds in straight lines, or in what may be taken for straight lines without any sensible error.

There are two circumstances essential to refraction. 1. That the rays of light shall pass out of one medium into another of a different density, or of a greater or less degree of resistance. 2. That they pass in an *oblique* direction. The denser the refracting medium, or that into which the ray enters, the greater will be its refracting power; and of two refracting mediums of the same density, that which is of an oily or inflammable nature will have a greater refracting power than the other. The nature of refraction may be more particularly explained and illustrated by the following figure and description:

Let *A D H I*, fig. 2, be a body of water, *A D* its surface, *C* a point in which a ray of light, *B C*, enters from the air into the water. This ray, by the greater density of the water, instead of passing straight forward in its first direction to *K*, will be bent at the point *C*, and pass along in the direction *C E*, which is called the *refracted* ray Let the line *F G* be drawn perpendicular to the surface of the water in *C*, then it is evident that the ray *B C*, in passing out of air, a *rare* medium, into a *dense* medium, as water, is refracted into a ray *C E*, which is *nearer* to the perpendicular *C G* than the incident ray *B C* and, on the contrary, the ray *E C*, passing out of a denser medium into a rarer, will be refracted into *C B*, which is *farther* from the perpendicular.

Fig. 2.



The same thing may be otherwise illustrated as follows: Suppose a hole made in one of the sides of the vessel as at *a*, and a lighted candle placed within two or three feet of it, when empty, so that its flame may be at *L*, a ray of light proceeding from it will pass through the hole, *a*, in a straight line, *L B C K*, until it reach the bottom of the vessel at *K*, where it will form a small circle of light. Having put a mark at the point *K*, pour water into the vessel until it rise to the hight *A D*, and the round spot that was formerly at *K* will appear at *E;* that is, the ray which went straight forward, when the vessel was empty, to *K*, has been bent at the point *C*, where it falls into the water, into the line *C E*. In this experiment it is necessary that the front of the vessel should be of glass, in order that the course of the ray may be seen; and if a little soap be mixed with the water so as to give it a little mistiness, the ray *C E* will be distinctly perceived. If, in place of fresh water, we pour in salt water, it will be found that the ray *B C* is more bent at *C*. In like manner, alcohol will refract the ray *B C* more than salt water, and oil more than alcohol, and a piece of solid glass, of the shape of the water, would refract the light still more than the oil.

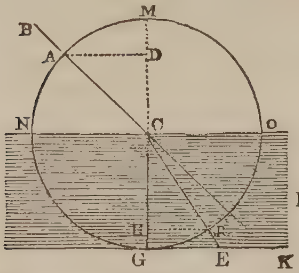
The angle of refraction depends on the obliquity of the rays falling on the refracting surface being always such, that the sine of the incident angle is to the sine of the refracted angle in a given proportion. The *incident* angle is the angle made by a ray of light and a line drawn perpendicular to the refracting surface, at the point where the light enters the surface. The *refracted* angle is the angle made by the ray in the refracting medium with the same perpendicular produced. The *sine* of the angle is a line which serves to measure the angle, being drawn from a point in one leg perpendicular to the other. The following figure (fig. 3) will tend to illustrate these definitions.

---

* By a *medium*, in optics, is meant the space in which a ray of light moves, whether pure space, air, water, glass, diamond, or any other transparent substance through which the rays of light can pass in straight lines.

In this figure, BC is the incident ray, CE the refracted ray, DG the perpendicular, AD the sine of the angle of incidence, ACD, and HR the sine of the angle of refraction GCE. Now, it is a proposition, in optics, that the sine AD of the angle of incidence BCD is either accurately or very nearly in a given proportion to the sine HR of the angle of refraction GCE. This ratio of the sines is as four to three, when the refraction is made out of air into water, that is, AD is to HR as four to three. When the refraction is out of air into glass, the proportion is about as thirty-one to twenty, or nearly as three to two. If the refraction be out of air into diamond, it is as five to two, that is $AD : HR :: 5 : 2$. The denser the medium is, the less is the angle and sine of refraction. If a ray of light, MC, were to pass from air into water, or from empty space into air, in the direction MC, perpendicular to the plane NO, which separates the two mediums, it would suffer no refraction, because one of the essentials to that effect is wanting, namely, the *obliquity* of the incidence.

Fig. 3.



It may also be proper to remark that a ray of light cannot pass out of a denser medium into a rarer, if the angle of incidence exceed a certain limit. Thus a ray of light will not pass out of glass into air, if the angle of incidence exceed $40^\circ 11'$; or out of glass into water, if the angle of incidence exceed $59^\circ 20'$. In such cases refraction will be changed into reflection.

The following common experiments, which are easily performed, will illustrate the doctrine of refraction: Put a shilling, or any other small object which is easily distinguished, into a basin or any other similar vessel, and then retire to such a distance as that the edge of the vessel shall just hide it from your sight. If then you cause another person to fill the vessel with water, you will find that the shilling is rendered perfectly visible, although you have not in the slightest degree changed your position. The reason of this is, that the rays of light, by which it is rendered visible *are bent out of their course.* Thus, suppose the shilling to have been placed at the bottom of the basin at E (fig. 2), the ray of light BC which passes obliquely from the air into water at C, instead of continuing its course to K, takes the direction of CE, and, consequently, an object at E would be rendered visible by rays proceeding in that direction, when they would not have touched it had they proceeded in their direct course.

The same principle is illustrated by the following experiment: Place a basin or square box on a table, and a candle at a small distance from it; lay a small rod or stick across the sides of the basin, and mark the place where the extremity of the shadow falls, by placing a shilling or other object at the point; then let water be poured into the basin, and the shadow will then fall much nearer to the side next the candle than before. This experiment may likewise be performed by simply observing the change produced on the shadow of the side of the basin itself. Again, put a long stick obliquely into deep water, and the stick will seem to be broken at the point where it appears at the surface of the water, the part which is immersed in the water appearing to be bent upward. Hence every one must have observed that in rowing a boat the ends of the oars appear bent or broken every time they are immersed in the water, and their appearance at such times is a representation of the course of the refracted rays. Again, fill a pretty deep jar with water, and you will observe the bottom of the jar considerably elevated, so that it appears much shallower than it did before the water was poured in, in the proportion of nearly a third of its depth which is owing to the same cause as that which makes the end of a stick immersed in water appear more elevated than it would do if there were no refraction. Another experiment may be just mentioned. Put a sixpence in a wine-glass, and pour upon it a little water. When viewed in a certain position, two sixpences will appear in the glass—one image of the sixpence from below, which comes directly to the eye, and another which appears considerably raised above the other, in consequence of the rays of light rising through the water, and being refracted. In this experiment the wine-glass should not be more than half filled with water.

The refraction of light explains the causes of many curious and interesting phenomena both in the heavens and on the earth. When we stand on the banks of a river, and look obliquely through the waters to its bottom, we are apt to think it is much shallower than it really is. If it be eight feet deep in reality, it will appear from the bank to be only six feet; if it be five feet and a half deep, it will appear only about four feet. This is owing to the effects of refraction, by which the bottom of the river is apparently raised by the refraction of the light passing through the water into air, so as to make the bottom appear higher than it really is, as in the experiment with the jar of water. This is a circumstance of some importance to be known and attended to in order to personal safety; for many school-boys and other young persons have lost their lives by attempting to ford a river, the bottom of which appeared to be within their reach when they viewed it from its banks; and even adult travelers on horseback have sometimes fallen victims to this optical deception; and this is not the only case in which a knowledge of the laws of nature may be useful in guarding us against dangers and fatal accidents.

It is likewise owing to this refractive power in water that a skillful marksman, who wishes to shoot fish under water, is obliged to take aim considerably *below* the fish as it appears, because it seems much nearer the top of the water than it really is. An acquaintance with this property of light is particularly useful to divers, for, in any of their movements or operations, should they aim directly at the object, they would arrive at a point considerably beyond it; whereas, by having some idea of the depth of the water, and the angle which a line drawn from the eye to the object makes with its surface, the point at the bottom of the water, between the eye and the object at which the aim is to be taken, may be easily determined. For the same reason, a person below water does not see objects distinctly. For, as the aqueous humor of the eye has the same refractive power as water, the rays of light from any object under water will undergo no refraction in passing through the cornea and aqueous humor, and will therefore meet in a point far beyond the retina. But if any person, accustomed to go below water, should use a pair of spectacles, consisting of two convex lenses, the radius of whose surface is three-tenths of an inch—which is nearly the radius of the convexity of the cornea—he will see objects as distinctly below water as above it.

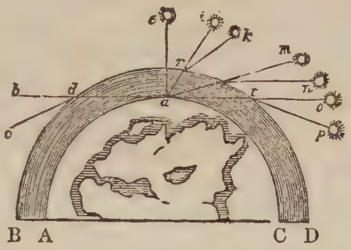
It is owing to refraction that we cannot judge so accurately of magnitudes and distances in water as in air. A fish looks considerably larger in water than when taken out of it. An object plunged *vertically* into water always appears contracted, and the more so as its upper extremity approaches nearer the surface of the water. Everything remaining in the same situation, if we take the object gradually out of the water, and it be of a slender form, we shall see it become larger and larger, by a rapid development, as it were, of all its parts. The distortion of objects, seen through a crooked pane of glass in a window, likewise arises from its unequal refraction of the rays that pass through it. It has been calculated that, in looking through the common glass of a window, objects appear about the one-thirtieth of an inch out of their real place, by means of the refraction.

Refraction likewise produces an effect upon the *heavenly bodies*, so that their apparent positions are generally different from their real. By the refractive power of the atmosphere the sun is seen before he comes to the horizon in the morning, and after he sinks beneath it in the evening; and hence this luminary is never seen in the place in which it really is, except when it passes the zenith at noon, to places within the torrid zone. The sun is visible when actually thirty-two minutes of a degree below the horizon, and when the opaque rotundity of the earth is interposed between our eye and that orb, just on the same principle as, in the experiment with the shilling and basin of water, the shilling was seen when the edge of the basin interposed between it and the sight. The refractive power of the atmosphere has been found to be much, greater in certain cases, than what has been now stated. In the year 1595, a company of Dutch sailors having been wrecked on the shores of Nova Zembla, and having been obliged to remain in that desolate region during a night of more than three months, beheld the sun make his appearance in the horizon about sixteen days before the time in which he should have risen according to calculation, and when his body was actually more than four degrees below the horizon; which circumstance has been attributed to the great refractive power of the atmosphere in those intensely cold regions. This refraction of the atmosphere, which renders the apparent rising and setting of the sun both earlier and later than the real, produces, at least, one important beneficial effect. It procures for us the benefit of a much longer day, at all seasons of the year, than we should enjoy did not this property of the atmosphere produce this effect. It is owing to the same cause that the discs of the sun and moon appear elliptical or oval when seen in the horizon, their horizontal diameters appearing longer than their vertical, which is caused by the greater refraction of the rays coming from the lower limb, which is immersed in the densest part of the atmosphere.

The illumination of the heavens which precedes the rising of the sun, and continues some time after he is set, or what is commonly called the morning and evening *twilight*, is likewise produced by the atmospherical refraction, which circumstance forms a very pleasing and beneficial arrangement in the system of nature. It not only prolongs to us the influence of the solar light, and adds nearly two hours to the length of our day, but prevents us from being transported all at once from the darkness of midnight to the splendor of noonday, and from the effulgence of day to the gloom and horrors of the night, which would bewilder the traveler and navigator in their journeys by sea or land, and strike the living world with terror and amazement.

The following figure will illustrate the position now stated, and the manner in which the refraction of the atmosphere produces these effects: Let *A a C*, fig. 4, represent one-half of our globe, and the dark space between that curve and *B r D*, the atmosphere. A person standing on the earth's surface at *a* would see the sun rise at *b*, when that luminary was in reality only at *c*, more than half a degree below the horizon. When the rays of the sun, after having proceeded in a straight line through empty space, strike the upper part of the atmosphere at the point *d*, they are bent out of their right-lined course by the refraction of the atmosphere, into the direction *d a*, so that the body of the sun, though actually intercepted by the curve of the earth's convexity, consisting of a dense mass of land or water, is actually beheld by the spectator at *a*. The refractive power of the atmosphere gradually diminishes from the horizon to the zenith, and increases from the zenith to the horizon, in proportion to the density of its different strata, being densest at its lower extremity next the earth, and more rare toward its higher regions. If a person at *a* had the sun, *e*, in his zenith, he would see him where he really is; for his rays coming perpendicularly through the atmosphere, would be equally attracted in all directions, and would, therefore, suffer no inflection. But, about two in the afternoon, he would see the sun at *i*, though, in reality, he was at *k*, thirty-three seconds lower than his apparent situation. At about four in the afternoon he would see him at *m*, when he is at *n*, one minute and thirty-eight seconds from his apparent situation. But at six o'clock, when we shall suppose he sets, he will be seen at *o*, though he is at that time at *p*, more than thirty-two minutes below the horizon. These phenomena arise from the different refractive powers of the atmosphere at different elevations, and from the obliquity with which the rays of light fall upon it; for we see every object along that line in which the rays from it are directed by the last medium through which they passed.

Fig. 4.



The same phenomena happen in relation to the moon, the planets, the comets, the stars, and every other celestial body, all of which appear more elevated, especially when near the horizon, than their true places. The variable and increasing refraction from the zenith to the horizon is a source of considerable trouble and difficulty in making astronomical observations, and in nautical calculations; for, in order to determine the real altitudes of the heavenly bodies, the exact degree of refraction at the observed elevation must be taken into account. To the same cause we are to ascribe a phenomenon that has sometimes occurred, namely, that the moon has been seen rising totally eclipsed, while the sun was still visible in the opposite quarter of the horizon. At the middle of a total eclipse of the moon, the sun and moon are in opposition, or 180 degrees asunder; and, therefore, were no atmosphere surrounding the earth, these luminaries, in such a position, could never be seen above the horizon at the same time. But, by the refraction of the atmosphere near the horizon, the bodies of the sun and moon are raised more than 32 minutes above their true places, which is equal, and sometimes more than equal, to the apparent diameters of these bodies.

EXTRAORDINARY CASES OF REFRACTION IN RELATION TO TERRESTRIAL OBJECTS.

In consequence of the accidental condensation of certain strata of the atmosphere, some very singular effects have been produced in the apparent elevation of terrestrial objects to a position much beyond that in which they usually appear. The following instance is worthy of notice. It is taken from the Philosophical Transactions of London for 1798, and was communicated by W. Latham, Esq., F. R. S., who observed the phenomenon from Hastings, on the south coast of England: "On July 26, 1797, about five o'clock in the afternoon, as I was sitting in my dining-room in this place, which is situated upon the Parade, close to the seashore, nearly fronting the south, my attention was excited by a number of people running down to the seaside. Upon inquiring the reason, I was informed that the coast of France was plainly to be distinguished by the naked eye. I immediately went down to the shore, and was surprised to find that, even without the assistance of a telescope, I could very plainly see the cliffs on the opposite coast, which, at the nearest part, are between forty and fifty miles distant, and are not to be discerned from that low situation by the aid of the best glasses. They appeared to be only a few miles off, and seemed to extend for some leagues along the coast. I pursued my walk along the shore eastward, close to the water's edge, conversing with the sailors and fishermen upon the subject. They at first would not be persuaded of the reality of the appearance; but they soon became so thoroughly convinced by the cliffs gradually appearing more elevated, and approaching nearer, as it were, that they pointed out and named to me the different places they had been accustomed to visit, such as the Bay, the Old Head, or Man, the Windmill, &c., at Bologne, St. Vallery, and other places on the coast of Picardy, which they afterward confirmed, when they viewed them through their telescopes. Their observations were, that the places appeared as near as if they were sailing, at a small distance, into the harbors. The day on which this phenomenon was seen was extremely hot; it was high water at Hastings about two o'clock, P. M., and not a breath of wind was stirring the whole day." From the summit of an adjacent hill, a most beautiful scene is said to have presented itself. At one glance the spectators could see Dungeness, Dover Cliffs, and the French coast, all along from Calais to St. Vallery, and, as some affirmed, as far to the westward as Dieppe, which could not be much less than eighty or ninety miles. By the telescope the French fishing-boats were plainly seen at anchor, and the different colors of the land on the hights, with the buildings, were perfectly discernible.

This singular phenomenon was doubtless occasioned by an extraordinary refraction, produced by an unusual expansion or condensation of the lower strata of the atmosphere, arising from circumstances connected with the extreme heat of the season. The objects seem to have been apparently raised far above their natural positions; for, from the beach at Hastings, a straight line drawn across toward the French coast, would have been intercepted by the curve of the waters. They seem, also, to have been magnified by the refraction, and brought, apparently, four or five times nearer the eye, than in the ordinary state of the atmosphere.

The following are likewise instances of unusual refraction: When Captain Colby was ranging over the coast of Caithness, with the telescope of his great Theodolite, on the 21st of June, 1819, at 8 o'clock, P. M., from Corryhabbie Hill, near Mortlich, in Banffshire, he observed a brig over the land of Caithness, sailing to the westward in the Pentland Frith, between the Dunnet and Duncansby heads. Having satisfied himself as to the fact, he requested his assistants, Lieutenants Robe and Dawson, to look through the telescope, which they immediately did, and observed the brig likewise. It was very distinctly visible for several minutes, while the party continued to look at it, and to satisfy themselves as to its position. The brig could not have been less than from ninety to one hundred miles distant; and, as the station on Corryhabbie is not above 850 yards above the sea, the phenomenon is interesting. The thermometer was at 44°. The night and day preceding the sight of the brig had been continually rainy and misty, and it was not until seven o'clock of the evening of the 21st that the clouds cleared off the hill.*

Captain Scoresby relates a singular phenomenon of this kind, which occurred while he was traversing the Polar seas. His ship had been separated by the ice from that of his father for a considerable time, and he was looking out for her every day with great anxiety. At length, one evening, to his utter astonishment, he saw her suspended in the air, in an inverted position, traced on the horizon in the clearest colors, and with the most distinct and perfect representation. He sailed in the direction in which he saw this visionary phenomenon, and actually found his father's vessel by its indication. He was divided from him by immense masses of icebergs, and at such a distance that it was quite impossible to have seen the ship in her actual situation, or to have seen her at all, if her spectrum had not been thus raised several degrees above the horizon into the sky by this extraordinary refraction. She was reckoned to be seventeen miles beyond the visible horizon, and thirty miles distant.

Mrs. Somerville states that a friend of hers, while standing on the plains of Hindostan, saw the whole upper chain of the Himalaya Mountains start into view, from a sudden change in the density of the air, occasioned by a heavy shower, after a long course of dry and hot weather. In looking at distant objects through a telescope, over the top of a ridge of hills, about two miles distant, I have several times observed that some of the more distant objects which are sometimes hid by the interposition of a ridge of hills, are at other times distinctly visible above them. I have sometimes observed that objects near the middle of the field of view of a telescope, which was in a fixed position, have suddenly appeared to descend to the lower part, or ascend to the upper part of the field, while the telescope remained unaltered. I have likewise seen, with a powerful telescope, the Bell Rock Lighthouse, at the distance of about twenty miles, to appear as if contracted to less than two-thirds of its usual apparent hight, while every part of it was quite distinct and well-defined, and in the course of an hour, or less, appeared to shoot up to its usual apparent elevation — all which phenomena are evidently produced by the same cause to which we have been adverting.

---

* Edinburgh Philosophical Journal for October 1819, p. 411.

Such are some of the striking effects produced by the refraction of light. It enables us to see objects in a direction where they are not; it raises, apparently, the bottoms of lakes and rivers; it magnifies objects when their light passes through dense mediums; it makes the sun appear above the horizon when he is actually below it, and thus increases the length of our day; it produces the Aurora and the evening twilight, which forms, in many instances, the most delightful part of a summer day; it prevents us from being involved in total darkness, the moment after the sun has descended beneath the horizon; it modifies the appearances of the celestial bodies, and the directions in which they are beheld; it tinges the sun, moon, and stars, as well as the clouds, with a ruddy hue when near the horizon; it elevates the appearance of terrestrial objects, and, in certain extraordinary cases, brings them nearer to our view, and enables us to behold them when beyond the line of our visible horizon. In combination with the power of reflection, it creates visionary landscapes, and a variety of grotesque and extraordinary appearances, which delight and astonish, and sometimes appall the beholders. In short, as we shall afterward see more particularly, the refraction of light through glasses of different figures forms the principle on which telescopes and microscopes are constructed, by which both the remote and the minute wonders of creation have been disclosed to view. So that, had there been no bodies capable of refracting the rays of light, we should have remained forever ignorant of many sublime and august objects in the remote regions of the universe, and of the admirable mechanism and the countless variety of minute objects which lie beyond the range of the unassisted eye in our lower creation, all of which are calculated to direct our views, and to enlarge our conceptions of the Almighty Creator.

In the operation of the law of refraction in these and numerous other instances, we have a specimen of the diversified and beneficent effects which the Almighty can produce by the agency of a single principle in nature. By the influence of the simple law of gravitation the planets are retained in their orbits, the moon directed in her course around the earth, and the whole of the bodies connected with the sun preserved in one harmonious system. By the same law the mountains of our globe rest on a solid basis, the rivers flow through the plains toward the seas, the ocean is confined to its prescribed boundaries, and the inhabitants of the earth are retained to its surface, and prevented from flying upward through the voids of space. In like manner, the law by which light is refracted produces a variety of beneficial effects essential to the present constitution of our world and the comfort of its inhabitants. When a ray of light enters obliquely into the atmosphere, instead of passing directly through it bends a little downward, so that the greater portion of the rays which thus enter the atmospheric mass descend by inflection to the earth. We then enjoy the benefits of that light which would otherwise have been totally lost. We perceive the light of day an hour before the solar orb makes its appearance, and a portion of its light is still retained when it has descended nearly eighteen degrees below our horizon. We thus enjoy, throughout the year, seven hundred and thirty hours of light which would have been lost had it not been refracted down upon us from the upper regions of the atmosphere. To the inhabitants of the polar regions this effect is still more interesting and beneficial. Were it not for their twilight, they would be involved, for a much longer period than they now are, in perpetual darkness; but by the powerful refraction of light which takes place in the frigid zones, the day sooner makes its appearance toward spring, and their long winter nights are, in certain cases, shortened by the period of thirty days. Under the poles, where the darkness of night would continue six months without intermission, if there were no refraction, total darkness does not prevail during the one-half of this period. When the sun sets, at the north pole, about the 23d of September, the inhabitants (if any) enjoy a perpetual aurora until he has descended eighteen degrees below the horizon. In his course through the ecliptic the sun is two months before he can reach this point, during which time there is a perpetual twilight. In two months more he arrives again at the same point, namely, eighteen degrees below the horizon, when a new twilight commences, which is continually increasing in brilliancy for other two months, at the end of which the body of this luminary is seen rising in all its glory. So that, in this region, the light of day is enjoyed in a greater or less degree, for ten months without interruption by the effects of atmospheric refraction; and, during the two months when the influence of the solar light is entirely withdrawn, the moon is shining above the horizon for two half months without intermission; and thus it happens that no more than two separate fortnights are passed in absolute darkness; and this darkness is alleviated by the light of the stars and the frequent coruscations of the Aurora Borealis. Hence it appears that there are no portions of our globe that enjoy, throughout the year, so large a portion of the solar light as these northern regions, which is chiefly owing to the refraction of the atmosphere.

The refraction of light by the atmosphere, combined with its power of reflecting it, is likewise the cause of that universal light and splendor which appears on all the objects around us. Were the earth disrobed of its atmosphere, and exposed naked to the solar beams, in this case we might see the sun without having day, strictly so called. His rising would not be preceded by any twilight as it now is. The most intense darkness would cover us until the very moment of his rising; he would then suddenly break out from under the horizon with the same splendor he would exhibit at the highest part of his course, and would not change his brightness until the very moment of his setting, when, in an instant, all would be black as the darkest night. At noonday we should see the sun like an intensely-brilliant globe shining in a sky as black as ebony, like a clear fire in the night seen in the midst of an extensive field, and his rays would show us the adjacent objects immediately around us: but the rays which fall on the objects remote from us would be forever lost in the expanse of the heavens. Instead of the beautiful azure of the sky, and the colors which distinguish the face of nature by day, we should see nothing but an abyss of darkness, and the stars shining from a vault as dark as chaos. Thus there would be no day, such as we now enjoy, without the atmosphere: since it is by the refraction and reflections connected with this aerial fluid that light is so modified and directed as to produce all that beauty, splendor, and harmony which appear on the concave of the sky, and on the objects which diversify our terrestrial abode.

The effect of refraction, in respect to *terrestrial* objects, is likewise of a beneficial nature. The quantity of this refraction is estimated by Dr. Maskelyne at one-tenth of the distance of the object observed, expressed in degrees of a great circle. Hence, if the distance be 10,000 fathoms, its tenth part 1000 fathoms, is the sixtieth part of a degree, or one minute, which is the refraction in altitude; Le Gendre estimates it at one-fourteenth, De Lambre at one-eleventh, and others at a twelfth of the distance; but it must be supposed to vary at different times and places according to the varying state of the atmosphere. This refraction, as it makes objects appear to be raised higher than they really are, enlarges the extent of our landscapes, and enables us to perceive distant objects which would otherwise have been invisible. It is particularly useful to the navigator at sea. It is one important object of the mariner, when traversing his course, to look out for capes and headlands, rocks and islands, so as to descry them as soon as they are within the reach of his eye Now, by means of refraction, the tops of hills and the elevated parts of coasts are apparently raised into the air, so that they may be discovered several leagues farther off on the sea than they would be did no such refractive power exist. This circumstance is therefore a considerable benefit to the science of navigation, in enabling the mariner to steer his course aright, and to give him the most early warning of the track he ought to take, or of the dangers to which he may be exposed.

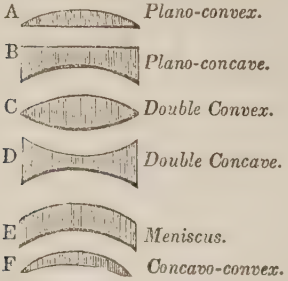
In short, the effects produced by the refraction and reflection of light on the scenery connected with our globe teach us that these principles, in the hand of the Almighty, might be so modified and directed as to produce the most picturesque, the most glorious, and wonderful phenomena, such as mortal eyes have never yet seen, and of which human imagination can form no conception; and in other worlds, more resplendent and magnificent than ours, such scenes may be fully realized, in combination with the operation of physical principles and agents with which we are at present unacquainted. From what we already know of the effects of the reflection and the refraction of light, it is not beyond the bounds of probability to suppose that, in certain regions of the universe, light may be reflected and refracted through different mediums, in such a manner as to present to the view of their inhabitants the prominent scenes connected with distant systems and worlds, and to an extent as shall infinitely surpass the effects produced by our most powerful telescopes.

CHAPTER III.

ON THE REFRACTION OF LIGHT THROUGH SPHERICAL TRANSPARENT SUBSTANCES, OR LENSES.

It is to the refraction of light that we are indebted for the use of lenses or artificial glasses to aid the powers of the vision. It lays the foundation of telescopes, microscopes, camera obscuras, phantasmagorias, and other optical instruments, by which so many beautiful, useful, and wonderful effects have been produced. In order, therefore, to illustrate the principles on which such instruments are constructed, it is necessary to explain the manner in which the rays of light are refracted and modified when passing through spherical mediums of different forms. I do not intend, however, to enter into the minutiæ of this subject, nor into any abstract mathematical demonstrations, but shall simply offer a few explanations of general principles, and several experimental illustrations, which may enable the general reader to understand the construction of the optical instruments to be afterward described.

Fig. 5.



A lens is a transparent substance of a different density from the surrounding medium, and terminating in two surfaces, either both spherical, or one spherical and the other plain. It is usually made of *glass*, but may also be formed of any other transparent substance, as ice, crystal, diamonds, pebbles, or fluids of different densities and refractive powers, inclosed between concave glasses. Lenses are ground into various forms, according to the purpose they are intended to serve. They may be generally distinguished as being either *convex* or *concave*. A convex glass is thickest in the middle, and thinner toward the extremities. Of these there are various forms, which are represented in fig. 5. *A* is a *plano-convex* lens, which has one side plane, and the other spherical or convex. *B* is a *plano-concave*, which is plane on the one side and concave on the other. *C* is a *double-convex*, or one which is spherical on both sides. *D*, a *double-concave*, or concave on both sides. *E* is called a *meniscus*, which is convex on one side and concave on the other. *F* is a *concavo-convex*, the convex side of which is of a smaller sphere than the concave. In regard to the *degree* of convexity or concavity in lenses, it is evident that there may be almost an infinite variety. For every convex surface is to be considered as the segment of a circle, the diameter and the radius of which may vary to almost any extent. Hence lenses have been formed by opticians, varying from one fiftieth of an inch in radius to two hundred feet. When we speak of the length of the radius of a lens, as, for instance when we say that a lens is two inches or forty inches radius, we mean that the convex surface of the glass is the part of a circle, the radius of which, or half the diameter, is two inches or forty inches; or, in other words, were the portion of the sphere on which it is ground formed into a globe of corresponding convexity, it would be four inches or eighty inches in diameter.

The *axis* of a lens is a straight line drawn through the center of its spherical surface; and, as the spherical sides of every lens are arches of circles, the axis of the lens would pass through the center of that circle of which its sides are segments. *Rays* are those emanations of light which proceed from a luminous body, or from a body that is illuminated. The *Radiant* is that body or object which emits the rays of light, whether it be a self-luminous body, or one that only reflects the rays of light. Rays may proceed from a Radiant in different directions. They may be either parallel, converging, or diverging. *Parallel* rays are those which proceed *equally distant* from each other through their whole course. Rays proceeding from the sun, the planets, the stars, and distant terrestrial objects are considered as parallel, as in fig. 6. *Converging* rays are such as, proceeding from a body, approach nearer and nearer in their progress, tending to a certain point where they all unite. Thus the rays proceeding from the object *A B* (fig. 7) to the point *F*, are said to converge toward that point. All convex glasses cause parallel rays which fall upon them to converge in a greater or less degree; and they render converging rays still more convergent. If *A B*, fig. 7, represent a convex lens, and *H G I* parallel rays falling upon it, they will be refracted, and converge toward the point *F*, which is called the *focus* or burning point; because when the sun's rays are thus converged to a point by a large lens, they set on fire combustible substances. In this point the rays meet and intersect each other. *Diverging rays* are those which, proceeding from any point, as *A*, fig. 8, continually recede from each other as they pass along in their course toward *B C*. All the rays which proceed from near objects, as a window in a room, or an adjacent house or garden, are more or less divergent. The following figures show the effects of parallel, converging, and diverging rays, in passing through a double convex lens:

Fig. 6.

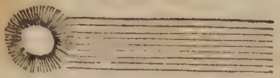


Fig. 7.

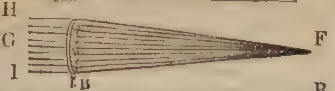

Fig. 8.

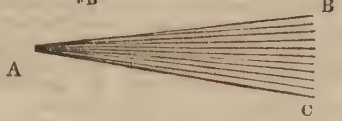

Fig. 11.

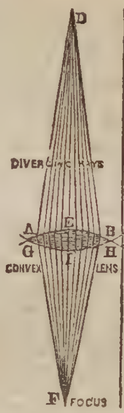

Fig. 9.

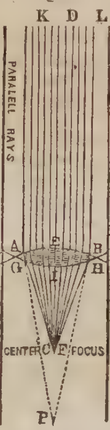

Fig. 10.

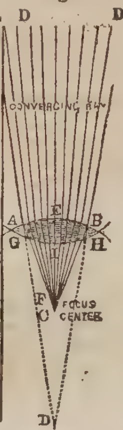

Fig. 9 shows the effects of parallel rays, *K A*, *D E*, *L B*, falling on a convex glass, *A B*. The rays which fall near the extremities at *A* and *B* are bent or refracted toward *C F*, the focus, and center of convexity. It will be observed that they are less refracted as they approach the center of the lens, and the central ray *D E C*, which is called the *axis* of the lens, and which passes through its center, suffers no refraction. Fig. 10 exhibits the course of *converging* rays when passing through a similar lens. In this case the rays converge to a focus *nearer* to the lens than the center; for a convex lens uniformly increases the convergence of converging rays. The converging rays here represented may be conceived as having been refracted by another convex lens of a longer focus, and passing on toward a point of convergence, were intercepted by the lens *A B*. The point *D* is the place where the rays would have converged to a focus, had they not been thus intercepted. Fig. 11 represents the course of diverging rays when falling on a double convex glass. In this case, the rays *D B*, *D A*, &c., after passing through the lens, converge to a focus at a point considerably farther from the lens than its center, as at *F*. Such rays must be considered as proceeding from near objects, and the fact may be illustrated by the following experiment: Take a common reading glass, and hold it in the rays of the sun, opposite a sheet of writing paper or a white wall, and observe *at what distance* from the glass the rays on the paper converge to a small, distinct white spot. This distance gives the focal length of the lens by parallel rays. If now we hold the glass within a few feet of a window, or a burning candle, and receive its image on the paper, the focal distance of the image from the glass will be found to be longer. If, in the former case, the focal distance was twelve inches, in the latter case it will be thirteen, fifteen, or sixteen inches, according to the distance of the window or the candle from the glass.

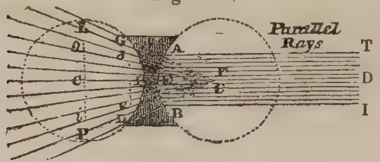
If the lens *A B*, fig. 9, on which parallel rays are represented as falling, were a *plano-convex*, as represented at A, fig. 5, the rays would converge to a point *P*, at double the radius, or the whole diameter of the sphere of which it is a segment. If the thickness, of a plano convex be considered, and if it be exposed on its convex side to parallel rays as those of the sun, the focus will be at the distance of *twice the radius, wanting two-thirds of the thickness of the lens*. But if the same lens be exposed with its plane side to parallel rays, the focus will then be precisely at the distance of twice the radius from the glass.

The effects of *concave* lenses are directly opposite to those of convex. Parallel rays, striking one of those glasses, instead of converging toward a point, are made to *diverge.* Rays already divergent are rendered more so, and convergent rays are made less convergent. Hence objects seen through concave glasses appear considerably smaller and more distant than they really are. The following diagram, fig. 12, represents the course of parallel rays through a double concave lens, where the parallel rays *T A*, *D E*, *I B*, &c. when passing through the concave glass *A B*, diverge into the rays *G L*, *E C*, *H P*, &c., as if they proceeded from *F*, a point before the lens, which is the principal focus of the lens:

Fig. 12.



The principal focal distance, *E F*, is the same as in convex lenses. Concave glasses are used to correct the imperfect vision of short-sighted persons. As the form of the eye of such persons is too convex, the rays are made to converge before they reach the optic nerve; and therefore a concave glass, causing a little divergency, assists this defect of vision, by diminishing the effect produced by the too great convexity of the eye, and lengthening its focus. These glasses are seldom used, in modern times, in the construction of optical instruments, except as eye-glasses for small pocket perspectives, and opera-glasses.

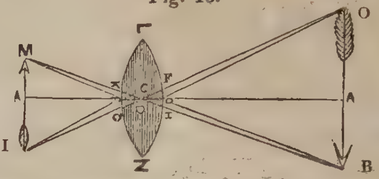
To find the focal distance of a concave glass.—Take a piece of pasteboard or card paper, and cut a round hole in it, not larger than the diameter of the lens; and on another piece of pasteboard describe a circle whose diameter is just double the diameter of the hole. Then apply the piece with the hole in it to the lens, and hold them in the sunbeams, with the other piece at such a distance behind that the light proceeding from the hole may spread or diverge so as precisely to fill the circle; then the distance of the circle from the lens is equal to its virtual focus, or to its radius, if it be a double concave, and to its diameter, if a plano-concave. Let *d*, *e* (fig. 12) represent the diameter of the hole, and *g*, *i*, the diameter of the circle, then the distance *C*, *I*, is the virtual focus of the lens.*

The *meniscus*, represented at *E*, fig. 5, is like the crystal of a common watch, and, as the convexity is the same as the concavity, it neither magnifies nor diminishes. Sometimes, however, it is made in the form of a crescent, as at *F*, fig. 5, and is called a *concavo-convex* lens; and, when the convexity is greater than the concavity, or when it is thickest in the middle, it acts nearly in the same way as a double or plano-convex lens of the same focal distance.

OF THE IMAGES FORMED BY CONVEX LENSES.

It is a remarkable circumstance, and which would naturally excite admiration, were it not so common and well known, that *when the rays of light from any object are refracted through a convex lens, they paint a distinct and accurate picture of the object before it, in all its colors, shades, and proportions.* Previous to experience, we could have had no conception that light, when passing through such substances, and converging to a point, could have produced so admirable an effect—an effect on which the construction and utility of all our optical instruments depend. The following figure will illustrate this position:

Fig. 13.



Let *L N* represent a double convex lens, *A*, C, *a* its axis, and *O B* an object perpendicular to it. A ray passing from the extremity of the object at *O*, after being refracted by the lens at *F*, will pass on in the direction *F I*, and form an image of that part of the object at *I*. This ray will be the axis of all the rays which fall on the lens from the point *O*, and *I* will be the focus where they will all be collected. In like manner, *B C M* is the axis of that parcel of rays which proceed from the extremity of the object *B*, and their focus will be at *M*; and since all the points in the object between *O* and *B* must necessarily have their foci between *I* and *M* a complete picture of the points from which they come will be depicted, and consequently an image of the whole object *O B*.

It is obvious, from the figure, that the image of the object is formed in the focus of the lens in an *inverted position.* It must necessarily be in this position, as the rays cross at *C*, the center of the lens; and as it is impossible that the rays from the upper part of the object, O, can be carried by refraction to the upper end of the image at *M*. This is a universal principle in relation to convex lenses of every description, and requires to be attended to in the construction and use of all kinds of telescopes and microscopes. It is easily illustrated by experiment. Take a convex lens of eight, twelve, or fifteen inches focal distance, such as a reading glass, or the glass belonging to a pair of spectacles, and holding it, at its focal distance from a white wall, in a line with a burning candle, the flame of the candle will be seen depicted on the wall in an inverted position, or turned upside down. The same experiment may be performed with a window-sash, or any other bright object. But the most beautiful exhibition of the images of objects formed by convex lenses is made by darkening a room, and placing a convex lens of a long focal distance in a hole cut out of the window-shutter; when a beautiful inverted landscape or picture of all the objects before the window, will be painted on a white paper or screen placed in the focus of the glass. The image thus formed exhibits not only the proportions and colors, but also the motions of all the objects opposite the lens, forming, as it were, a living landscape. This property of lenses lays the foundation of the camera obscura, an instrument to be afterward described.

The following principles in relation to images formed by convex lenses, may be stated: 1. That *the image subtends the same angle at the center of*

---

* This mode of finding the focus of a concave lens may be varied as follows: Let the lens be covered with paper, having two small circular holes; and, on the paper for receiving the light, describe also two small circles, but with their centers at twice the distance from each other of the centers of the circles. Then move the paper to and from, until the middle of the sun's light, coming through the holes, falls exactly on the middle of the circles; that distance of the paper from the lens will be the focal length required.

the glass as the object itself does. Were an eye placed at *C*, the center of the lens *L N*, fig. 13, it would see the object *O B* and the image *I M* under the same optical angle, or, in other words, they would appear equally large; for, whenever right lines intersect each other, as *O I* and *B M*, the opposite angles are always equal, that is, the angle *M C I* is equal to the angle *O C B*. 2. *The length of the image formed by a convex lens is, to the length of the object, as the distance of the image is to the distance of the object from the lens;* that is, *M I* is to *O B*: :as C A to *C A*. Suppose the distance of the object *C A* from the lens to be forty-eight inches, the length of the object *O B*=sixteen inches, and the distance of the image from the lens six inches, then the length of the image will be found by the following proportion, 48: 16: :6: 2, that is, the length of the image, in such a case, is two inches. 3. *If the object be at an infinite distance, the image will be formed exactly in the focus.* 4. *If the object be at the same distance from the lens as its focus, the image is removed to an infinite distance on the opposite side;* in other words, the rays will proceed in a *parallel* direction. On this principle, lamps on the streets are sometimes directed to throw a bright light along a footpath where it is wanted, when a large convex glass is placed at its focal distance from the burner; and on the same principle, light is thrown to a great distance from lighthouses, either by a very large convex lens of a short focal distance, or by a concave reflector. 5. *If the object be at double the distance of the focus from the glass, the image will also be at double the distance of the focus from the glass.* Thus, if a lens of six inches focal distance be held at twelve inches' distance from a candle, the image of the candle will be formed at twelve inches from the glass on the other side. 6. *If the object be a little farther from the lens than its focal distance, an image will be formed at a distance from the object, which will be greater or smaller in proportion to the distance* For example, if a lens five inches focus be held at a little more than five inches from a candle, and a wall or screen at five feet six inches' distance receive the image, a large and inverted image of the candle will be depicted, which will be magnified in proportion as the distance of the wall from the candle exceeds the distance of the lens from the candle. Suppose the distance of the lens to be five and a half inches, then the distance of the wall where the image is formed, being twelve times greater, the image of the candle will be magnified twelve times. If *M I* (fig. 13) be considered as the object, then *O B* will represent the magnified image on the wall. On this principle, the image of the object is formed by the small object-glass of a compound microscope. On the same principle, the large pictures are formed by the Magic Lantern and the Phantasmagoria; and in the same way small objects are represented in a magnified form on a sheet or wall by the Solar microscope. 7. *All convex lenses magnify the objects seen through them, in a greater or less degree.* The shorter the focal distance of the lens, the greater is the magnifying power. A lens four inches focal distance will magnify objects placed in the focus two times in length and breadth; a lens two inches focus will magnify four times; a lens one inch focus, eight times; a lens half an inch focus, sixteen times, &c., supposing eight inches to be the least distance at which we see near objects distinctly. In viewing objects with small lenses, the object to be magnified should be placed exactly at the focal distance of the lens, and the eye at about the same distance on the other side of the lens. When we speak of magnifying power, as, for example, that a lens one inch focal distance magnifies objects eight times, it is to be understood of the *lineal* dimensions of the object. But as every object at which we look has breadth as well as length, the *surface* of the object is in reality magnified sixty-four times, or the square of its lineal dimensions; and for the same reason a lens half an inch focal distance magnifies the *surfaces* of objects 256 times.

REFLECTIONS DEDUCED FROM THE PRECEDING SUBJECT.

Such are some of the leading principles which require to be recognized in the construction of refracting telescopes, microscopes, and other dioptric instruments whose performance chiefly depends on the *refraction* of light. It is worthy of particular notice, that all the phenomena of optical lenses now described depend upon that peculiar property which the Creator has impressed upon the rays of light, that, *when they are refracted to a focus by a convex transparent substance, they depict an accurate image of the objects whence they proceed.* This, however common, and however much overlooked by the bulk of mankind, is, indeed, a very wonderful property with which light has been indued. Previous to experience, we could have had no conception that such an effect would be produced; and, in the first instance, we could not possibly have traced it to all its consequences. All the objects in creation might have been illuminated as they now are, for aught we know, without sending forth either direct or reflected rays *with the property of forming exact representations of the objects whence they proceed.* But this we find to be a universal law in regard to light of every description, whether as emanating directly from the sun, or as reflected from the objects he illuminates, or as proceeding from bodies artificially enlightened. It is a law or a property of light not only in our own system, but throughout all the systems of the universe to which mortal eyes have yet penetrated. The rays from the most distant star which astronomers have described are indued with this property, otherwise they could never have been perceived by means of our optical instruments; for it is by the pictures or images formed in these instruments that such distant objects are brought to view. Without this property of light, therefore, we should have had no telescopes, and, consequently, we could not have surveyed, as we can now do, the hills and vales, the deep caverns, the extensive plains, the circular ranges of mountains, and many other novel scenes which diversify the surface of our moon. We should have known nothing of the stupendous spots which appear on the surface of the sun—of the phases of Venus—of the satellites and belts of Jupiter—of the majestic rings of Saturn—of the existence of Uranus and his six moons, or of the planets Vesta, Juno, Ceres, and Pallas, nor could the exact bulks of any of these bodies have been accurately determined. But, above all, we should have been entirely ignorant of the wonderful phenomena of double stars—which demonstrate that suns revolve around suns—of the thousands and millions of stars which crowd the profundities of the Milky Way and other regions of the heavens—of the thousands of nebulæ or starry systems which are dispersed throughout the immensity of the firmament, and many other objects of sublimity and grandeur, which fill the contemplative mind with admiration and awe, and raise its faculties to higher conceptions than it could otherwise have formed of the omnipotence and grandeur of the Almighty Creator.

Without this property of the rays of light, we should, likewise, have wanted the use of the microscope, an instrument which has disclosed a world invisible to common eyes, and has opened to our view the most astonishing exhibitions of Divine mechanism, and of the wisdom and intelligence of the Eternal Mind. We should have been ignorant of those tribes of living beings, invisible to the unassisted eye, which are found in water, vinegar, and many other fluids, many of which are twenty thousand times smaller than the least visible point, and yet display the same admirable skill and contrivance in their construction as are manifested in the formation of the larger animals. We should never have beheld the purple tide of life, and even the globules of the blood rolling with swiftness through veins and arteries smaller than the finest hair; or had the least conception that numberless species of animated beings, so minute that a million of them are less than a grain of sand, could have been rendered visible to human eyes, or that such a number of vessels, fluids, movements, diversified organs of sensation, and such a profusion of the richest ornaments and the gayest colors could have been concentrated in a single point. We should never have conceived that even the atmosphere is replenished with invisible animation, that the waters abound with countless myriads of sensitive existence, that the whole earth is full of life, and that there is scarcely a tree, plant, or flower but affords food and shelter to a species of inhabitants peculiar to itself, which enjoy the pleasures of existence and share in the bounty of the Creator. We could have formed no conception of the beauties and the varieties of mechanism which are displayed in the scenery of that invisible world to which the microscope introduces us—beauties and varieties, in point of ornament and delicate contrivance, which even surpass what is beheld in the visible operations and aspect of nature around us. We find joints, muscles, a heart, stomach, entrails, veins, arteries, a variety of motions, a diversity of forms, and a multiplicity of parts and functions in breathing atoms. We behold in a small fiber of a peacock's feather, not more than one-eighth of an inch in length, a profusion of beauties no less admirable than is presented by the whole feather to the naked eye, a stem sending out multitudes of lateral branches, each of which emits numbers of little sprigs, which consist of a multitude of bright shining globular parts, adorned with a rich variety of colors. In the sections of plants, we see thousands and ten thousands of tubes and pores, and other vessels for the conveyance of air and juices for the sustenance of the plant; in some instances, more than ten hundred thousand of these being compressed within the space of a quarter of an inch in diameter, and presenting to the eye the most beautiful configurations. There is not a weed, nor a moss, nor the most insignificant vegetable, which does not show a multiplicity of vessels disposed in the most curious manner for the circulation of sap for its nourishment, and which is not adorned with innumerable graces for its embellishment. All these and ten thousands of other wonders which lie beyond the limits of natural vision, in this new and unexplored region of the universe, would have been forever concealed from our view had not the Creator indued the rays of light with the power of *depicting the images of objects*, when refracted by convex transparent substances.

In this instance, as well as in many others, we behold a specimen of the admirable and diversified effects which the Creator can produce from the agency of a single principle in nature. By means of optical instruments, we are now enabled to take a more minute and expansive view of the amazing operations of nature, both in heaven and on earth, than former generations could have surmised. These views tend to raise our conceptions of the attributes of that Almighty Being who presides over all the arrangements of the material system, and to present them to our contemplation in a new, a more elevated, and expansive point of view. There is, therefore, a connection which may be traced between the apparently accidental principle of the rays of light forming images of objects and the comprehensive views we are now enabled to take of the character and perfections of the Divinity. Without the existence of the law or principle alluded to, we could not, in the present state, have formed precisely the same conceptions either of the Omnipotence, or of the wisdom and intelligence of the Almighty. Had no microscope ever been invented, the idea never could have entered into the mind of man that worlds of living beings exist beyond the range of natural vision, that organized beings, possessed of animation, exist, whose whole bulk is less than the ten hundred thousandth part of the smallest grain of sand; that, descending from a visible point to thousands of degrees beyond it, an invisible world exists, peopled with tribes of every form and size, the extent of which, and how far it verges toward infinity downward, mortals have never yet explored, and perhaps will never be able to comprehend. This circumstance alone presents before us the perfections of the Divinity in a new aspect, and plainly intimates that it is the will and the intention of the Deity that we should explore his works, and investigate the laws by which the material world is regulated, that we may acquire more expansive views of his character and operations. The inventions of man, in relation to art and science, are not, therefore, to be considered as mere accidental occurrences, but as special arrangements in the Divine government, for the purpose of carrying forward the human mind to more clear and ample views of the scenes of the universe, and of the attributes and the agency of Him "who is wonderful in counsel and excellent in working"

CHAPTER IV.

ON THE REFLECTION OF LIGHT.

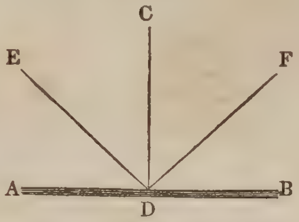
The *reflection* of the rays of light is that property by which, after approaching the surfaces of bodies, they are thrown back, or repelled. It is in consequence of this property that all the objects around us, and all the diversified landscapes on our globe are rendered visible. It is by light reflected from their surfaces that we perceive the planetary bodies and their satellites, the belts of Jupiter, the rings of Saturn, the various objects which diversify the surface of the Moon, and all the bodies in the universe which have no light of their own. When the rays of light fall upon rough and uneven surfaces, they are reflected very irregularly, and scattered in all directions, in consequence of which thousands of eyes, at the same time, may perceive the same objects, in all their peculiar colors, aspects and relations. But when they fall upon certain smooth and polished surfaces, they are reflected with regularity, and according to certain laws. Such surfaces, when highly polished, are called *Mirrors* or *Speculums;* and it is to the reflection of light from such surfaces, and the effects it produces, that I am now to direct the attention of the reader.

Mirrors, or specula, may be distinguished into three kinds, *plane*, *concave*, and *convex*, according as they are bounded by plane or spherical surfaces. These are made either of *metal* or of *glass*, and have their surfaces highly polished for the purpose of reflecting the greatest number of rays. Those made of glass are foliated or quicksilvered on one side; and the metallic specula are generally formed of a composition of different metallic substances, which, when accurately polished, is found to reflect the greatest quantity of light.—I shall, in the first place, illustrate the phenomena of reflection produced by *plane mirrors.*

When light impinges, or falls, upon a polished flat surface, rather more than the half of it is reflected, or thrown back in a direction similar to that of its approach; that is to say, if it fall *perpendicularly* on the polished surface, it will be perpendicularly reflected, but if it fall *obliquely*, it will be reflected with the same obliquity. Hence, the following fundamental law regarding the reflection of light has been deduced both from experiment and mathematical demonstration, namely, that *the angle of reflection is, in all cases, exactly equal to the angle of incidence.* This is a law which is universal in all cases of reflection, whether it be from plane or spherical surfaces, or whether these surfaces be concave or convex, and which requires to be recognized in the construction of all instruments which depend on the reflection of the rays of light. The following figure (fig. 14) will illustrate the position now stated:

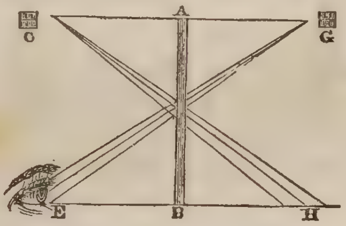
Let $A\ B$ represent a plane mirror, and $C\ D$ a line or ray of light perpendicular to it. Let $F\ D$ represent the *incident* ray from any object, then $D\ E$ will be the reflected ray, thrown back in the direction from D to E, and it will make, with the perpendicular $C D$, the same angle which the incident ray $F\ D$ did with the same perpendicular; that is, the angle $F\ D\ C$ will be equal to the angle $E\ D\ C$, in all cases of obliquity. The incident ray of light may be considered as rebounding from the mirror, like a tennis ball from a marble pavement, or the wall of a court.

Fig. 14.



In viewing objects by reflection, we see them in a different direction from that in which they really are, namely, along the line in which the rays come to us last. Thus, if $A\ B$ (fig. 15) represent a plane mirror, the image of an object, C, appears to the eye at E, behind the mirror, in the direction $E\ G$, and always in the intersection G of the perpendicular $C\ G$, and the reflected ray $E\ G$; and, consequently, at G as far behind the mirror as the object C is before it. We therefore see the image in the line $E\ G$, the direction in which the reflected rays proceed. A plane mirror does not alter the figure or size of objects; but the whole image is equal and similar to the whole object, and has a like situation with respect to one side of the plane, that the object has with respect to the other.

Fig. 15.



Mr. Walker illustrates the manner in which we see our faces in a mirror by the following figure (16) A B represents a mirror, and O C a person looking into it. If we conceive a ray proceeding from the forehead C E, it will be sent to the eye at O, agreeably to the angle of incidence and reflection. But the mind puts C E O into one line, and the forehead is seen at H, as if the lines C E O had turned on a hinge at E. It seems a wonderful faculty of the mind to put the two oblique lines C E and O E into one straight line O H, yet it is seen every time we look at a mirror. For the ray has really travelled from C to E, and from E to O, and it is that journey which determines the distance of the object; and hence we see ourselves as far beyond the mirror as we stand from it.—Though a ray is here taken only from one part of the face, it may be easily conceived that rays from every part of the face must produce a similar effect.

Fig. 16.

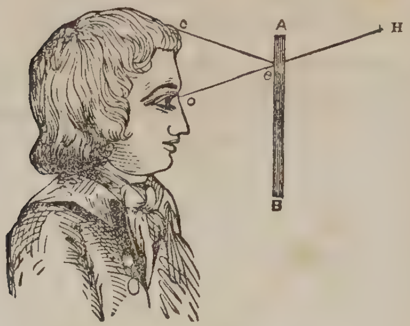


Fig. 17.

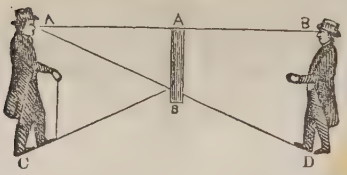


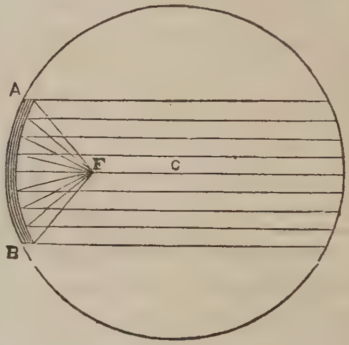
In every plane mirror the image is always equal to the object, at what distance soever it may be placed; and, as the mirror is only at half the distance of the image from the eye, it will completely receive an image of *twice* its own length. Hence, a man six feet high may view himself completely in a looking-glass of three feet in length and half his own breadth; and this will be the case at whatever distance he may stand from the glass. Thus, the man *A C* (fig. 17) will see the whole of his own image in the glass A B, which is but one half as large as himself. The rays from the head pass to the mirror in the line A A, perpendicular to the mirror, and are returned to the eye in the same line; consequently, having traveled twice the length A A, the man must see his head at *B*. From his feet, *C*, rays will be sent to the bottom of the mirror, at B; these will be reflected at an equal angle to the eye in the direction B A, as if they had proceeded in the direction *D* B *A*, so that the man will see his foot at *D*, and, consequently, his whole figure at *B D*.

A person, when looking into a mirror, will always see his own image as far beyond the mirror as he is before it; and as he moves to or from it, the image will, at the same time move toward or from him on the other side, but apparently with a double velocity, because the two motions are equal and contrary. In like manner, if, while the spectator is at rest, an object be in motion, its image behind the mirror will be seen to move at the same time. And if the spectator moves, the images of objects that are at rest will appear to approach or recede from him, after the same manner as when he moves toward real objects; plane mirrors reflecting not only the object, but the distance also, and that exactly in its natural dimensions. The following principle is sufficient for explaining most of the phenomena seen in a plane mirror, namely: *That the image of an object seen in a plane mirror is always in a perpendicular to the mirror joining the object and the image, and that the image is as much on one side the mirror as the object is on the other.*

REFLECTION BY CONVEX AND CONCAVE MIRRORS.

Both convex and concave mirrors are formed of portions of a sphere. A convex speculum is ground and polished in a *concave* dish or tool which is a portion of a sphere, and a concave speculum is ground upon a convex tool. The inner surface of a sphere brings parallel rays to a focus at *one-fourth* of its diameter, as represented in the following figure, where *C* is the center of the sphere on which the concave speculum *A B* is formed, and *F* the focus where parallel rays from a distant object would be united after reflection, that is, at one-half the radius, or one-fourth of the diameter from the surface of the speculum Were a speculum of this kind presented to the sun, *F* would be the point where the reflected rays would be converged to a focus, and set fire to combustible substances if the speculum be of a large diameter, and of a short focal distance.—Were a candle placed in that focus, its light would be reflected parallel, as represented in the figure. These are properties of concave specula which require to be particularly attended to in the construction of reflecting telescopes. It follows, from what has been now stated, that if we intend to form a speculum of a certain focal distance, for example, two feet, it is necessary that *it should be ground upon a tool whose radius is double that distance*, or four feet.

Fig. 18.



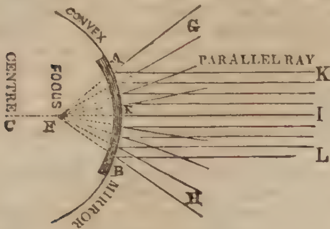
PROPERTIES OF CONVEX MIRRORS.

From a convex surface, parallel rays, when reflected, are made to diverge: convergent rays are reflected less convergent; and divergent rays are rendered more divergent. It is the nature of all convex mirrors and surfaces to scatter or *disperse* the rays of light, and in every instance to impede their convergence. The following figure shows the course of parallel rays as reflected from a convex mirror. *A E B* is the convex surface of the mirror, and *K A*, *I E*, *L B* parallel rays falling upon it. These rays, when they strike the mirror, are made to diverge in the direction *A G*, *B H*, &c., and both the parallel and divergent rays are here represented as they appear in a dark chamber when a convex mirror is presented to the solar rays. The dotted lines denote only the course or tendency of the reflected rays toward the *virtual* focus *F*, were they not intercepted by the mirror

This virtual focus is just equal to half the radius *C E.*

The following are some of the properties of convex mirrors: 1. The image appears always erect, and behind the reflecting surface. 2. *The image is smaller than the object,* and the diminution is greater in proportion as the object is farther from the mirror; but if the object touch the mirror, the image at the point of contact is of the same size as the object. 3. The image does not appear so far behind the reflecting surface as in a plane mirror. 4. The image of a straight object, placed either parallel or oblique to the mirror, is seen *curved* in the mirror, because the different points of the object are not all at an equal distance from the surface of the mirror. 5. Concave mirrors have a *real* focus where an image is actually formed; but convex specula have only a *virtual* focus, and this focus is behind the mirror, no image of any object being formed before it.

Fig. 19.



The following are some of the purposes to which convex mirrors are applied: They are frequently employed by painters for reducing the proportions of the objects they wish to represent, as the images of objects diminish in proportion to the smallness of the radius of convexity, and to the distances of objects from the surface of the mirror. They form a fashionable part of modern furniture, as they exhibit a large company assembled in a room, with all the furniture it contains, in a very small compass, so that a large hall, with all its objects, and even an extensive landscape, being reduced in size, may be seen from one point of view. They are likewise used as the small specula of those reflecting telescopes which are fitted up on the *Cassegrainian* plan, and in the construction of Smith's Reflecting Microscope. But, on the whole, they are very little used in the construction of optical instruments.

PROPERTIES OF CONCAVE SPECULUMS.

Concave specula have properties very different from those which are convex; they are of more importance in the construction of reflecting telescopes and other optical instruments, and therefore require more minute description and illustration. Concave mirrors cause parallel rays to converge; they increase the convergence of rays that are already converging; they diminish the divergence of diverging rays, and in some cases render them parallel, and even convergent; which effects are all in proportion to the concavity of the mirror. The following figures show the course of diverging and parallel rays as reflected from concave mirrors.

Fig. 20 represents the course of *parallel* rays, and *A B* the concave mirror on which they fall. In this case they are reflected so as to unite at *F*, which point is distant from its surface *one-fourth* of the diameter of the sphere of the mirror. This point is called the focus of parallel rays, or *the true focus of the mirror;* and, since the sunbeams are parallel among themselves, if they are received on a concave mirror, they will be reflected to that point, and there burn in proportion to the quantity of rays collected by the mirror. Fig. 21 shows the direction of *diverging* rays, or those which proceed from a near object. These rays proceeding from an object farther from the mirror than the true focal point, as from *D* to *A* and to *B*, are reflected converging, and meet at a point *F*, *farther from the mirror* than the focal point of parallel rays. If the distance of the radiant, or object *D*, be equal to the radius *C E*, then will the focal distance be likewise equal to the radius; that is, if an object be placed in the center of a concave speculum, the image will be reflected upon the object, or they will seem to meet and embrace each other in the center. If the distance of the radiant be equal to half the radius, its image will be reflected to an infinite distance, for the rays will then be parallel. If, therefore, a luminous body be placed at half the radius from a concave speculum, it will enlighten places directly before it at great distances. Hence their use when placed behind a candle in a common lantern; hence their utility in throwing light upon objects in the Magic Lantern and Phantasmagoria; and hence the vast importance of very large mirrors of this description, as now used in most of our lighthouses, for throwing a brilliant light to great distances at sea, to guide the mariner when directing his course under the cloud of night.

Fig. 20.

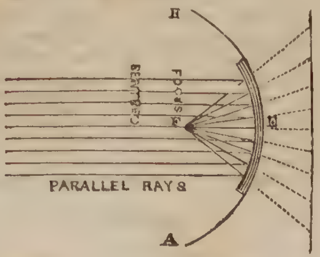


Fig. 21.

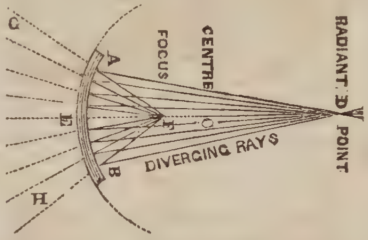
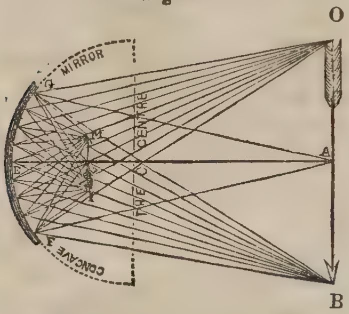


When *converging* rays fall upon a concave mirror, they are reflected more converging, and unite at a point between the focus of parallel rays and the mirror; that is, nearer the mirror than one-half the radius; and their precise degree of convergency will be greater than that wherein they converged before reflection.

OF THE IMAGES FORMED BY CONCAVE MIRRORS.

If rays proceeding from a distant object fall upon a concave speculum, they will paint an image or representation of the object on its focus *before* the mirror. This image will be inverted, because the rays cross at the points where the image is formed. We have already seen that a convex glass forms an image of an object *behind* it; the rays of light from objects *pass through* the glass, and the picture is formed on the side farthest from the object. But in concave mirrors the images of distant objects—and of all objects that are farther from its surface than its principal focus—are formed *before* the mirror, or on the same side as the object. In almost every other respect, however, the effect of a concave mirror is the same as that of a convex lens, in regard to the formation of images, and the course pursued by the rays of light, except that the effect is produced in the one case by refraction, and in the other by reflection. The following figure represents the manner in which images are formed by concave mirrors; *G F* represents the reflecting surface of the mirror; *O A B*, the object; and *I* A *M* the image formed by the mirror. The rays proceeding from O will be carried to the mirror in the direction *O G*, and, according to the law that the angle of incidence is equal to the angle of reflection, will be reflected to *I* in the direction *G I*. In like manner, the rays from *B* will be reflected from *F* to *M*, the rays from *A* will be reflected to A, and so of all the intermediate rays, so that an inverted image of the object *O B* will be formed at *I M*. If the rays proceeded from objects at a very great distance, the image would be formed in the real focus of the mirror, or at one-fourth the diameter of the sphere from its surface; but nearer objects, which send forth diverging rays, will have their images formed a little farther from the surface of the mirror.

Fig. 22.



If we suppose a real object placed at *I M*, then *O B* will represent its magnified image, which will be larger than the object in proportion to its distance from the mirror. This may be experimentally illustrated by a concave mirror and a candle. Suppose a concave mirror whose focal distance is five inches, and that a candle is placed before it at a little beyond its focus (as at *I M*), suppose at five and a half inches, and that a wall or white screen receives the image, at the distance of five feet six inches from the mirror, an image of the candle will be formed on the wall which will be twelve times longer and broader than the candle itself. In this way concave mirrors may be made to magnify the images of objects to an indefinite extent. This experiment is an exact counterpart of what is effected in similar circumstances by a convex lens, as described p. 29; the mirror performing the same thing by reflection as the lens did by refraction.

From what has been stated in relation to concave mirrors, it will be easily understood how they make such powerful burning-glasses. Suppose the focal distance of a concave mirror to be twelve inches, and its diameter or breadth twelve inches. When the sun's rays fall on such a mirror, they form an image of the sun at the focal point, whose diameter is found to be about one-tenth of an inch. All the rays which fall upon the mirror are converged into this small point, and, consequently, their intensity is in proportion as the square of the surface of the mirror is to the square of the image. The squares of these diameters are as 14,400 to 1, and, consequently, the density of the sun's rays, in the focus, is to their density on the surface of the mirror as 14,400 to 1. That is, the heat of the solar rays in the focus of such a mirror will be fourteen thousand four hundred times greater than before: a heat which is capable of producing very powerful effects in melting and setting fire to substances of almost every description.

Were we desirous of forming an image by a concave speculum which shall be exactly equal to the object, the object must be placed exactly in the center; and, by an experiment of this kind, the center of the concavity of a mirror may be found.

In the cases now stated, the images of objects are all formed in the front of the mirror, or between it and the object. But there is a case in which the image is formed behind the mirror. This happens when the object is placed between the mirror and the focus of parallel rays, and then the image is larger than the object. In fig. 23, *G F* is a concave mirror, whose focus of parallel rays is at *E*. If an object *O B* be placed a little within this focus, as at *A*, a large image, *I M*, will be seen *behind* the mirror, somewhat curved and erect, which will be seen by an eye looking directly into the front of the mirror. Here the image appears at a greater distance behind the mirror than the object is before it, and the object appears magnified in proportion to its distance from the focus and the mirror. If the mirror be one inch focal distance, and the object be placed eight-tenths of an inch from its surface, the image would be five times as large as the object in length and breadth, and, consequently, twenty-five times larger in

Fig. 23.

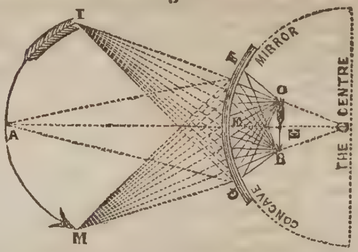


Fig. 24.

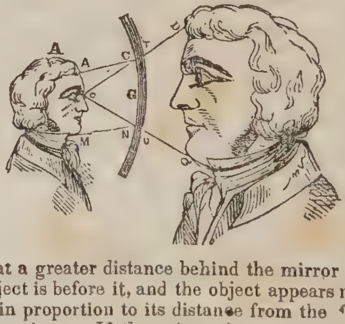

surface. In this way small objects may be magnified by reflection, as such objects are magnified by refraction, in the case of deep convex lenses. When such mirrors are large, for example six inches diameter, and eight or ten inches focal distance, they exhibit the human face as of an enormous bulk. This is illustrated by the foregoing figure: Let C N, fig. 24, represent the surface of a concave mirror, and *A*, a human face looking into it, the face will appear magnified as represented by the image behind the mirror, D. Q. Suppose a ray, A C, proceeding from the forehead, and another, M N, from the chin; these rays are reflected to the person's eye at O, which, consequently, sees the image of the lines of reflection O D, O Q, and in the angle D O Q, and, consequently, magnified much beyond the natural size, and at a small distance behind the mirror.

If we suppose the side T U to represent a *convex* mirror, and the figure D Q a head of an ordinary size, then the figure *A* will represent the diminished appearance which a person's face exhibits when viewed in such a mirror. It will not only appear reduced, but somewhat distorted; because, from the form of the mirror, one part of the object is nearer to it than another, and, consequently, will be reflected under a different angle.

The effect we have now mentioned as produced by *concave* mirrors will only take place when the eye is nearer the mirror than its principal focus. If the spectator retire beyond this focus—suppose to the distance of five or six feet—he will not see the image *behind* the mirror, but he will see his image in a diminished form, hanging upside down, and suspended in the air, in a line between his eye and the mirror. In this case, his image is formed *before* the mirror, as represented at *I M*, fig. 22. In this situation, if you hold out your hand toward the mirror, the hand of the image will come out toward your hand, and, when at the center of concavity, it will be of an equal size with it, and you may shake hands with this aerial image. If you move your hand farther, you will find the hand of the image pass by your hand, and come between it and your body. If you move your hand toward either side, the hand of the image will move toward the other side; the image moving always in a contrary direction to the object. All this while the bystanders, if any, see nothing of the image, because none of the reflected rays that form it can enter their eyes. The following figure represents a phenomenon produced in the same manner. A B is a concave mirror of a large size; C represents a hand presented before the mirror, at a point farther distant than its focus. In this case an inverted image of the hand is formed, which is seen hanging down in the air at M. The rays C and D go diverging from the two opposite points of the object, and, by the action of the mirror, they are again made to converge to points at O and S, where they cross, form an image, and again proceed divergent to the eye.*

In consequence of the properties of concave mirrors now described, many curious experiments and optical deceptions have been exhibited. The appearance of images in the air, suspended between the mirror and the object, have sometimes been displayed with such dexterity, and an air of mystery, as to have struck with astonishment those who were ignorant of the cause. In this way birds, flying angels, specters, and other objects have been exhibited; and when the hand attempts to lay hold on them, it finds them to be nothing, and they seem to vanish into air. An apple or a beautiful flower is presented, and when a spectator attempts to touch it, it instantly vanishes, and a death's head immediately appears, and seems to snap his fingers. A person with a drawn sword appears before him, in an attitude as if about to run him through, or one terrific phantom starts up after another, or sometimes the resemblances of deceased persons are made to appear, as if, by the art of conjuration, they had been forced to return from the world of spirits. In all such exhibitions a very large concave mirror is requisite, a brilliant light must be thrown upon the objects, and every arrangement is made, by means of partitions, &c., to prevent either the light, the mirror, or the object from being seen by the spectators. The following representation (fig. 26) shows one of the methods by which this is effected: A is a large concave mirror, either of metal or of glass, placed on the back part of a dark box; D is the performer, concealed from the spectators by the cross partition C; E is a strong light, which is likewise concealed by the partition I, which is thrown upon the actor D or upon anything he may hold in his hand. If he hold a book, as represented in the figure, the light reflected from it will pass between the partitions C and I to the mirror, and will be reflected from thence to Z, where the image of the book will appear so distinct and tangible, that a spectator looking through the opening at X will imagine that it is in his power to take hold of it. In like manner, the person situated at D may exhibit his own head or body, a portrait, a painting, a specter, a landscape, or any object or device which he can strongly illuminate.

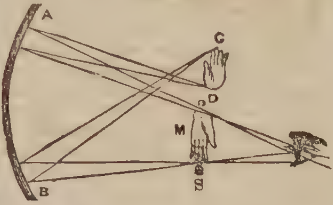

Fig 26.

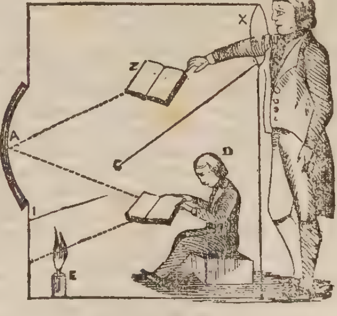

---

[*] Small glass mirrors for performing some of the experiments, and illustrating some of the principles above alluded to, may be made of the flattest kind of common watch glasses, by foliating or covering with tin leaf and quicksilver the convex surfaces of such glasses. Their focal distances will generally be from one to two inches. Such mirrors afford a very large and beautiful view of the eye, when held within their focal distance of that organ. Such mirrors will also serve the purpose of reflecting light on the objects viewed by microscopes. Larger mirrors, of from four to eight inches diameter, may be had of the optician at different prices, varying from five to ten or fifteen shillings.

There is another experiment, made with a concave mirror, which has somewhat puzzled philosophers to account for the phenomena. Take a glass bottle, A C (fig. 27), and fill it with water to the point B; leave the upper part, B C, empty, and cork it in the common manner. Place this bottle opposite a concave mirror, and beyond its focus, that it may appear reversed, and before the mirror place yourself still farther distant from the bottle, and it will appear in the situation A B C. Now it is remarkable, in this apparent bottle, that the water, which, according to the laws of catoptrics, should appear at A B, appears, on the contrary, at B C, and, consequently, the part A B appears empty. If the bottle be inverted and placed before the mirror, its image will appear in its natural erect position, and the water, which is in reality at B C (fig. 28), is seen at A B. If, while the bottle is inverted, it be uncorked, and the water run gently out, it will appear that, while the part, B C is emptying, that of A B in the image is filling, and, what is remarkable, as soon as the bottle is empty the illusion ceases, the image also appearing entirely empty. The remarkable circumstances in this experiment are, first, not only to see the object where it is not, but also where its *image* is not; and, secondly, that of two objects which are really in the same place, as the surface of the bottle and the water it contains, the one is seen at one place, and the other at another; and to see the bottle in the place of its image, and the water where neither it nor its image is.

Fig. 27.

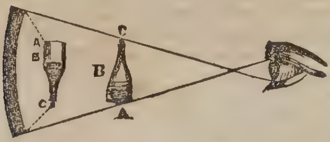

Fig. 28.

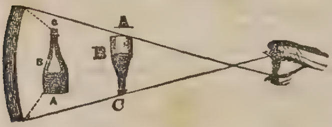


The following experiments are stated by Mr. Ferguson, in his "Lectures on Select Subjects," &c.: "If a fire be made in a large room, and a smooth mahogany table be placed at a good distance near the wall, before a large concave mirror, so placed that the light of the fire may be reflected from the mirror to its focus upon the table; if a person stand by the table, he will see nothing upon it but a longish beam of light: but if he stand at a distance toward the fire, not directly between the fire and mirror, he will see an image of the fire upon the table, large and erect. And if another person, who knows nothing of the matter beforehand, should chance to come into the room, and should look from the fire toward the table, he would be startled at the appearance, for the table would seem to be on fire, and by being near the wainscot, to endanger the whole house. In this experiment there should be no light in the room but what proceeds from the fire, and the mirror ought to be at least fifteen inches in diameter. If the fire be darkened by a screen, and a large candle be placed at the back of the screen, a person standing by the candle will see the appearance of a very fine large star, or, rather, planet, upon the table, as bright as Venus or Jupiter. And if a small wax taper—whose flame is much less than the flame of the candle—be placed near the candle, a satellite to the planet will appear on the table; and if the taper be moved round the candle, the satellite will go round the planet."

Many other illustrations of the effects of concave specula might have been given, but I shall conclude this department by briefly stating some of the *general properties of speculums.*

1. There is a great resemblance between the properties of *convex* lenses and *concave* mirrors. They both form an inverted focal image of any remote object, by the convergence of the pencil of rays. In those instruments whose performances are the effects of reflection, as reflecting telescopes, the concave mirror is substituted in the place of the convex lens. The whole effect of these instruments, in bringing to view remote objects in heaven and on earth, entirely depends on the property of a concave mirror in forming images of objects in its focus. 2. The image of an object placed beyond the center is less than the object; if the object be placed between the principal focus and the center, the image is greater than the object. In both cases the image is inverted. 3. When the object is placed between the focus and the mirror, the image situated behind the mirror is greater than the object, and it has the same direction; in proportion as the object approaches the focus, the image becomes larger and more distant. These and similar results are proved by placing a lighted candle at different distances from a concave mirror. 4. An eye cannot see an image in the air except it be placed in the diverging rays; but if the image be received on a piece of white paper, it may be seen in any position of the eye, as the rays are then reflected in every direction. 5. If a picture, drawn according to the rules of perspective, be placed before a large concave speculum, a little nearer than its principal focus, the image of the picture will appear extremely natural, and very nearly like the real objects whence it was taken. Not only are the objects considerably magnified, so as to approach to their natural size, but they have also different apparent distances, as in nature, so that the view of the inside of a church appears very like what it is in reality, and representations of landscapes appear very nearly as they do from the spot whence they were taken. In this respect a large concave speculum may be made to serve nearly the same purpose as the Optical Diagonal Machine in viewing perspective prints. 6. The concave speculum is that alone which is used as the great mirror which forms the first image in reflecting telescopes; and it is likewise the only kind of speculum used as the small mirror, in that construction of the instrument called the *Gregorian Reflector.*

QUANTITY OF LIGHT REFLECTED BY POLISHED SURFACES.

As this is a circumstance connected with the construction of reflecting telescopes, it may not be improper, in this place, to state some of the results of the accurate experiments of M Bouguer on this subject. This philosopher ascertained that of the light reflected from mercury, or quicksilver, more than *one-fourth* is lost, though it is probable that no substance reflects more light than this. The rays were received at an angle of eleven and a half degrees of incidence, measured from the surface of the reflecting body, and not from the perpendicular. The reflection from water was found to be almost as great as that of quicksilver; so that in very small angles it reflects nearly three-fourths of the direct light. This is the reason why so strong a reflection appears on the water, when one walks, in still weather, on the brink of a lake opposite to the sun. The direct light of the sun diminishes gradually as it approaches the horizon, while the reflected light at the same time grows stronger; so that there is a certain elevation of the sun in which the united force of the direct and reflected light will be the greatest possible, and this is when he is twelve or thirteen degrees in altitude. On the other hand, light reflected from water at *great angles* of incidence is extremely small. When the light was perpendicular, it reflected no more than the thirty-seventh part which mercury does in the same circumstances, and only the fifty-fifth part of what fell upon it in this case.

Using a smooth piece of glass, one line in thickness, he found that, when it was placed at an angle of fifteen degrees with the incident rays, it reflected 628 parts of 1000 which fell upon it; at the same time, a metallic mirror, which he tried in the same circumstances, reflecting only 561 of them. At a less angle of incidence much more light was reflected; so that at an angle of three degrees the glass reflected 700 parts, and the metal something less, as in the former case. The most striking observations made by this experimenter relate to the very great difference in the quantity of light reflected at different angles of incidence. He found that for 1000 incident rays, the reflected rays at different angles of incidence, were as follows:

Angles of incidence.	Rays reflected by water.	Rays reflected by glass.
5°	501	549
10	333	412
15	211	299
30	65	112
50	22	34
70	18	25
90	18	25

With regard to such mirrors as the specula of reflecting telescopes, it will be found in general, that they reflect little more than the one-half of the rays which fall upon them.

UNCOMMON APPEARANCES IN NATURE PRODUCED BY THE COMBINED INFLUENCES OF REFLECTION AND REFRACTION.

The reflection and refraction of the rays of light frequently produce phenomena which astonish the beholders, and which have been regarded by the ignorant and the superstitious as the effects of supernatural agency. Of these phenomena I shall state a few examples.

One of the most striking appearances of this kind is what has been termed the *Fata Morgana*, or optical appearances of figures in the sea and the air, as seen in the Faro of Messina. The following account is translated from a work of Minasi, who witnessed the phenomenon, and wrote a dissertation on the subject: "When the rising sun shines from that point whence its incident ray forms an angle of about forty-five degrees to the sea of Riggio, and the bright surface of the water in the bay is not disturbed either by the wind or the current, the spectator being placed on an eminence of the city, with his back to the sun and his face to the sea; on a sudden there appear on the water, as in a catoptric theater, various multiplied objects, that is to say, numberless series of pilasters, arches, castles well delineated, regular columns, lofty towers, superb palaces, with balconies and windows, extended alleys of trees, delightful plains with herds and flocks, armies of men on foot and horseback, and many other strange images, in their natural colors and proper actions, passing rapidly in succession along the surface of the sea, during the whole of the short period of time, while the above-mentioned causes remain. But if, in addition to the circumstances now described, the atmosphere be highly impregnated with vapor and dense exhalations, not previously dispersed by the winds or the sun, it then happens that, in this vapor, as in a curtain extended along the channel at the hight of about thirty palms, and nearly down to the sea, the observer will behold the scene of the same objects, not only reflected from the surface of the sea, but likewise in the air, though not so distant or well-defined as the former objects from the sea. Lastly, if the air be slightly hazy or opaque, and, at the same time, dewy and adapted to form the iris, the then above-mentioned objects will appear only at the surface of the sea, as in the first case, but all vividly colored or fringed with red, green, blue, and other prismatic colors."*

It is somewhat difficult to account for all the appearances here described, but, in all probability, they are produced by a calm sea, and one or more strata of superincumbent air, differing in refractive, and, consequently, in reflective power. At any rate, reflection and refraction are some of the essential causes which operate in the production of the phenomena.

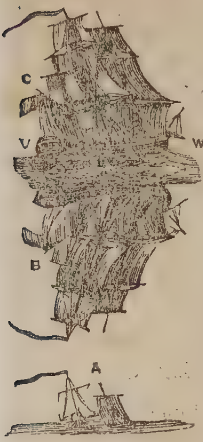
The *Mirage*, seen in the deserts of Africa, is a phenomenon, in all probability, produced by a similar cause. M. Monge, who accompanied the French army to Egypt, relates that, when in the desert between Alexandria and Cairo, the mirage of the blue sky was inverted, and so mingled with the sand below as to give to the desolate and arid wilderness an appearance of the most rich and beautiful country. They saw, in all directions, green islands, surrounded with extensive lakes of pure, transparent water. Nothing could be conceived more lovely and picturesque than the landscape. In the tranquil surface of the lakes, the trees and houses with which the islands were covered were strongly reflected with vivid and varied hues, and the party hastened forward to enjoy the cool refreshments of shade and stream which these populous villages proffered to them. When they arrived, the lake on whose bosom they floated, the trees among whose foliage they were embowered, and the people who stood on the shore inviting their approach, had all vanished, and nothing remained but a uniform and irksome desert of sand and sky, with a few naked huts and ragged Arabs. Had they not been undeceived by their nearer approach, there was not a man in the French army who would not have sworn that the visionary trees and lakes had a real existence in the midst of the desert.

Dr. Clark observed precisely the same appearance at Rosetta. The city seemed surrounded with a beautiful sheet of water; and so certain was his Greek interpreter—who was unacquainted with the country—of this fact, that he was quite indignant at an Arab who attempted to explain to him that it was a mere optical delusion. At length they reached Rosetta in about two hours, without meeting with any water; and on looking back on the sand they had just crossed, it seemed to them as if they had waded through a vast blue lake.

---

* Nicholson's Journal of Natural Philosophy, &c., 4to series, p. 225.

Fig. 29.



On the 1st of August, 1798, Dr. Vince observed at Ramsgate a ship which appeared as at A (fig. 29), the topmast being the only part of it that was seen above the horizon. An inverted image of it was seen at B, immediately above the real ship A, and an erect image at C, both of them being complete and well-defined. The sea was distinctly seen between them, as at V W. As the ship rose to the horizon, the image C gradually disappeared, and, while this was going on, the image B descended, but the mainmast of B did not meet the mainmast of A. The two images, B C, were perfectly visible when the whole ship was actually below the horizon. Dr. Vince then directed his telescope to another ship whose hull was just in the horizon, and he observed a complete inverted image of it, the mainmast of which just touched the mainmast of the ship itself. He saw at the same time several other ships whose images appeared in nearly a similar manner, in one of which the two images were visible when the whole ship was beneath the horizon. These phenomena must have been produced by the same cause which operated in the case formerly mentioned, in relation to Capt. Scoresby, when he saw the figure of his father's ship inverted in the distant horizon. Such cases are, perhaps, not uncommon, especially in calm and sultry weather, but they are seldom observed, except when a person's attention is accidentally directed to the phenomenon, and, unless he uses a telescope, it will not be so distinctly perceived.

The following phenomenon, of a description nearly related to the above, has been supposed to be chiefly owing to *reflection:* On the 18th of November, 1804, Dr. Buchan, when watching the rising sun, about a mile to the east of Brighton, just as the solar disc emerged from the surface of the water, saw the face of the cliff on which he was standing, a windmill, his own figure, and the figure of his friend, distinctly represented, precisely opposite, at some distance from the ocean. This appearance lasted about ten minutes, until the sun had risen nearly his own diameter above the sea. The whole then seemed to be elevated into the air, and successively disappeared. The surface of the sun was covered with a dense fog of many yards in hight, which gradually receded from the rays of the sun as he ascended from the horizon.

The following appearance, most probably, arose chiefly from the *reflection* of the atmosphere: It was beheld at Ramsgate by Dr. Vince, of Cambridge, and another gentleman. It is well known that the four turrets of Dover Castle are seen at Ramsgate, over a hill which intervenes between a full prospect of the whole. On the 2d of August, 1806, not only were the four turrets visible, but the castle itself appeared as though situated on that side of the hill nearest Ramsgate, and so striking was the appearance that for a long time the doctor thought it an illusion; but at last by accurate observation, was convinced that it was an actual image of the castle. He, with another individual, observed it attentively for twenty minutes, but were prevented by rain from making further observations. Between the observers and the land from which the hill rises there were about six miles of sea, and from thence to the top of the hill there was about the same distance; their own hight above the surface of the water was about seventy feet. The cause of this phenomenon was undoubtedly *unequal refraction.* The air being more dense near the ground and above the sea than at greater hights, reached the eye of the observer, not in straight but in curvilinear lines. If the rays of the castle had in their path struck an eye at a much greater distance than Ramsgate, the probability is that the image of the castle would have been inverted in the air; but, in the present case, the rays from the turret and the base of the castle had not crossed each other.

To similar causes as those now alluded to are to be attributed such phenomena as the following:

The specter of the Brocken. This is wonderful, and, at first sight, a terrific phenomenon, which is sometimes seen from the summit of the Hartz Mountains in Hanover, which is about 3300 feet above the level of the sea, and overlooks all the country fifteen miles round. From this mountain the most gigantic and terrific specters have been seen, which have terrified the credulous and gratified the curious, in a very high degree. M. Hawe, who witnessed this phenomenon, says the sun rose about four o'clock, after he had ascended to the summit, in a serene sky, free of clouds; and, about a quarter past five, when looking round to see if the sky continued clear, he suddenly beheld at a little distance, a human figure of *a monstrous size* turned toward him, and glaring at him. While gazing on this gigantic specter, with a mixture of awe and apprehension, a sudden gust of wind nearly carried off his hat, and he clapped his hand to his head to detain it, when to his great delight, the colossal specter did the same. He changed his body into a variety of attitudes, all which the specter exactly imitated, and then suddenly vanished without any apparent cause, and in a short time as suddenly appeared. Being joined by another spectator, after the first visions had disappeared, they kept steadily looking for the aerial specters, when two gigantic monsters suddenly appeared. These specters had been long considered as preternatural by the inhabitants of the adjacent districts, and the whole country had been filled with awe and terror. Some of the lakes of Ireland are found to be susceptible of producing illusions, particularly the Lake of *Killarney.* This romantic sheet of water is bounded on one side by a semicircle of rugged mountains, and on the other by a flat morass; and the vapors generated in the marsh, and broken by the mountains, continually represent the most fantastic objects. Frequently men riding along the shore are seen as if they were moving across the lake, which is supposed to have given rise to the legend of O'Donougho, a magician, who is said to be visible on the lake every May morning.

There can be little doubt that most of those visionary appearances which have been frequently seen in the sky and in mountainous regions, are phantoms produced by the cause to which I am adverting, such as armies of footmen and horsemen, which some have asserted to have been seen in the air near the horizon. A well-authenticated instance of this kind occurred in the highlands of Scotland: Mr. Wren, of Wetton Hall, and

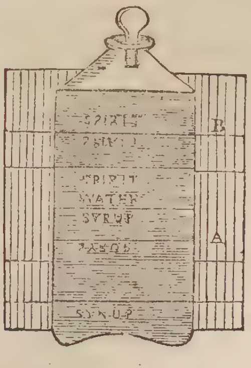
D. Stricket, his servant, in the year 1744, were sitting at the door of the house in a summer evening, when they were surprised to see opposite to them, on the side of Sonterfell hill—a place so extremely steep that scarce a horse could *walk* slowly along it—the figure of a man with a dog pursuing several horses, all running at a most rapid pace. Onward they passed, until at last they disappeared at the lower end of the Fell. In expectation of finding the man dashed to pieces by so tremendous a fall, they went early next morning and made a search, but no trace of man or horse, or the prints of their feet on the turf could be found. Some time afterward, about seven in the evening, on the same spot, they beheld a troop of horsemen advancing in close ranks and at a brisk pace. The inmates of every cottage for a mile round beheld the wondrous scene, though they had formerly ridiculed the story told by Mr. Wren and his servant, and were struck with surprise and fear. The figures were seen for upward of two hours, until the approach of darkness rendered them invisible. The various evolutions and changes through which the troops passed were distinctly visible, and were marked by all the observers. It is not improbable that these aerial troopers were produced by the same cause which made the castle of Dover to appear on the side of the hill next to Ramsgate, and it is supposed that they were images of a body of rebels, on the other side of the hill, exercising themselves previous to the rebellion in 1745.*

I shall mention only another instance of this description which lately occurred in France, and for a time caused a powerful sensation among all ranks. On Sunday, the 17th of December, 1826, the clergy in the parish of Migne, in the vicinity of Poictiers, were engaged in the exercises of the Jubilee which preceded the festival of Christmas, and a number of persons, to the amount of 3,000 souls assisted in the service. They had planted, as part of the ceremony, a large cross, twenty-five feet high, and painted red, in the open air beside the church. While one of the preachers, about five in the evening, was addressing the multitude, he reminded them of the miraculous cross which appeared in the sky to Constantine and his army, and the effect it produced, when suddenly a similar celestial cross appeared in the heavens just before the porch of the church, about 200 feet above the horizon, and 140 feet in length, and its breadth from three to four feet, of a bright silver color, tinged with red. The curate and congregation fixed their wondering gaze upon this extraordinary phenomenon, and the effect produced on the minds of the assembly was strong and solemn; they spontaneously threw themselves on their knees; and many, who had been remiss in their religious duties, humbly confessed their sins, and made vows of penance and reformation. A commission was appointed to investigate the truth of this extraordinary appearance, and a memorial stating the above and other facts, was subscribed by more than forty persons of rank and intelligence, so that no doubt was entertained as to the reality of the phenomenon. By many it was considered as strictly miraculous, as having happened at the time and in the circumstances mentioned. But it is evident, from what we have already stated, that it may be accounted for on physical principles. The large cross of wood painted red was doubtless the real object which produced the magnified image. The state of the atmosphere, according to the descriptions given in the memorial, must have been favorable for the production of such images.—The spectrum of the wooden cross must have been cast on the concave surface of some atmospheric mirror, and so reflected back to the eyes of the spectators from an opposite place, retaining exactly the same shape and proportions, but dilated in size; and, what is worthy of attention, it was tinged with red, the very color of the object of which it was the reflected image.

Such phenomena as we have now described, and the causes of them which science is able to unfold, are worthy of consideration, in order to divest the mind of superstitious terrors, and enable it clearly to perceive the laws by which the Almighty directs the movements of the material system. When any appearance in nature, exactly the reverse of everything we could have previously conceived, presents itself to view, and when we know of no material cause by which it could be produced, the mind must feel a certain degree of awe and terror, and will naturally resort to supernatural agency as acting either in opposition to the established laws of the universe, or beyond the range to which they are confined. Beside the fears and apprehensions to which such erroneous conceptions give rise, they tend to convey false and distorted impressions of the attributes of the Deity, and of His moral government.—Science, therefore, performs an invaluable service to man, by removing the cause of superstitious alarms, by investigating the laws and principles which operate in the physical system, and by assigning reasons for those occasional phenomena which at first sight appeared beyond the range of the operation of natural causes.

The late ingenious Dr. Wollaston illustrated the causes of some of the phenomena we have described, in the following manner: He looked along the side of a red-hot poker at a word or object ten or twelve feet distant; and at a distance less than three-eighths of an inch from the line of the poker, an *inverted* image was seen, and within and without that image, an *erect* image, in consequence of the change produced, by the heat of the poker, in the density of the air. He also suggested the following experiment as another illustration of the same principle, namely, on viewing an object through a stratum of spirit of wine lying above water, or a stratum of water laid above one of sirup. He poured into a *square* vial a small quantity of clear sirup, and above

Fig. 30.



---

*There can be little doubt that some of the facts ascribed, in the western highlands of Scotland, to *second sight*, have been owing to the unusual refraction of the atmosphere; as one of the peculiarities attributed to those who possessed this faculty was, that they were enabled to descry boats and ships before they appeared in the horizon.

this he poured an equal quantity of *water*, which, gradually combined with the sirup, as seen at *A*, fig. 30. The word "sirup," on a card held behind the bottle appeared erect when seen through the pure spirit, but inverted when seen through the mixture of water and sirup. He afterward put nearly the same quantity of rectified spirits of wine above the water, as seen at *B*, and he saw the appearance as represented, namely, the true place of the word "Spirit," and the inverted and erect images below. These substances, by their gradual incorporation, produce refracting power, diminishing from the *spirit of wine* to the *water*, or from the *sirup* to the *water;* so that, by looking through the mixed stratum, an inverted image of any object is seen behind the bottle. These experiments show that the *mirage* and several other atmospherical phenomena may be produced by variations in the refractive power of different strata of the atmosphere.

It is not unlikely that phenomena of a new and different description from any we have hitherto observed, may be produced from the same causes to which we have adverted. A certain optical writer remarks: "If the variation of the refractive power of the air takes place in a horizontal line perpendicular to the line of vision, that is, from right to left, then we may have a *lateral* mirage, that is, an image of a ship may be seen on the right or left hand of the real ship, or on both, if the variation of refractive power is the same on each side of the line of vision, and a fact of this kind was once observed on the Lake of Geneva. If there should happen at the same time both a vertical and a lateral variation of refractive power in the air, and if the variation should be such as to expand or elongate the object in both directions, then the object would be magnified as if seen through a telescope, and might be seen and recognized at a distance at which it would otherwise have been invisible. If the refracting power, on the contrary, varied so as to construct the object in both directions, the image of it would be diminished as if seen through a concave lens."

REMARKS AND REFLECTIONS IN REFERENCE TO THE PHENOMENA DESCRIBED ABOVE.

Such, then, are some of the striking and interesting effects produced by the refraction and the reflection of the rays of light. As the formation of the *images* of objects by convex lenses lays the foundation of the construction of refracting telescopes and microscopes, and of all the discoveries they have brought to light, so the property of *concave specula*, in forming similar images, is that on which the construction of *reflecting* telescopes entirely depends. To this circumstance Herschel was indebted for the powerful telescopes he was enabled to construct—which were all formed on the principle of reflection—and for all the discoveries they enabled him to make in the planetary system, and in the sidereal heavens. The same principles which operate in optical instruments, under the agency of man, we have reason to believe, frequently act on a more expansive scale in various parts of the system of nature. The magnificent *cross* which astonished the preacher and the immense congregation assembled at Migne, was, in all probability, caused by a vast atmospherical speculum formed by the hand of nature, and representing its objects on a scale far superior to that of human art; and probably to the same cause is to be attributed the singular phenomenon of the coast of France having been made to appear within two or three miles of the town of Hastings, as formerly described (see p. 24).—Many other phenomena which we have never witnessed, and of which we can form no conception, may be produced by the same cause operating in an infinity of modes.

The facts we have stated above, and the variety of modes by which light may be refracted and reflected by different substances in nature, lead us to form some conception of the magnificent and diversified scenes which light may produce in other systems and worlds under the arrangements of the all-wise and beneficent Creator. Light, in all its modifications and varieties of color and reflection, may be considered as the beauty and glory of the universe, and the source of unnumbered enjoyments to all its inhabitants. It is a symbol of the Divinity himself; for "GOD IS LIGHT, and in Him is no darkness at all." It is a representative of Him who is exhibited in the sacred oracles as "The SUN of Righteousness," and "the LIGHT of the world." It is an emblem of the glories and felicities of that future world where knowledge shall be perfected and happiness complete; for its inhabitants are designated "the saints in *light;*" and it is declared in sacred history to have been the first-born of created beings. In our lower world, its effects on the objects which surround us, and its influences upon all sensitive beings, are multifarious and highly admirable. While passing from infinitude to infinitude, it reveals the depth and immensity of the heavens, the glory of the sun, the beauty of the stars, the arrangements of the planets, the rainbow encompassing the sky with its glorious circle, the embroidery of flowers, the rich clothing of the meadows, the valleys standing thick with corn, "the cattle on a thousand hills," the rivers rolling through the plains, and the wide expanse of the ocean. But in other worlds the scenes it creates may be far more resplendent and magnificent. This may depend upon the refractive and reflective powers with which the Creator has endowed the atmospheres of other planets, and the peculiar constitution of the various objects with which they are connected. It is evident, from what we already know of the reflection of light, that very slight modifications of certain physical principles, and very slight additions to the arrangements of our terrestrial system, might produce scenes of beauty, magnificence, and splendor, of which at present we can form no conception. And it is not unlikely that by such diversities of arrangement in other worlds *an infinite variety* of natural scenery is produced throughout the universe.

In the arrangements connected with the planet Saturn, and the immense rings with which it is encompassed, and in the various positions which its satellites daily assume with regard to one another, to the planet itself, and to these rings, there is, in all probability, a combination of refractions, reflections, light, and shadows, which produce scenes wonderfully diversified, and surpassing in grandeur what we can now distinctly conceive. In the remote regions of the heavens there are certain bodies composed of immense masses of luminous matter, not yet formed into any regular system, and which are known by the name of *nebulæ*. What should hinder us from supposing that certain exterior portions of those masses form speculums of enormous size, as some parts of our atmosphere are sometimes found to do? Such specula may be conceived to be hundreds and even thousands of miles in diameter, and that they may form images of the most distant objects in the heavens, on a scale of immense magnitude and extent, and which may be reflected, in all their grandeur, to the eyes of intelligences at a vast distance. And, if the organs of vision of such beings be far superior to ours in acuteness and penetrating power, they may thus be enabled to take a survey of an immense sphere of vision, and to descry magnificent objects at distances the most remote from the sphere they occupy. Whatever grounds there may be for such suppositions, it must be admitted that all the knowledge we have hitherto acquired respecting the operation of light, and the splendid effects it is capable of producing, is small indeed, and limited to a narrow circle, compared with the immensity of its range, the infinite modifications it may undergo, and the wondrous scenes it may create in regions of creation to which human eyes have never yet penetrated, and which may present to view objects of brilliancy and magnificence such as "Eye hath not yet seen, nor ear heard, nor hath it entered into the heart of man to conceive."

CHAPTER V.

SECTION I.

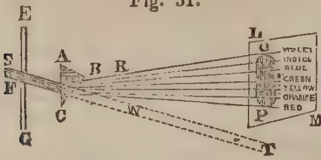
ON THE COLORS OF LIGHT.

We have hitherto considered light chiefly as a simple homogeneous substance, as if all its rays were white, and as if they were all refracted in the same manner by the different lenses on which they fall. Investigations, however, into the nature of this wonderful fluid have demonstrated that this is not the case, and that it is possessed of certain additional properties of the utmost importance in the system of nature. Had every ray of light been a pure white, and incapable of being separated into any other colors, the scene of the universe would have exhibited a very different aspect from what we now behold. One uniform hue would have appeared over the whole face of nature, and one object could scarcely have been distinguished from another. The different shades of verdure which now diversify every landscape, the brilliant coloring of the flowery fields, and almost all the beauties and sublimities which adorn this lower creation would have been withdrawn. But it is now ascertained that every ray of white light is composed of an assemblage of colors, whence proceed that infinite variety of shade and color with which the whole of our terrestrial habitation is arrayed. Those colors are found not to be in the objects themselves, but in the rays of light which fall upon them, without which they would either be invisible or wear a uniform aspect. In reference to this point, Goldsmith has well observed: "The blushing beauties of the rose, the modest blue of the violet, are not in the flowers themselves, but in the light that adorns them. Odor, softness and beauty of figure are their own; but it is light alone that dresses them up in those robes which shame the monarch's glory."

Many strange opinions and hypotheses were entertained respecting colors by the ancients, and even by many modern writers, prior to the time of Sir Isaac Newton. The Pythagoreans called color the *superficies* of bodies; Plato said that it was a flame issuing from them. According to Zeno, it is the first configuration of matter; and according to Aristotle, it is that which moves bodies actually transparent. Among the moderns, Des Cartes imagined that the difference of color proceeds from the prevalence of the direct or rotatory motion of the particles of light. Grimaldi, Dechales, and others, thought the differences of color depended upon the quick or slow vibrations of a certain elastic medium filling the whole universe. Rohault imagined that the different colors were made by the rays of light entering the eye at different angles with respect to the optic axis; and Dr. Hook conceived that color is caused by the sensation of the oblique or uneven pulse of light; and this being capable of no more than two varieties, he concluded that there could be no more than two primary colors. Such were some of the crude opinions which prevailed before the era of the illustrious Newton, by whose enlightened investigations the true theory of colors was at last discovered. In the year 1666 this philosopher began to investigate the subject, and finding the colored image of the sun, formed by a glass prism, to be of an oblong, and not of a circular form, as, according to the laws of refraction, it ought to be, he was surprised at the great disproportion between its length and breadth, the former being *five* times the length of the latter; and he began to conjecture that light is not *homogeneal*, but that it consists of rays, some of which are much more refrangible than others. Prior to this period, philosophers supposed that *all* light, in passing out of one medium into another of different density, was *equally* refracted in the same or like circumstances; but Newton discovered that this is not the fact; but that there are *different species* of light, and that each species is disposed both to suffer a different degree of refrangibility in passing out of one medium into another, and to excite in us the idea of a *different color* from the rest; and that bodies appear of that color which arises from the peculiar rays they are disposed to reflect. It is now, therefore, universally acknowledged that the light of the sun, which to us seems perfectly homogeneal and white, is composed of no fewer than *seven* different colors, namely, *Red Orange, Yellow, Green, Blue, Indigo, and Violet.* A body which appears of a red color has the property of reflecting the red rays more powerfully than any of the others; a body of a green color reflects the green rays more copiously than rays of any other color, and so of the orange, yellow, blue, purple, and violet. A body which is of a *black* color, instead of reflecting, *absorbs* all, or the greater part of the rays that fall upon it; and, on the contrary, a body that appears *white* reflects the greater part of the rays indiscriminately, without separating the one from the other.

Before proceeding to describe the experiments by which the above results were obtained, it may be proper to give some idea of the form and effects of the *prism* by which such experiments are made. This instrument is triangular and straight, and generally about three or four inches long. It is commonly made of white glass, as free as possible from veins and bubbles, and other similar defects, and is solid throughout. Its lateral faces, or sides, should be perfectly plane, and of a fine polish. The angle formed by the two faces, one receiving the ray of light that is refracted in the instrument, and the other affording it an issue on its returning into the air, is called the *refracting angle* of the prism, as *A C B* (fig. 31). The manner in which Newton performed his experiments, and established the discovery to which we have alluded, is as follows:

Fig. 31.

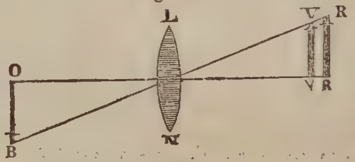


In the window-shutter, *E G* (fig. 31,) of a dark room, a hole, *F*, was made, of about one-third of an inch diameter, and behind it was placed a glass prism, *A C B*, so that the beam of light, *S F*, proceeding directly from the sun, was made to pass through the prism. Before the interposition of the prism, the beam proceeded in a straight line toward *T*, where it formed a round, white spot; but, being now bent out of its course by the prism, it formed an oblong image, *O P*, upon the white pasteboard, or screen, *L M*, containing the seven colors marked in the figure, the *red* being the *least*, and the *violet* the *most* refracted from the original direction of the solar beam, *S T*. This oblong image is called the *prismatic spectrum*. If the refracting angle of the prism, *A C B*, be 64 degrees, and the distance of the pasteboard from the prism about 18 feet, the length of the image, *O P*, will be about ten inches, and the breadth 2 inches. The sides of the spectrum are right lines distinctly bounded, and the ends are semicircular. From this circumstance, it is evident that it is still the image of the sun, but elongated by the refractive power of the prism. It is evident from the figure that, since some part of the beam, *R O*, is refracted much farther out of its natural course *W T* than some other part of the beam, as *W P*, the rays toward *R O* have a much greater disposition to be refracted than those toward *W P;* and that this disposition arises from the naturally different qualites of those rays, is evident from this consideration, that the refracting angle or power of the prism is the same in regard to the superior part of the beam as to the inferior.

By making a hole in the screen, *L M*, opposite any one of the colors of the spectrum, so as to allow that color alone to pass—and by letting the color thus separated fall upon a second prism—Newton found that the light of each of the colors was alike refrangible, because the second prism could not separate them into an oblong image, or into any other color. Hence he called all the seven colors *simple* or homogeneous, in opposition to *white* light, which he called *compound*, or heterogeneous. With the prism which this philosopher used, he found the lengths of the colors and spaces of the spectrum to be as follows: Red, 45; Orange, 27; Yellow, 40; Green, 60; Blue, 60; Indigo, 48; Violet, 80; or 360 in all. But these spaces vary a little with prisms formed of different substances, and, as they are not separated by distinct limits, it is difficult to obtain anything like an accurate measure of their relative extents. Newton examined the ratio between the sines of incidence and refraction of these decompounded rays (see p. 18), and found that each of the seven primary color-making rays had certain limits within which they were confined. Thus, let the sine of incidence in glass be divided into 50 equal parts, the sine of refraction into air of the *least* refrangible, and the *most* refrangible rays will contain respectively 77 and 78 such parts. The sines of refraction of all the degrees of *red* will have the intermediate degrees of magnitude, from 77 to 77 one-eighth; *Orange*, from 77 one-eighth to 77 one-fifth; *Yellow*, from 77 one-fifth to 77 one-third; *Green*, from 77 one-third to 77 one-half; *Blue*, from 77 one-half to 77 two-thirds; *Indigo*, from 77 two-thirds to 77 seven-ninths; and *Violet*, from 77 seven-ninths to 78.

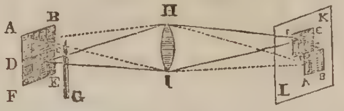
From what has been now stated, it is evident that, in proportion as any portion of an optic glass bears a resemblance to the form of a prism, the component rays that pass through it must be necessarily separated, and will consequently paint or tinge the object with colors. The edges of every convex lens approach to this form, and it is on this account that the extremities of objects, when viewed through them, are found to be tinged with the prismatic colors. In such a glass, therefore, those different colored rays will have *different foci*, and will form their respective images at different distances from the lens. Thus, suppose *L N* (fig. 32) to represent a double convex lens, and *O B*, an object at some distance from it. If the object *O B* was of a pure red color, the rays proceeding from it would form a red image at *R* r; if the object was of a violet color, an image of that color would be formed at V v, *nearer* the lens; and if the object was white, or any other combination of the color-making rays, those rays would have their respective foci at different distances from the lens, and form a succession of images, in the order of the prismatic colors, between the space *R* r and *V* v.

Fig. 32.



This may be illustrated in the following manner: Take a card or slip of white pasteboard, as *A B E F* (fig. 33), and paint one-half, *A B C D*, *red*, the other half, *C F*, *violet* or indigo, and, tying black threads across it, set it near the flame of a candle, *G;* then take a lens, *H I*, and, holding a sheet of white paper behind it, move it backward and forward upon the edge of a graduated ruler until you see the black threads most distinctly in the image, and you will find the focus of the violet f e much nearer than that of the red a c, which plainly shows that bodies of different colors can never be depicted by convex lenses without some degree of confusion.

Fig. 33.



The quantity of dispersion of the colored rays in convex lenses depends upon the focal length of the glass, the space which the colored images occupy being about the twenty-eighth part. Thus, if the lens be twenty-eight inches focal distance, the space between *R* r and *V* v (fig. 32) will be about one inch; if it be twenty-eight feet focus, the same space will be about one foot, and so on in proportion Now, when such a succession of images, formed by the different colored rays, is viewed through an eye-glass, it will seem to form but one image, and, consequently, very indistinct, and tinged with various colors; and as the red figure, *R* R, is largest, or seen under the greatest angle, the extreme parts of this confused image will be red, and a succession of the prismatic colors will be formed within this red fringe, as is generally found in common refracting telescopes, constructed with a single object-glass. It is owing to this circumstance that the common refracting telescope cannot be much improved without having recourse to lenses of a very long focal distance; and hence, about 150 years ago, such telescopes were constructed of 80, and 100, and 120 feet in length. But still, the image was not formed so distinctly as was desired, and the aperture of the object-glass was obliged to be limited. This is a defect which was long regarded as without a remedy, and even Newton himself despaired of discovering any means by which the defects of refracting telescopes might be removed, and their improvement effected. This, however, was accomplished by Dollond to an extent far surpassing what could have been expected, of which a particular account will be given in the sequel.

It was originally remarked by Newton, and the fact has since been confirmed by the experiments of Sir W. Herschel, that *the different colored rays have not the same illuminating power.* The violet rays appear to have the least illuminating effect; the indigo more, and the effect increases in the order of the colors, the *green* being very great; between the green and the yellow the greatest of all; the yellow the same as the green; but the red less than the yellow. Herschel also endeavored to determine whether the power of the differently-colored rays to *heat* bodies varied with their power to illuminate them. He introduced a beam of light into a dark room, which was decomposed by a prism, and then exposed a very sensible thermometer to all the rays in succession, and observed the hights to which it rose in a given time. He found that their heating power increased from the violet to the red. The mercury in the thermometer rose higher when its bulb was placed in the indigo than when it was placed in the violet, still higher in blue, and highest of all at red. Upon placing the bulb of the thermometer below the red, quite out of the spectrum, he was surprised to find that the mercury rose highest of all, and concluded that *rays proceed from the sun, which have the power of* HEATING but *not of illuminating bodies.* These rays have been called *invisible* solar rays; they were about half an inch from the commencement of the red rays; at a greater distance from this point the heat began to diminish, but was very perceptible, even at a distance of 1½ inch. He determined that the heating power of the *red* to that of the *green* rays was 2¾ to 1, and 3½ to 1, in red to *violet.* He afterward made experiments to collect those invisible caloric rays, and caused them to act independently of the light, from which he concluded that they are sufficient to account for all the effects produced by the solar rays in exciting heat; that they are capable of passing through glass, and of being refracted and reflected, after they have been finally detached from the solar beam.

M. Ritter, of Jena, Wollaston, Beckman, and others, have found that the rays of the spectrum are possessed of certain *chemical properties;* that beyond the least brilliant extremity, namely, a little beyond the violet ray, there are invisible rays, which act chemically, while they have neither the power of heating nor illuminating bodies. Muriate of silver, exposed to the action of the red rays, becomes blackish; a greater effect is produced by the yellow; a still greater by the violet, and the greatest of all by the invisible rays beyond the violet. When phosphorus is exposed to the action of the invisible rays beyond the red, it emits white fumes, but the invisible rays beyond the violet extinguish them. The influence of these rays is daily seen in the change produced upon vegetable colors, which fade when frequently exposed to the direct influence of the sun. Whatever object they are destined to accomplish in the general economy of nature is not yet distinctly known; we cannot, however, doubt that they are essentially requisite to various processes going forward in the material system. And we know that not only the comfort of all the tribes of the living world, but the very existence of the animal and vegetable creation depends upon the unremitting agency of the *calorific* rays.

It has likewise been lately discovered that certain rays of the spectrum, particularly the *violet, possess the property of communicating the magnetic power.* Mr. *Morichini*, of Rome, appears to have been the first who found that the violet rays of the spectrum had this property. The result of his experiments, however, was involved in doubt until it was established by a series of experiments instituted by Mrs. Somerville, whose name is so well known in the scientific world. This lady having covered half a sewing-needle, about an inch long, with paper, she exposed the other half for two hours to the violet rays. The needle had then acquired north polarity. The indigo rays produced nearly the same effect; and the blue and green rays produced it in a still less degree. In the yellow, orange, red, and invisible rays no magnetic influence was exhibited, even though the experiment was continued for three successive days. The same effects were produced by inclosing the needle in blue or green glass, or wrapping it in blue or green ribbon, or half of the needle being always covered with paper.

One of the most curious discoveries of modern times, in reference to the solar spectrum, is that of Fraunhofer, of Munich, one of the most distinguished artists and opticians on the Continent.* He discovered that the spectrum is covered with dark and colored lines, parallel to one another, and perpendicular to the length of the spectrum:

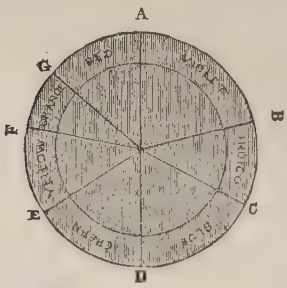
---

* Fraunhofer was, in the highest sense of the word, an *optician*, an original discoverer in the most abstruse and delicate departments of this science, a competent mathematician, an admirable mechanist, and a man of a truly philosophical turn of mind. By his extraordinary talents, he was soon raised from the lowest station in a manufacturing establishment to the direction of the *optical* department of the business, in which he originally labored as an ordinary workman. He then applied the whole power of his mind to the perfection of the achromatic telescope, the defects of which, in reference to the optical properties of the materials used, he attempted to remedy; and, by a series of admirable experiments, succeeded in giving to optical determinations the precision of astronomical observations, surpassing in this respect all who had gone before him, except, perhaps, the illustrious Newton. It was in the course of these researches that he was led to the important discovery of the dark lines which occur in the solar spectrum. His achromatic telescopes are scattered over Europe, and are the largest and best that have hitherto been constructed. He died at Munich, at a premature age, in 1826; his death, it is said, being accelerated by the unwholesome nature of the processes employed in his glass-house; leaving behind him a reputation rarely attained by one so young. His memoir "On the refractive and dispersive Power of the different Species of Glass, in reference to the Improvement of Achromatic Telescopes, and an Account of the Lines of the Spectrum," will be found in the "Edinburgh Philosophical Journal," vol. ix p. 288—299; and vol. x, p. 26—40, for 1823, '4.

and he counted no less than 590 of these lines. In order to observe these lines, it is necessary to use prisms of the most perfect construction, of very pure glass, free of veins, to exclude all extraneous light, and even to stop those rays which form the colored spaces which we are not examining. It is necessary, also, to use a magnifying instrument, and the light must enter and emerge from the prism at equal angles. One of the important practical results of this discovery is, that those lines are fixed points in the spectrum, or rather, that they have always the same position in the colored spaces in which they are found. Fraunhofer likewise discovered, in the spectrum produced by the light of Venus, the same streaks as in the solar spectrum; in the spectrum of the light of Sirius he perceived three large streaks, which, according to appearance, had no resemblance to those of the light of the sun; one of them was in the green, two in the blue. The stars appear to differ from one another in their streaks. The electric light differs very much from the light of the sun and that of a lamp in regard to the streaks of the spectrum. "This experiment may also be made, though in an imperfect manner, by viewing a narrow slit between two nearly closed window-shutters through a very excellent glass prism, held close to the eye, with the refracting angle parallel to the line of light. When the spectrum is formed by the sun's rays, either direct or indirect, as from the sky, clouds, rainbow, moon, or planets, the black bands are always found to be in the same parts of the spectrum, and under all circumstances to maintain the same relative position, breadth, and intensities."

From what has been stated in reference to the solar spectrum, it will evidently appear that white light is nothing else than a compound of all the prismatic colors; and this may be still further illustrated by showing that the seven primary colors, when again put together, recompose white light. This may be rudely proved, for the purpose of illustration, by mixing together seven different powders, having the colors and proportion of the spectrum; but the best mode, on the whole, is the following: Let two circles be drawn on a smooth round board, covered with white paper, as in figure 34; let the outermost be divided into 360 equal parts; then draw seven right lines, as *A*, *B*, *C*, *&c.*, from the center to the outermost circle, making the lines *A* and *B* include 80 degrees of that circle. The lines *B* and *C*, 40 degrees; *C* and *D*, 60; *D* and *E*, 60; *E* and *F*, 48; *F* and *G*, 27; *G* and *A*, 45. Then between these two circles paint the space *A G* red, inclining to orange near *G*; *G F* orange, inclining to yellow near *F*; *F E* yellow, inclining to green near *E*; *E D* green, inclining to blue near *D*; *D C* blue, inclining to indigo near *C*; *C B* indigo, inclining to violet near *B*; and *B A* violet, inclining to a soft red near *A*. This done, paint all that part of the board black which lies within the inner circle; and, putting an axis through the center of the board, let it be turned swiftly round that axis, so that the rays proceeding from the above colors may be all blended and mixed together in coming to the eye. Then the whole colored part will appear like a white ring a little grayish—not perfectly white, because no art can prepare or lay on perfect colors, in all their delicate shades, as found in the real spectrum.

Fig. 34.



That all the colors of light, when blended together in their proper proportions, produce a pure *white*, is rendered certain by the following experiment: Take a large convex glass, and place it in the room of the paper or screen on which the solar spectrum was depicted (L. M. fig. 31); the glass will unite all the rays that come from the prism, if a paper is placed to receive them, and you will see a circular spot of pure lively white. The rays will cross each other in the focus of the glass, and, if the paper be removed a little farther from that point, you will see the prismatic colors again displayed, but in an inverted order, owing to the crossing of the rays.

SECTION II.

ON THE COLORS OF NATURAL OBJECTS.

From what has been stated above we may learn the true cause of those diversified hues exhibited by natural and artificial objects, and the variegated coloring which appears on the face of nature. It is owing to the surfaces of bodies being disposed to reflect one color rather than another. When this disposition is such that the body reflects every kind of ray, in the mixed state in which it receives them, that body appears white to us, which, properly speaking, is no color, but rather the assemblage of all colors. If the body has a fitness to reflect one sort of rays more abundantly than others, by absorbing all the others, it will appear of the color belonging to that species of rays. Thus, the grass is green, because it absorbs all the rays except the green. It is these green rays only, which the grass, the trees, the shrubs, and all the other verdant parts of the landscape reflect to our sight, and which make them appear green. In the same manner, the different flowers reflect their respective colors; the rose, the red rays; the violet, the blue; the jonquil, the yellow; the marigold, the orange; and every object, whether natural or artificial, appears of that color which its peculiar texture is fitted to reflect. A great number of bodies are fitted to reflect at once several kinds of rays, and of consequence, they appear under mixed colors. It may even happen that of two bodies which should be green, for example, one may reflect the pure green of light, and the other, the mixture of yellow and blue. This quality, which varies to infinity, occasions the different kinds of rays to unite in every possible manner, and every possible proportion; and hence the inexhaustible variety of shades and hues which nature has diffused over the landscape of the world. When a body absorbs nearly all the light which reaches it, that body appears *black*; it transmits to the eye so few reflected rays that it is scarcely perceptible in itself, and its presence and form make no impression upon us unless as it interrupts the brightness of the surrounding space. Black is, therefore, the absence of all the colored rays.

It is evident, then, that all the various assemblages of colors which we see in the objects around us *are not in the bodies themselves*, but in the light which falls upon them. There is no color *inherent* in the grass, the trees, the fruits, and the flowers, nor even in the most splendid and variegated dress that adorns a lady. All such objects are as destitute of color, in themselves, as bodies which are placed in the center of the earth, or as the chaotic materials out of which our globe was formed before light was created; for, where there is no light, there is no color. Every object is black, or without color, in the dark, and it only appears colored as soon as light renders it visible. This is further evident from the following experiment: If we place a colored body in one of the colors of the spectrum which is formed by the prism, it appears of the color of the rays in which it is placed. Take, for example, a red rose, and expose it first to the red rays, and it will appear of a more brilliant ruddy hue; hold it in the blue rays, and it appears no longer red, but of a dingy blue color, and in like manner its color will appear different when placed in all the other differently-colored rays. This is the reason why the colors of objects are essentially altered by the nature of the light in which they are seen. The colors of ribbons, and various pieces of silk or woolen stuff, are not the same when viewed by candlelight as in the day-time. In the light of a candle or a lamp, blue often appears green, and yellow objects assume a whitish aspect. The reason is, that the light of a candle is not so pure a white as that of the sun, but has a yellowish tinge, and therefore, when refracted by the prism, the yellowish rays are found to predominate, and the superabundance of yellow rays gives to blue objects a greenish hue.

The doctrine we are now illustrating is one which a great many persons, especially among the fair sex, find it difficult to admit. They cannot conceive it possible that there is no color really inherent in their splendid attire, and no tints of beauty in their countenances. "What," said a certain lady, "are there no colors in my shawl, and in the ribbons that adorn my headdress, and are we all as black as negroes in the dark? I should almost shudder to think of it." Such persons, however, need be in no alarm at the idea, but may console themselves with the reflection that, when they are stripped of all their colored ornaments in the dark, they are certain that *they will never be seen by any one* in that state; and therefore there is no reason to regret the temporary loss of those beauties which light creates, when they themselves, and all surrounding objects, are *invisible.* But, to give a still more palpable proof of this position, the following popular experiments may be stated:

Take a pint of common spirit and pour it into a soup dish, and then set it on fire; as it begins to blaze, throw a handful of salt into the burning spirit, and keep stirring it with a spoon. Several handfuls may thus be successively thrown in, and then the spectators, standing around the flame, will see each other frightfully changed, their colors being altered into a ghastly blackness, in consequence of the nature of the light which falls upon them, which produces colors very different from those of the solar light. The following experiment, as described by Sir D. Brewster, illustrates the same principle: "Having obtained the means of illuminating any apartment with *yellow* light, let the exhibition be made in a room with furniture of various bright colors, and with oil or water-colored paintings on the wall. The party which is to witness the experiment should be dressed in a diversity of the gayest colors, and the brightest colored flowers and highly colored drawings should be placed on the tables. The room being at first lighted with ordinary lights, the bright and gay colors of everything that it contains will be finely displayed. If the white lights are now suddenly extinguished, and the yellow lamps lighted, the most appalling metamorphosis will be exhibited. The astonished individuals will no longer be able to recognize each other. All the furniture of the room, and all the objects it contains, will exhibit only *one* color. The flowers will lose their hues; the paintings and drawings will appear as if they were executed in China ink, and the gayest dresses, the brightest scarlets, the purest lilacs, the richest blues, and the most vivid greens, will all be converted into one monotonous yellow. The complexions of the parties, too, will suffer a corresponding change. One pallid death-like yellow,

> Like the unnatural hue
> Which autumn paints upon the perished leaf,

will envelop the young and the old, and the *sallow* face will alone escape from the metamorphosis. Each individual derives merriment from the cadaverous appearance of his neighbor, without being sensible that he is one of the ghastly assemblage."

From such experiments as these we might conclude that, were the solar rays of a very different description from what they are now found to be, the colors which embellish the face of nature, and the whole scene of our sublunary creation, would assume a new aspect, and appear very different from what we now behold around us in every landscape. We find that the stars display great diversity of color, which is doubtless owing to the different kinds of light which are emitted from those bodies; and hence we may conclude that the coloring thrown upon the various objects of the universe is different in every different system, and that thus, along with other arrangements, an infinite variety of coloring and of scenery is distributed throughout the immensity of creation.

The *atmosphere*, in consequence of its different refractive and reflective powers, is the source of a variety of colors which frequently embellish and diversify the aspect of our sky. The air *reflects* the blue rays most plentifully, and must therefore *transmit* the red, orange, and yellow more copiously than the other rays. When the sun and other heavenly bodies are at a high elevation, their light is transmitted without any perceptible change; but when they are near the horizon, their light must pass through a long and dense track of air, and must therefore be considerably modified before it reach the eye of the observer. The momentum of the red rays being greater than that of the violet, will force their way through the resisting medium, while the violet rays will be either reflected or absorbed. If the light of the setting sun, by thus passing through a long track of air, be divested of the green, blue, indigo, and violet rays, the remaining rays which are transmitted through the atmosphere will illuminate the western clouds, first, with an orange color, and then, as the sun gradually sinks into the horizon, the track through which the rays must pass becoming longer, the yellow and orange are reflected, and the clouds grow more deeply *red*, until at length the disappearance of the sun leaves them of a leaden hue, by the reflection of the blue light through the air. Similar changes of color are sometimes seen on the eastern and western fronts of white buildings. St. Paul's Church, in London, is frequently seen, at sunset, tinged with a very considerable degree of redness, and the same cause occasions the moon to assume a ruddy color, by the light transmitted through the atmosphere. From such atmospherical refractions and reflections are produced those rich and beautiful hues with which our sky is gilded by the setting sun, and the glowing red which tinges the morning and evening clouds, until their ruddy glare is tempered by the purple of twilight, and the reflected azure of the sky.

When a direct spectrum is thrown on colors darker than itself, it mixes with them, as the yellow spectrum of the setting sun, thrown on the green grass, becomes a greener yellow. But when a direct spectrum is thrown on colors brighter than itself, it becomes instantly changed into the reverse spectrum, which mixes with those brighter colors. Thus the yellow spectrum of the setting sun, thrown on the luminous sky, becomes blue, and changes with the color or brightness of the clouds on which it appears. The red part of light being capable of struggling through thick and resisting mediums which intercept all other colors, is likewise the cause why the sun appears red when seen through a fog; why distant light, though transmitted through blue or green glass, appears red; why lamps at a distance, seen through the smoke of a long street, are red, while those that are near are white. To the same cause it is owing that a diver at the bottom of the sea is surrounded with the red light which has pierced through the superincumbent fluid, and that the blue rays are reflected from the *surface* of the ocean. Hence Dr. Halley informs us that, when he was in a diving-bell at the bottom of the sea, his hand always appeared red in the water.

The *blue* rays, as already noticed, being unable to resist the obstructions they meet with in their course through the atmosphere, are either reflected or absorbed in their passage. It is to this cause that most philosophers ascribe *the blue color of the sky*, the faintness and obscurity of distant objects, and the bright azure which tinges the mountains of a distant landscape.

SECTION III.

Phenomena of the rainbow.

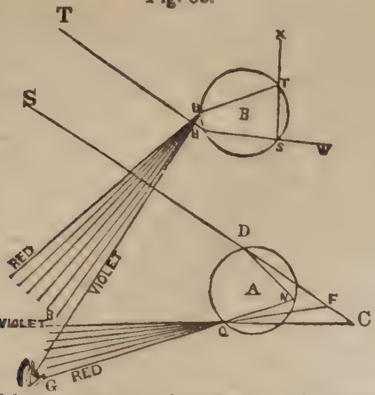
Since the rays of light are found to be decomposed by refracting surfaces, and reflected in an infinite variety of modes and shades of color, we need not be surprised at the changes produced in any scene or object by the intervention of another, and by the numerous modifications of which the primary colors of nature are susceptible. The vivid colors which gild the rising and the setting sun must necessarily differ from those which adorn its noonday splendor. Variety of atmospheric scenery will thus necessarily be produced, greater than the most lively fancy can well imagine. The clouds will sometimes assume the most fantastic forms, and at other times will be irradiated with beams of light, or, covered with the darkest hues, will assume a lowering aspect, prognostic of the thunder's roar and the lightning's flash, all in accordance with the different rays that are reflected to our eyes, or the quantity absorbed by the vapors which float in the atmosphere.

Light, which embellishes with so much magnificence a pure and serene sky, by means of innumerable bright starry orbs which are spread over it, sometimes, in a dark and cloudy sky, exhibits an ornament which, by its pomp, splendor, and variety of colors, attracts the attention of every eye that has an opportunity of beholding it. At certain times, when there is a shower either around us, or at a distance from us in an opposite quarter to that of the sun, a species of arch or bow is seen in the sky, adorned with all the seven primary colors of light. This phenomenon, which is one of the most beautiful meteors in nature, has obtained the name of the Rainbow. The rainbow was, for ages, considered as an inexplicable mystery, and by some nations it was adored as a deity. Even after the dawn of true philosophy, it was a considerable time before any discovery of importance was made as to the true causes which operate in the production of this phenomenon. About the year 1571, M. Fletcher, of Breslau, made a certain approximation to the discovery of the true cause, by endeavoring to account for the colors of the rainbow by means of a double refraction and one reflection. A nearer approximation was made by Antonio de Dominis, bishop of Spalatro, about 1601. He maintained that the double refraction of Fletcher, *with an intervening reflection*, was sufficient to produce the colors of the bow, and also to bring the rays that formed them to the eye of the spectator, without any subsequent reflection. To verify this hypothesis, he procured a small globe of solid glass, and viewing it when it was exposed to the rays of the sun, with his back to that luminary, in the same manner as he had supposed the drops of rain were situated with respect to them, he observed the same colors which he had seen in the rainbow, and in the same order. But he could give no good reason *why* the bow should be colored, and, much less, any satisfactory account of the *order* in which the colors appear. It was not until Sir I. Newton discovered the different refrangibility of the rays of light that a complete and satisfactory explanation could be given of all the circumstances connected with this phenomenon.

As the full elucidation of this subject involves a variety of optical and mathematical investigations, I shall do little more than explain the general principle on which the prominent phenomena of the rainbow may be accounted for, and some of the facts and results which theory and observation have deduced.

We have just now alluded to an experiment with a glass globe: If, then, we take either a solid glass globe, or a hollow globe filled with water, and suspend it so high in the solar rays above the eye that the spectator, with his back to the sun, can see the globe *red;* if it be lowered slowly, he will see it orange, then yellow, then green, then blue, then indigo, and then violet; so that the drop, at different hights, shall present to the eye the seven primitive colors in succession. In this case, the globe, from its form, will act in some measure like a prism, and the ray will be separated into its component parts. The following figure will more particularly illustrate this point. Suppose *A* (fig. 35) to represent a drop of rain—which may be considered as a globe of glass in miniature, and will produce the same effect on the rays of light—and let *S* D represent a ray from the sun falling upon the upper part of the drop at D. At the point of entering the drop it will suffer a refraction, and, instead of going forward to C, it will be bent to N. From N a part of the light will be reflected to Q—some part of it will, of course pass through the drop. By the obliquity with which it falls on the side of the

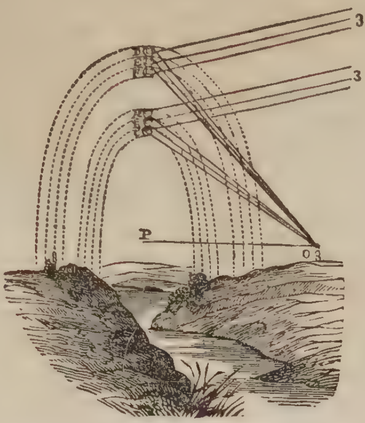
Fig. 35.



drop at Q, that part becomes a kind of prism, and separates the ray into its primitive colors. It is found by computation, that after a ray has suffered two refractions and one reflection, as here represented, the least refrangible part of it, namely, the *red* ray, will make an angle with the incident solar ray of 42° 2′, as *S* F Q; and the violet, or greatest refrangible ray, will make, with the solar ray, an angle of 40° 17′, as *S* C Q; and thus all the particles of water within the difference of those two angles, namely, 1° 45′ (supposing the ray to proceed merely from the center of the sun), will exhibit severally the colors of the prism, and constitute the *interior* bow of the cloud. This holds good at whatever hight the sun may chance to be in a shower of rain. If he be at a high altitude, the rainbow will be low; if he be at a low elevation, the rainbow must be high; and if a shower happen in a vale, when the spectator is on a mountain, he will sometimes see the bow in the form of a *complete circle* below him. We have at present described the phenomena only of a single drop; but it is to be considered that in a shower of rain there are drops at all hights and at all distances, and therefore the eye situated at G will see all the different colors. All those drops that are in a certain position with respect to the spectator will reflect the red rays, all those in the next station the orange, those in the next the green, and so on with regard to all the other colors.

It appears, then, that the first or primary bow is formed by two refractions and one reflection; but there is frequently a second bow on the outside of the other, which is considerably fainter. This is produced by drops of rain above the drop we have supposed at *A*. If *B* (fig. 35) represent one of these drops, the ray to be sent to the eye enters the drop near the bottom, and suffers *two refractions* and *two reflections*, by which means the colors become reversed, that is, the violet is lowest in the *exterior* bow, and the red is lowest in the *interior* one, and the other colors are reversed accordingly. The ray *T* is refracted at R: a part of it is reflected from S to T, and at T it suffers another reflection from T to U. At the points S and T part of the ray *passes through* the drop, on account of its transparency, toward W and X, and therefore we say that *part* only of the ray is reflected. By these losses and reflections the exterior bow becomes faint and ill-defined in comparison of the interior or primary bow. In this case the upper part of the secondary bow will not be seen when the sun is above 54° 10′ above the horizon, and the lower part of the bow will not be seen when the sun is 60° 58′ above the horizon.

Fig. 36.



For the further illustrations of this subject, we may introduce the following section of a bow (fig. 36), and, in order to prevent confusion in attempting to represent all the different colors, let us suppose only three drops of rain, and three different colors, as shown in the figure. The spectator, *O*, being in the center of the two bows here represented—the planes of which must be considered as perpendicular to his view—the drops *A*, *B*, and *C* produce part of the interior bow by two refractions and one reflection, as stated before, and the drops *D*, *E*, *F* will produce the exterior bow by two refractions and two reflections, the sun's rays being represented by 3, 3. It is evident that the angle *C O P* is less than the angle *B O P*, and that the angle *A O P* is the greatest of the three. The largest angle, then, is formed by the red rays, the middle one consists of the green, and the smallest the purple or violet. All the drops of rain, therefore, that happen to be in a certain position with respect to the spectator's eye, will reflect the red rays, and form a band or semicircle of red, and so of the other colors from drops in other positions. If the spectator alters his station, he will see a bow, but not the same as before; and if there be many spectators, they will each see a different bow, though it appears to be the same.

The rainbow assumes a *semicircular* appearance, because it is only at certain angles that the refracted rays are visible to our eyes, as is evident from the experiment of the glass globe formerly alluded to, which will refract the rays only in a certain position. We have already stated that the red rays make an angle of 42° 2′, and the violet an angle of 40° 17′. Now, if a line be drawn horizontally from the spectator's eye, it is evident that angles formed with this line, of a certain dimension, in every direction, will produce a circle, as will appear by attaching a cord of a given length to a certain point, round which it may turn as round its axis; and, in every point, will describe an angle with the horizontal line of a certain and determinate extent.

Sometimes it happens that *three* or more bows are visible, though with different degrees of distinctness. I have more than once observed this phenomenon, particularly in Edinburgh, in the month of August, 1825, when three rainbows were distinctly seen in the same quarter of the sky, and, if I recollect right, a fragment of the fourth made its appearance. This happens when the rays suffer a third or fourth reflection; but on account of the light lost by so many reflections, such bows are, for the most part, altogether imperceptible.

If there were no ground to intercept the rain and the view of the observer, the rainbow would form a *complete circle*, the center of which is diametrically opposite to the sun. Such circles are sometimes seen in the spray of the sea or of a cascade, or from the tops of lofty mountains, when the showers happen in the vales below.—Rainbows of various descriptions are frequently observed rising amid the spray and exhalations of waterfalls, and among the waves of the sea, whose tops are blown by the wind into small drops.—There is one regularly seen when the sun is shining, and the spectator in a proper position, at the fall of Staubback, in the bosom of the Alps; one near Schaffhausen; one at the cascade of Lauffen, and one at the cataract of Niagara in North America. A still more beautiful one is said to be seen at Terni, where the whole current of the River Velino, rushing from a steep precipice of nearly 200 feet high, presents to the spectator below a variegated circle, overarching the fall, and two other bows suddenly reflected on the right and left. Don Ulloa, in the account of his journeys in South America, relates that circular rainbows are frequently seen on the montains above Quito in Peru. It is said that a rainbow was once seen near London, caused by the exhalations of that city, after the sun had been below the horizon more than twenty minutes.* A naval friend, says Mr. Bucke, informed me that, as he was one day watching the sun's effect upon the exhalations near Juan Fernandez, he saw upward of five-and-twenty *ires marinæ* animate the sea at the same time. In these marine bows the concave sides were turned upward, the drops of water rising from below, and not falling from above, as in the instances of the aerial arches.—Rainbows are also occasionally seen on the grass in the morning dew, and likewise when the hoarfrost is descending. Dr. Langwith once saw a bow lying on the ground, the colors of which were almost as lively as those of a common rainbow. It was not round, but oblong, and was extended several hundred yards. The colors took up less space, and were much more lively in those parts of the bow which were near him than in those which were at a distance. When M. Labillardiere was on Mount Teneriffe, he saw the contour of his body traced on the clouds beneath him in all the colors of the solar bow. He had previously witnessed this phenomenon on the Kesrouan, in Asia Minor. The rainbows of Greenland are said to be frequently of a pale white, fringed with a brownish yellow arising from the rays of the sun being reflected from a frozen cloud.

The following is a summary view of the principal facts which have been ascertained respecting the rainbow: 1. The rainbow can only be seen when it rains, and in that point of the heavens which is opposite to the sun. 2. Both the primary and secondary bows are variegated with all the prismatic colors—the red being the highest color in the primary, or brightest bow, and the violet the highest in the exterior. 3. The primary rainbow can never be a greater arc than a semicircle; and, when the sun is set, no bow, in ordinary circumstances, can be seen. 4. The breadth of the inner or primary bow—supposing the sun but a point—is 1° 45′, and the breadth of the exterior bow 3° 12′, which is nearly twice as great as that of the other; and the distance between the bows is 8° 55′. But since the body of the sun subtends an angle of about half a degree, by so much will each bow be increased, and their distance diminished; and therefore the breadth of the interior bow will be 2° 15′, and that of the exterior 3° 42′, and their distance 8° 25′. The greatest semidiameter of the interior bow, on the same grounds, will be 42° 17′, and the least of the exterior bow 50° 43′. 5. When the sun is in the horizon, either in the morning or evening, the bows will appear complete semicircles. On the other hand, when the sun's altitude is equal to 42° 2′, or to 54° 10′, the summits of the bows will be depressed below the horizon. Hence, during the days of summer, within a certain interval each day, no visible rainbows can be formed, on account of the sun's high altitude above the horizon. 6. The altitude of the bows above the horizon or surface of the earth varies according to the elevation of the sun. The altitude, at any time, may be taken by a common quadrant, or any other angular instrument; but if the sun's altitude at any particular time be known, the hight of the summit of any of the bows may be found by subtracting the sun's altitude from 42° 2′ for the inner bow, and from 54° 10′ for the outer. Thus, if the sun's altitude be 26°, the hight of the primary bow would be 16° 2′, and of the secondary, 28° 10′. It follows that the hight and the size of the bows diminish as the altitude of the sun increases. 7. If the sun's altitude is more than 42°, and less than 54°, the exterior bow may be seen, though the interior bow is invisible. 8. Sometimes only a portion of an arch will be visible, while all the other parts of the bow are invisible. This happens when the rain does not occupy a space of sufficient extent to complete the bow; and the appearance of this position, and even of the bow itself, will be various, according to the nature of the situation, and the space occupied by the rain.

The appearance of the rainbow may be produced by artificial means at any time, when the sun is shining, and not too highly elevated above the horizon. This is effected by means of artificial fountains, or *jet d'eaus*, which are intended to throw up streams of water to a great hight. These streams, when they spread very wide, and blend together in their upper parts, form, when falling, a shower of artificial rain.—If, then, when the fountain is playing, we move between it and the sun, at a proper distance from the fountain, until our shadow point directly toward it, and look at the shower, we shall observe the colors of the rainbow strong and vivid; and, what is particularly worthy of notice, the bow appears, notwithstanding the nearness of the shower, to be as large and as far off as the rainbow which we see in a natural shower of rain. The same experiment may be made by candle-light, and with any instrument that will form an artificial shower.

Lunar Rainbows.—A lunar bow is sometimes formed at night, by the rays of the moon striking on a rain-cloud, especially when she is about the full. But such a phenomenon is very rare. Aristotle is said to have considered himself the first who had seen a lunar rainbow. For more than a hundred years prior to the middle of the last century, we find only two or three instances recorded in which such phenomena are described with accuracy. In the Philosophical Transactions for 1783, however, we have an account of three having been seen in one year, and all in the same place, but they are by no means common phenomena. I have had an opportunity within the last twenty years of witnessing two phenomena of this description, one of which was seen at Perth, on a Sabbath evening, in the autumn of 1825, and the other at Edinburgh, on Wednesday, the 9th of September, 1840, about eight o'clock in the evening, of both which I gave a detailed description in some of the public journals. The moon, in both cases, was within a day or two of the full; the arches were seen in the northern quarter of the heavens, and extended nearly from east to west, the moon being not far from the southern meridian. The bows appeared distinct and well defined, but no distinct traces of the prismatic colors could be perceived on any of them. That which appeared in 1825 was the most distinctly formed, and continued visible for more than an hour. The other was much fainter, and lasted little more than half an hour, dark clouds having obscured the face of the moon.—These bows bore a certain resemblance to some of the luminous arches which sometimes accompany the Aurora Borealis, and this latter phenomenon has not unfrequently been mistaken for a lunar rainbow; but they may be always distinguished by attending to the phases and position of the moon. If the moon be not visible above the horizon, if she be in her first or last quarter, or if any observed phenomenon be not in a direction opposite to the moon, we may conclude with certainty that, whatever appearance is presented, there is no lunar rainbow.

---

* Philosophical Transactions, vol. 1, p. 294.

The rainbow is an object which has engaged universal attention, and its beautiful colors and form have excited universal admiration. The poets have embellished their writings with many beautiful allusions to this splendid meteor; and the playful schoolboy, while viewing the "bright enchantment," has frequently run "to catch the falling glory." When its arch rests on the opposite sides of a narrow valley, or on the summits of two adjacent mountains, its appearance is both beautiful and grand. In all probability, its figure first suggested the idea of *arches*, which are now found of so much utility in forming aqueducts and bridges, and for adorning the architecture of palaces and temples. It is scarcely possible seriously to contemplate this splendid phenomenon without feeling admiration and gratitude toward that wise and beneficent Being whose hands have bent it into so graceful and majestic a form, and decked it with all the pride of colors. "Look upon the rainbow," says the son of Sirach,* "and praise Him that made it: very beautiful it is in the brightness thereof. It compasseth the heaven about with a glorious circle, and the hands of the Most High have bended it." To this grand ethereal bow the inspired writers frequently allude as one of the emblems of the majesty and splendor of the Almighty. In the prophesies of Ezekiel, the throne of Deity is represented as adorned with a brightness "like the appearance of the bow that is in the cloud in the day of rain—the appearance of the likeness of the glory of Jehovah." And, in the visions recorded in the Book of the Revelations, where the Most High is represented as sitting upon a throne, "there was a rainbow round about the throne, in sight like unto an emerald," as an emblem of his propitious character, and of his faithfulness and mercy. After the deluge, this bow was appointed as a sign and memorial of the covenant which God made with Noah and his sons, that a flood of waters should never again be permitted to deluge the earth and its inhabitants, and as a pledge of inviolable fidelity and Divine benignity. When, therefore, we at any time behold "the bow in the cloud," we have not only a beautiful and sublime phenomenon presented to the eye of sense, but also a memorial exhibited to the mental eye, assuring us that, "While the earth remaineth, seed-time and harvest, and cold and heat, and summer and winter, and day and night, *shall not cease*."*

> "On the broad sky is seen
> A dewy cloud, and in the cloud a bow
> Conspicuous, with seven listed colors gay,
> Betokening peace with God and covenant new.
> He gives a promise never to destroy
> The earth again by flood, nor let the sea
> Surpass his bounds, nor rain to drown the world."

SECTION IV

REFLECTIONS ON THE BEAUTY AND UTILITY OF COLORS.

COLOR is one of the properties of light which constitutes chiefly the beauty and sublimity of the universe. It is color, in all its diversified shades, which presents to our view that almost infinite variety of aspect which appears on the scene of nature, which gives delight to the eye and the imagination, and which adds a fresh pleasure to every new landscape we behold. Every flower which decks our fields and gardens is compounded of different hues: every plain is covered with shrubs and trees of different degrees of verdure; and almost every mountain is clothed with herbs and grass of different shade from those which appear on the hills and landscape with which it is surrounded. In the country, during summer, nature is every day, and almost every hour, varying her appearance by the multitude and variety of her hues and decorations, so that the eye wanders with pleasure over objects continually diversified, and extending as far as the sight can reach. In the flowers with which every landscape is adorned, what a lovely assemblage of colors, and what a wonderful art in the disposition of their shades! Here a light pencil seems to have laid on the delicate tints; there they are blended according to the nicest rules of art. Although green is the general color which prevails over the scene of sublunary nature, yet it is diversified by a thousand different shades, so that every species of tree, shrub, and herb is clothed with its own peculiar verdure. The dark green of the forests is thus easily distinguished from the lighter shades of cornfields and the verdure of the lawns. The system of animated nature likewise displays a diversified assemblage of beautiful colors. The plumage of birds, the brilliant feathers of the peacock, the ruby and emerald hues which adorn the little humming-bird, and the various embellishments of many species of the insect tribe, present to the eye in every region of the globe, a scene of diversified beauty and embellishment. Nor is the mineral kingdom destitute of such embellishments; for some of the darkest and most unshapely stones and pebbles, when polished by the hand of art, display a mixture of the most delicate and variegated colors. All which beauties and varieties in the scene around us are entirely owing to that property, in every ray of light, by which it is capable of being separated into the primitive colors.

---

* Ecclesiasticus, xliii, 11, 12.

* It is a question which has been frequently started, whether there was any rainbow before the flood? Some have conceived that the rainbow was something of a *miraculous* production, and that it was never seen before the flood. The equivocal sense of the word "set," in our translation, has occasioned a mistaken impression of this kind. The Hebrew word, thus translated, signifies more properly "I do give," or "I *appoint*." The whole passage in reference to this circumstance, literally translated, runs thus: "I appoint my bow which is in the cloud, that it may be for a sign or token of a covenant between me and the earth; and it shall come to pass, when I bring a cloud over the earth, and the bow shall be seen in the cloud, that I will remember my covenant that is between me and you," &c. As the rainbow is produced by the immutable laws of refraction and reflection, as applied to the rays of the sun striking on drops of falling rain, the phenomenon must have been occasionally exhibited from the beginning of the world; unless we suppose that there was no rain before the flood, and that the constitution of things in the physical system was very different from what it is now. The passage affirms no more than that the rainbow was *then appointed* to be a *symbol* of the covenant between God and man; and although it may have been frequently seen before, it would serve the purpose of a sign equally well as if it had been miraculously formed for this purpose, and even better, as its frequent appearance, according to natural laws, is a perpetual memorial to man of the Divine faithfulness and mercy.

To the same cause, likewise, are to be ascribed those beautiful and diversified appearances which frequently adorn the face of the sky—the yellow, orange, and ruby hues which embellish the firmament at the rising of the sun, and when he is about to descend below the western horizon; and those aerial landscapes, so frequently beheld in tropical climes, where rivers, castles, and mountains are depicted rolling over each other along the circle of the horizon. The clouds, especially in some countries, reflect almost every color in nature. Sometimes they wear the modest blush of the rose; sometimes they appear like stripes of deep vermillion, and sometimes as large, brilliant masses tinged with various hues; now they are white as ivory, and now as yellow as native gold. In some tropical countries, according to St. Pierre, the clouds roll themselves up into enormous masses as white as snow, and are piled upon each other, like the Cordilleras of Peru, and are molded into the shape of mountains, of caverns, and of rocks. When the sun sets behind this magnificent aerial net-work, a multitude of luminous rays are transmitted through each particular interstice, which produce such an effect that the two sides of the lozenge illuminated by them have the appearance of being begirt with a fillet of gold; and the other two, which are in the shade, seem tinged with a superb ruddy orange. Four or five divergent streams of light, emanating from the setting sun up to the zenith, clothe with fringes of gold the undeterminate summits of this celestial barrier, and proceed to strike with the reflexes of their fires the pyramids of the collateral aerial mountains, which then appear to consist of silver and vermilion. In short, color diversifies every sublunary scene, whether on the earth or in the atmosphere; it imparts a beauty to the phenomena of falling stars, of luminous arches, and the coruscations of the Aurora Borealis, and gives a splendor and sublimity to the spacious vault of heaven.

Let us now consider for a moment what would be the aspect of nature if, instead of the beautiful variety of embellishments which now appear on every landscape, and on the concave of the sky, *one* uniform color had been thrown over the scenery of the universe. Let us conceive the whole of terrestrial nature to be covered with snow, so that not an object on earth should appear with any other hue, and that the vast expanse of the firmament presented precisely the same uniform aspect. What would be the consequence? The light of the sun would be strongly reflected from all the objects within the bounds of our horizon, and would produce a luster which would dazzle every eye. The day would acquire a greater *brightness* than it now exhibits, and our eyes might, after some time, be enabled freely to expatiate over the surrounding landscape; but everything, though enlightened, would appear *confused*, and particular objects would scarcely be distinguishable. A tree, a house, or a church near at hand might possibly be distinguished, on account of its elevation above the general surface of the ground, and the bed of a river by reason of its being depressed below it. But we should be obliged rather to guess, and to form a conjecture as to the particular object we wished to distinguish, than to arrive at any certain conclusion respecting it; and if it lay at a considerable distance, it would be impossible, with any degree of probability, to discriminate any one object from another. Notwithstanding the universal brightness of the scene, the uniformity of color thrown on every object would most certainly prevent us from distinguishing a church from a palace, a cottage from a knoll or heap of rubbish, a splendid mansion from rugged rocks, the trees from the hills on which they grow, or a barren desert from rich and fertile plains. In such a case human beings would be confounded, and even friends and neighbors be at a loss to recognize one another.

The vault of heaven, too, would wear a uniform aspect. Neither planets nor comets would be visible to any eye, nor those millions of stars which now shine forth with so much brilliancy, and diversify the nocturnal sky; for it is by the contrast produced by the deep azure of the heavens and the white radiance of the stars that those bodies are rendered visible. Were they depicted on a pure white ground. they would not be distinguished from that ground, and would, consequently, be invisible, unless any of them occasionally assumed a different color. Of course, all that beautiful variety of aspect which now appears on the face of sublunary nature—the rich verdure of the fields, the stately port of the forest, the rivers meandering through the valleys, the splendid hues that diversify and adorn our gardens and meadows, the gay coloring of the morning and evening clouds, and all that variety which distinguishes the different seasons, would entirely disappear. As every landscape would exhibit nearly the same aspect, there would be no inducement to the poet and the philosopher to visit distant countries to investigate the scenes of nature, and journeyings from one region to another would scarcely be productive of enjoyment. Were any other single color to prevail, nearly the same results would ensue. Were a deep ruddy hue to be uniformly spread over the scene of creation, it would not only be offensive to the eye, but would likewise prevent all distinction of objects. Were a dark blue or a deep violet to prevail, it would produce a similar effect, and, at the same time, present the scene of nature as covered with a dismal gloom. Even if creation were arrayed in a robe of *green* which is a more pleasant color to the eye, were it not diversified with the different shades it now exhibits, every object would be equally undistinguishable.

Such would have been the aspect of creation, and the inconveniences to which we should have been subjected, had the Creator afforded us light without that intermixture of colors which now appears over all nature, and which serves to discriminate one object from another. Even our very apartments would have been tame and insipid, incapable of the least degree of ornament, and the articles with which they are furnished almost undistinguishable, so that, in discriminating one object from another, we should have been as much indebted to the sense of touch as to the sense of vision. Our friends and fellow-men would have presented no objects of interest in our daily associations. The sparkling eye, the benignant smile, the modest blush, the blended hues of white and vermilion in the human face, and the beauty of the female countenance, would all have vanished, and we should have appeared to one another as so many moving marble statues, cast nearly in the same mold. But what would have been worst of all, the numerous delays, uncertainties, and perplexities to which we should have been subjected, had we been under the necessity every moment of distinguishing objects by trains of reasoning, and by circumstances of time, place, and relative position? An artist, when commencing his work in the morning, with a hundred tools of nearly the same size and shape around him, would have spent a considerable portion of his time before he could have selected those proper for his purpose, or the objects to which they were to be applied; and in every department of society, and in all our excursions from one place to another, similar difficulties and perplexities would have occurred. The one-half of our time must thus have been employed in uncertain guesses and perplexing reasonings respecting the real nature and individuality of objects, rather than in a regular train of thinking and of employment; and, after all our perplexities and conjectures, we must have remained in the utmost uncertainty as to the thousands of scenes and objects which are now obvious to us, through the instrumentality of colors, as soon as we open our eyes.

In short, without color we could have had no books nor writings: we could neither have corresponded with our friends by letters, nor have known anything with certainty of the events which happened in former ages. No written revelation of the will of God, and of his character, such as we now enjoy, could have been handed down to us from remote periods and generations. The discoveries of science and the improvements of art would have remained unrecorded. Universal ignorance would have prevailed throughout the world, and the human mind have remained in a state of demoralization and debasement. All these, and many other inconveniences and evils would have inevitably followed, had not God painted the rays of light with a diversity of colors. And hence we may learn that the most important scenes and events in the universe may depend upon the existence of a single principle in nature, and even upon the most minute circumstances, which we may be apt to overlook, in the arrangements of the material world.

In the existing state of things in the visible creation, we cannot but admire the wisdom and beneficence of the Deity in thus enabling us to distinguish objects by so easy and expeditious a mode as *that of color*, which in a moment discriminates every object and its several relations. We rise in the morning to our respective employments, and our food, our drink, our tools, our books, and whatever is requisite for our comfort, are at once discriminated. Without the least hesitation or uncertainty, and without any perplexing process of reasoning, we can lay our hands on whatever articles we require. Color clothes every object with its peculiar livery, and infallibly directs the hand in its movements, and the eye in its surveys and contemplations. But this is not the only end which the Divine Being had in view in impressing on the rays of light a diversity of colors. It is evident that he likewise intended to minister to our *pleasures* as well as to our wants. To every man of taste, and almost to every human being, the combination of colors in flowers, the delicate tints with which they are painted, the diversified shades of green with which the hills and dales, the mountains and the vales are arrayed, and that beautiful variety which appears in a bright summer day on all the objects of this lower creation, are sources of the purest enjoyment and delight. It is color, too, as well as magnitude, that adds to the *sublimity* of objects. Were the canopy of heaven of one uniform hue, it would fail in producing those lofty conceptions, and those delightful and transporting emotions, which a contemplation of its august scenery is calculated to inspire. Colors are likewise of considerable utility in the intercourse of general society. They serve both for ornaments, and for distinguishing the different ranks and conditions of the community; they add to the beauty and gracefulness of our furniture and clothing. At a glance, they enable us at once to distinguish the noble from the ignoble, the prince from his subjects, the master from his servant, and the widow, clothed with sable weeds, from the bride adorned with her nuptial ornaments.

Since colors, then, are of so much value and importance, they may be reckoned as holding a rank among the noblest natural gifts of the Creator. As they are of such essential service to the inhabitants of our globe, there can be no doubt that they serve similar or analogous purposes throughout all the worlds in the universe. The colors displayed in the solar beams are common to all the globes which compose the planetary system, and must necessarily be reflected, in all their diversified hues, from objects on their surfaces. The light which radiates from the fixed stars displays a similar diversity of colors. Some of the double stars are found to emit light of different hues; the larger star exhibiting light of a ruddy or orange hue, and the smaller one a radiance which approaches to blue or green. There is, therefore, reason to conclude that the objects connected with the planets which revolve round such stars—being occasionally enlightened by suns of different hues—will display a more variegated and splendid scenery of coloring than is ever beheld in the world on which we dwell; and that one of the distinguishing characteristics of different worlds, in regard to their embellishments, may consist in the splendor and variety of colors with which the objects on their surfaces are adorned In the metaphorical description of the glories of the New Jerusalem, recorded in the Book of Revelation, one of the chief characteristics of that city is said to consist in the splendor and diversity of hues with which it is adorned. It is represented as "coming down from heaven, *prepared as a bride adorned for her husband*," and as reflecting all the beautiful and variegated colors which the finest gems on earth can exhibit; evidently indicating that splendor and variety of coloring are some of the grandest features of celestial scenery.

On the whole, the subject of colors, when seriously considered, is calculated to excite us to the adoration of the goodness and intelligence of that Almighty Being whose wisdom planned all the arrangements of the universe, and to inspire us with gratitude for the numerous conveniences and pleasures we derive from those properties and laws he has impressed on the material system. He might have afforded us light, and even splendid illumination, without the pleasures and advantages which diversified colors now produce, and man and other animated beings might have existed in such a state. But what a very different scene would the world have presented from what it now exhibits! Of how many thousands of pleasures should we have been deprived! and to what numerous inconveniences and perplexities should we have been subjected! The sublimity and glories of the firmament, and the endless beauties and varieties which now embellish our terrestrial system, would have been forever unknown, and man could have had little or no incitement to study and investigate the works of his Creator. In this, as well as in many other arrangements in nature, we have a sensible proof of the presence and agency of that Almighty Intelligence "in whom we live, and move, and have our being." None but an infinitely Wise and Beneficent Being, intimately present in all places, could thus so regularly create in us, by means of color, those exquisite sensations which afford so much delight, and which unite us, as it were, with everything around us. In the diversity of hues spread over the face of creation, we have as real a display of the Divine presence as Moses enjoyed at the burning bush. The only difference is, that the one was out of the common order of Divine procedure, and the other in accordance with those permanent laws which regulate the economy of the universe. In every color, then, which we contemplate, we have a sensible memorial of the presence of that Being "whose Spirit garnished the heavens and laid the foundations of the earth," and whose "merciful visitation" sustains us every moment in existence. But the revelation of God to our senses, through the various objects of the material world, has become so familiar, that we are apt to forget the Author of all our enjoyments, even at the moment when we are investigating his works and participating of his benefits. "O that men would praise Jehovah for his goodness, and for his wonderful works toward the children of men."

PART II.

ON TELESCOPES.

CHAPTER I.

HISTORY OF THE INVENTION OF TELESCOPES.

The telescope is an optical instrument for viewing objects at a distance. Its name is compounded of two Greek words, τηλε, which signifies *at a distance* or *far off*, and σχοπειν, *to view* or to *contemplate*. By means of telescopes, remote objects are represented as if they were near, small apparent magnitudes are enlarged, confused objects are rendered distinct, and the invisible and obscure parts of very distant scenes are rendered perceptible and clear to the organ of vision. The telescope is justly considered as a grand and noble instrument. It is not a little surprising that it should be in the power of man to invent and construct an instrument by which objects, too remote for the unassisted eye to distinguish, should be brought within the range of distinct vision, as if they were only a few yards from our eye, and that thousands of august objects in the heavens, which had been concealed from mortals for numerous ages, should be brought within the limits of our contemplation, and be as distinctly perceived as if we had been transported many millions of miles from the space we occupy through the celestial regions. The celebrated Huygens remarks, in reference to this instrument, that, in his opinion, "the wit and industry of man has not produced anything so noble and so worthy of his faculties as this sort of knowledge (namely, of the telescope); insomuch that if any particular person had been so diligent and sagacious as to invent this instrument from the principles of nature and geometry, for my part, I should have thought his abilities were more than human; but the case is so far from this, that the most learned men have not yet been able sufficiently to explain the reason of the effects of this casual invention."

The persons who constructed the first telescopes, and the exact period when they were first invented, are involved in some degree of obscurity. It does not certainly appear that such instruments were known to the ancients, although we ought not to be perfectly decisive on this point. The cabinets of the curious contain some very ancient gems of admirable workmanship, the figures on which are so small that they appear beautiful through a magnifying glass, but altogether confused and indistinct to the naked eye; and therefore it may be asked, If they cannot be *viewed*, how could they *be wrought*, without the assistance of glasses? And as some of the ancients have declared that the moon has a form like that of the earth, and has plains, hills, and valleys in it, how could they know this, unless by mere conjecture, without the use of a telescope? And how could they have known that the *Milky Way* is formed by the combined rays of an infinite number of stars? For Ovid states, in reference to this zone, "its groundwork is of stars." But, whatever knowledge the ancients may have possessed of the telescope or other optical glasses, it is quite evident that they never had telescopes of such size and power as those which we now possess, and that no discoveries in the heavens, such as are now brought to light, were made by any of the ancient astronomers, otherwise some allusions to them must have been found in their writings.

Among the moderns, the illustrious Friar Bacon appears to have acquired some rude ideas respecting the construction of telescopes. "Lenses and specula," says he, "may be so figured that one object may be multiplied into many, that those which are situated at a great distance may be made to appear very near, that those which are small may be made to appear very large, and those which are obscure, very plain; and we can make stars to appear wherever we will." From these expressions, it appears highly probable that this philosopher was acquainted with the general principle both of telescopes and microscopes, and that he may have constructed telescopes of small magnifying power for his own observation and amusement, although they never came into general use. He was a man of extensive learning, and made so rapid a progress in the sciences, when attending the University of Paris, that he was esteemed the glory of that seat of learning. He prosecuted his favorite study of experimental philosophy with unremitting ardor, and in this pursuit, in the course of twenty years, he expended no less than £2000 in experiments, instruments, and in procuring scarce books. In consequence of such extraordinary talents and such astonishing progress in the sciences in that ignorant age, he was represented, by the envy of his illiterate fraternity, as having dealings with the devil; and, under this pretense, he was restrained from reading lectures, and at length, in 1278, when sixty-four years of age, he was imprisoned in his cell, where he remained in confinement for ten years. He shone like a single bright star in a dark hemisphere—the glory of our country—and died at Oxford, in the year 1294, in the eightieth year of his age. "Friar Bacon," says the Rev. Mr. Jones, "may be considered as the first of English philosophers; his profound skill in mechanics, optics, astronomy, and chemistry would make an honorable figure in the present age. But he is entitled to further praise, as he made all his studies subservient to theology, and directed all his writings, as much as could be, to the glory of God. He had the highest regard for the sacred Scriptures, and was persuaded they contain the principles of all true science."

The next person who is supposed to have acquired a knowledge of telescopes was Joannes Baptista Porta, of Naples, who flourished in the sixteenth century. He discovered the *Camera Obscura*, the knowledge of which might naturally have led to the invention of the telescope; but it does not appear that he ever constructed such an instrument. Des Cartes considers James Metius, a Dutchman, as the first constructor of a telescope, and says that, "as he was amusing himself with making mirrors and burning-glasses, he casually thought of looking through two of his lenses at a time, and found that distant objects appeared very large and distinct." Others say that this great discovery was first made by John Lippersheim, a maker of spectacles at Middleburg, or, rather, by his children, who were diverting themselves with looking through two glasses at a time, and placing them at different distances from each other. But Borellus, who wrote a book "on the invention of the telescope," gives this honor to Zacharias Jansen, another spectacle maker in the same town, who, he says, made the first telescope in 1590. Jansen was a diligent inquirer into nature, and, being engaged in such pursuits, he was trying what use could be made of lenses for those purposes, when he fortunately hit upon the construction. Having found the arrangement of glasses which produced the effect desired, he inclosed them in a tube, and ran with his instrument to Prince Maurice, who, immediately conceiving that it might be of use to him in his wars, desired the author to keep it a secret. Such are the rude conceptions and selfish views of princely *warriors*, who would apply every invention in their power for the destruction of mankind. But the telescope was soon destined to more noble and honorable achievements. Jansen, it is said, directed his instrument toward celestial objects, and distinctly saw the spots on the surface of the moon, and discovered many new stars, particularly several pretty considerable ones in the Great Bear. His son Joannes is said to have noticed the lucid circle near the lower limb of the moon, now named *Tycho*, from whence several bright rays seemed to dart in different directions. In viewing Jupiter, he perceived two, sometimes three, and, at the most, four small stars, a little above or below him, and thought that they performed revolutions around him. This was probably the first observation of the satellites of Jupiter, though the person who made it was not aware of the importance of his discovery.[*]

It is not improbable that different persons about Middleburg hit upon the invention, in different modes, about the same time. Lippersheim seems to have made his first rude telescope by adjusting two glasses on a board, and supporting them on brass circles.[†] Other workmen, particularly Metius and Jansen, in emulation of each other, seem to have made use of that discovery, and by the new form they gave it, made all the honor of it their own. One of them, considering the effects of light as injurious to distinctness, placed the glasses in a tube blackened within. The other, still more cautious, placed the same glasses within tubes capable of sliding one in another, both to vary the prospects, by lengthening the instrument, according to the pleasure of the observer, and to render it portable and commodious. Thus it is probable that different persons had a share in the invention, and jointly contributed to its improvement. At any rate, it is undoubtedly to the Dutch that we owe the original invention. The first telescope made by Jansen did not exceed fifteen or sixteen inches in length, and therefore its magnifying power could not have been very great.

The famous Galileo has frequently been supposed to have been the inventor of the telescope, but he acknowledges that he had not the honor of being the original inventor, having first learned from a German that such an instrument had already been made; although, from his own account, it appears that he had actually reinvented this instrument. The following is the account, in his own words, of the circumstances which led him to construct a telescope: "Nearly ten months ago (namely, in April or May, 1609), it was reported that a certain Dutchman had made a perspective through which many distant objects appeared as distinct as if they were near. Several effects of this wonderful instrument were reported, which some believed and others denied; but, having it confirmed to me a few days after by a letter from the noble John Badoverie, at Paris, I applied myself to consider the reason of it, and by what means I might contrive a similar instrument, which I afterward attained to by the doctrine of refractions. And, first, I prepared a leaden tube, to whose extremities I fitted two spectacle glasses, both of them plane on one side, and on the other side one of them was spherically convex, and the other concave. Then applying my eye to the concave, I saw objects appear pretty large and pretty near me. They appeared three times nearer and nine times larger in surface than to the naked eye; and soon after I made another, which represented objects about sixty times larger, and eight times nearer; and at last, having spared no labor or expense, I made an instrument so excellent as to show things almost a thousand times larger, and above thirty times nearer, than to the naked eye." In another part of his writings, Galileo informs us that "he was at Venice when he heard of Prince Maurice's instrument, but nothing of its construction; that the first night after he returned to Padua he solved the problem, and made his instrument the next day, and soon after presented it to the doge at Venice, who, to do him honor for his grand invention, gave him the ducal letters which settled him for life in his lectureship at Padua; and the Republic, on the 25th of August, in the same year (1610), more than tripled his salary as professor."

---

[*] Though Borellus mentions this circumstance, yet there is some reason to doubt the accuracy of this statement, as young Jansen appears to have been at that period not more than six years old; so that it is more probable that Galileo was the first discoverer of Jupiter's satellites.

[†] The reader may see an engraving of this instrument in the author's work entitled "*The Improvement of Society.*"

The following is the account which this philosopher gives of the process of reasoning which led him to the construction of a telescope: "I argued in the following manner: The contrivance consists either of one glass or more: one is not sufficient, since it must be either convex, concave, or plane; the last does not produce any sensible alteration in objects, the concave diminishes them; it is true that the convex magnifies, but it renders them confused and indistinct, consequently, one glass is insufficient to produce the desired effect. Proceeding to consider two glasses, and bearing in mind that the plane glass causes no change, I determined that the instrument could not consist of the combination of a plane glass with either of the other two. I therefore applied myself to make experiments on combinations of the two other kinds, and thus obtained that of which I was in search." If the true inventor is the person who makes the discovery by reasoning and reflection, by tracing facts and principles to their consequences, and by applying his invention to important purposes, then Galileo may be considered as the real inventor of the telescope. No sooner had he constructed this instrument—before he had seen any similar one—than he directed his tube to the celestial regions, and his unwearied diligence and ardor were soon rewarded by a series of new and splendid discoveries. He descried the four satellites of Jupiter, and marked the periods of their revolutions; he discovered the phases of Venus, and thus was enabled to adduce a new proof of the Corpernican system, and to remove an objection that had been brought against it. He traced on the lunar orb a resemblance to the structure of the earth, and plainly perceived the outlines of mountains and vales, casting their shadows over different parts of its surface. He observed that, when Mars was in quadrature, his figure varied slightly from a perfect circle, and that Saturn consisted of a triple body, having a small globe on each side, which deception was owing to the imperfect power of his telescope, which was insufficient to show him that the phenomenon was in reality a ring. In viewing the sun, he discovered large dark spots on the surface of that luminary, by which he ascertained that that mighty orb performed a revolution round its axis. He brought to view multitudes of stars imperceptible to the naked eye, and ascertained that those nebulous appearances in the heavens which constitute the Milky Way consist of a vast collection of minute stars too closely compacted together to produce an impression on our unassisted vision.

The results of Galileo's observations were given to the world in a small work, entitled "*Nuncius Sidereus*," or, "News from the Starry Regions," which produced an extraordinary sensation among the learned. These discoveries soon spread throughout Europe, and were incessantly talked of, and were the cause of much speculation and debate among the circles of philosophers. Many doubted; many positively refused to believe so novel and unlooked-for announcements, because they ran counter to the philosophy of Aristotle and all the preconceived notions which then prevailed in the learned world. It is curious, and may be instructive, to consider to what a length of absurdity ignorance and prejudice carried many of those who made pretensions to learning and science. Some tried to reason against the facts alleged to be discovered; others contented themselves, and endeavored to satisfy others with the simple *assertion* that such things were not, and could not possibly be; and the manner in which they supported themselves in their incredulity was truly ridiculous. "O my dear Kepler," says Galileo, in a letter to that astronomer, "how I wish we could have one hearty laugh together. Here at Padua is the principal professor of philosophy, whom I have repeatedly and urgently requested to look at the moon and planets through my glass, which *he pertinaciously refuses to do*, lest his opinions should be overturned. Why are you not here? what shouts of laughter we should have at this glorious folly! and to hear the professor of philosophy at Pisa laboring with the Grand-duke with logical arguments, as if with magical incantations to charm the new planets out of the sky." Another opponent of Galileo, one Christmann, says, in a book he published, "We are not to think that Jupiter has four satellites given him by nature, in order, by revolving round him, to immortalize the Medici who first had notice of the observation. These are the *dreams of idle men*, who love ludicrous ideas better than our laborious and industrious correction of the heavens. Nature abhors so horrible a chaos, and to the truly wise such vanity is detestable." One Martin Horky, a would-be philosopher, declared to Kepler, "I will never concede his four new planets to that Italian from Padua, *though I should die for it*;" and he followed up this declaration by publishing a book against Galileo, in which he examines four principal questions respecting the alleged planets: 1. Whether they exist? 2. What they are? 3. What they are like? 4. Why they are? The first question is soon disposed of by declaring positively that he has examined the heavens with Galileo's own glass, and that no such thing as a satellite about Jupiter exists. To the second, he declares solemnly that he does not more surely know that he has a soul in his body than that reflected rays are the sole cause of Galileo's erroneous observations. In regard to the third question, he says that these planets are like the smallest fly compared to an elephant; and finally concludes, on the fourth, that the only use of them is to gratify Galileo's "thirst of gold," and to afford himself a subject of discussion. Kepler, in a letter to Galileo, when alluding to Horky, says, "He begged so hard to be forgiven, that I have taken him again into favor upon this preliminary condition, that I am to show him Jupiter's satellites, AND HE IS TO SEE THEM, and own that they are there."

The following is a specimen of the reasoning of certain pretended philosophers of that age against the discoveries of Galileo: Sizzi, a Florentine astronomer reasons in this strain: "There are seven windows given to animals in the domicil of the head, through which the air is admitted to the rest of the tabernacle of the body, to enlighten, to warm, and to nourish it; two nostrils, two eyes, two ears, and a mouth; so in the heavens, or the great world, there are two favorable stars, two unpropitious, two luminaries, and Mercury alone undecided and indifferent. From which, and many other similar phenomena in nature, such as the seven metals, &c., we gather that the number of planets is *necessarily seven*. Moreover, the satellites are invisible to the naked eye, and therefore can exert no influence on the earth, and therefore would be useless, *and therefore do not exist*. Beside, as well the Jews as other ancient nations have adopted the division of the week into seven days, and have named them from the seven planets. Now, if we increase the number of the planets, this whole system falls to the ground." The opinions which then prevailed in regard to Galileo's observations on the moon were such as the following: Some thought that the dark shades on the moon's surface arose from the interposition of opaque bodies floating between her and the sun, which prevent his light from reaching those parts; others imagined that, on account of her vicinity to the earth, she was partly tainted with the imperfections of our terrestrial and elementary nature, and was not of that entirely pure and refined substance of which the more remote heavens consist; and a third party looked on her as a vast mirror, and maintained that the dark parts of her surface were the reflected images of our earthly forests and mountains.

Such learned nonsense is a disgrace to our species, and to the rational faculties with which man is endowed, and exhibits, in a most ludicrous manner, the imbecility and prejudice of those who made bold pretensions to erudition and philosophy. The statement of such facts, however, may be instructive, if they tend to guard us against those prejudices and preconceived opinions which prevent the mind from the cordial reception of truth, and from the admission of improvements in society which run counter to long-established customs. For the same principles and prejudices, though in a different form, still operate in society, and retard the improvement of the social state, the march of science, and the progress of Christianity. How ridiculous is it for a man calling himself a philosopher to be afraid to look through a glass to an existing object in the heavens, lest it should endanger his previous opinions! And how foolish is it to resist any improvement or reformation in society because it does not exactly accord with existing opinions and with "the wisdom of our ancestors!"

It is not a little surprising that Galileo should have first hit on that construction of a telescope which goes by his name, and which was formed with a *concave* glass next the eye. This construction of a telescope is more difficult to be understood in theory than one which is composed solely of convex glasses; and its field of view is comparatively very small, so that it is almost useless when attempted to be made of a great length. In the present day, we cannot help wondering that Galileo and other astronomers should have made such discoveries as they did with such an instrument, the use of which must have required a great degree of patience and address. Galileo's best telescope, which he constructed "with great trouble and expense," magnified the diameters of objects only thirty-three times; but its length is not stated, which would depend upon the focal distance of the concave eyeglass. If the eyeglass was two inches focus, the length of the instrument would be five feet four inches; if it was only one inch, the length would be two feet eight inches, which is the least we can allow to it—the object-glass being thirty-three inches focus, and the eyeglass placed an inch within this focus With this telescope Galileo discovered the satellites of Jupiter, the crescent of Venus, and the other celestial objects to which we have alluded. The telescopes made in Holland are supposed to have been constructed solely of *convex* glasses, on the principle of the astronomical telescope; and if so, Galileo's telescope was in reality a new invention.

Certain other claimants of the invention of the telescope have appeared, beside those already mentioned. Francis Fontana, in his "Celestial Observations," says that he was assured by a Mr. Hardy, advocate of the Parliament of Paris, a person of great learning and undoubted integrity, that, on the death of his father, there was found among his things an old tube by which distant objects were distinctly seen, and that it was of a date long prior to the telescope lately invented, and had been kept by him as a secret. Mr. Leonard Digges, a gentleman who lived near Bristol in the seventeenth century, and was possessed of great and various knowledge, positively asserts in his "*Stratoticos*," and in another work, that his father, a military gentleman, had an instrument which he used in the field, by which he could bring distant objects near, and could know a man at the distance of three miles. Mr. Thomas Digges, in the preface to his "Pantometria," published in 1591, declares, "My father, by his continual painful practices, assisted by demonstrations mathematical, was able, and sundry times hath, by proportional glasses, duly situate in convenient angles, not only discovered things far off, read letters, numbered pieces of money, with the very coin and superscription thereof, cast by some of his friends of purpose, upon downs in open fields, but also, seven miles off, declared what hath been done that instant in private places. He hath also, sundry times, by the sunbeams, fired powder and discharged ordnance half a mile and more distant, and many other matters far more strange and rare, of which there are yet living divers witnesses."

It is by no means unlikely that persons accustomed to reflection, and imbued with a certain degree of curiosity, when handling spectacle glasses, and amusing themselves with their magnifying powers and other properties, might sometimes hit upon the construction of a telescope, as it only requires two lenses of different focal distances to be held at a certain distance from each other, in order to show distant objects magnified. Nay, even one lens, of a long focal distance, is sufficient to constitute a telescope of a moderate magnifying power, as I shall show in the sequel. But such instruments, when they happen to be constructed accidentally, appear to have been kept as secrets, and confined to the cabinets of the curious, so that they never came into general use; and as their magnifying power would probably be comparatively small, the appearance of the heavenly bodies would not be much enlarged by such instruments, nor is it likely that they would be often directed to the heavens. On the whole, therefore, we may conclude that the period when instruments of this description came into general use, and were applied to useful purposes, was when Galileo constructed his first telescopes.

CHAPTER II.

OF THE CAMERA OBSCURA.

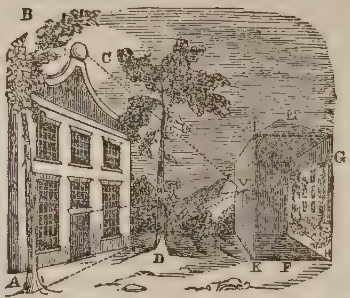
Before proceeding to a particular description of the different kinds of telescopes, I shall first give a brief description of the camera obscura, as the phenomena exhibited by this instrument tend to illustrate the principle of a refracting telescope.

The term *camera obscura* literally signifies a darkened vault or roof, and hence it came to denote a chamber, or box, or any other place made dark for the purpose of optical experiments. The camera obscura, though a simple, is yet a very curious and noble contrivance, as it naturally and clearly explains the manner in which vision is performed, and the principle of the telescope, and entertains the spectator with a most exquisite picture of surrounding objects, painted in the most accurate proportions and colors by the hand of nature. The manner of exhibiting the pictures of objects in a dark room is as follows: In one of the window-shutters of a room which commands a good prospect of objects not very distant, a circular hole should be cut of four or five inches diameter. In this hole an instrument should be placed called a *scioptric ball*, which has three parts, a frame, a ball, and a lens. The ball has a circular hole cut through the middle, in which the lens is fixed, and its use is to turn every way, so as to take in a view of objects on every side. The chamber should be made perfectly dark, and a white screen, or a large sheet of elephant paper, should be placed opposite to the lens, and in its focus, to receive the image. If, then, the objects without be strongly enlightened by the sun, there will be a beautiful living picture of the scene delineated on the white screen, where every object is beheld in its proportions, and with its colors even more vivid than life. Green objects appear in the picture more intensely green; and yellow, blue, red, or white flowers appear much more beautiful in the picture than in nature. If the lens be a good one, and the room perfectly dark, the perspective is seen in perfection. The lights and shadows are not only perfectly just, but also greatly heightened; and, what is peculiar to this delineation, and which no other picture or painting can exhibit, the *motions* of all the objects are exactly expressed in the picture; the boughs of the trees wave, the leaves quiver, the smoke ascends in a waving form, the people walk, the children at their sports leap and run, the horse and cart move along, the ships sail, the clouds soar and shift their aspects, and all as natural as in the real objects; the motions being somewhat quicker, as they are performed in a more contracted scene.

These are the *inimitable* perfections of a picture drawn by the rays of light as the only pencil in nature's hand, and which are finished in a moment; for no sensible interval elapses before the painting is completed, when the ground on which it is painted is prepared and adjusted. In comparison of such a picture, the finest productions of the most celebrated artists, the proportions of Raphael, the natural tints and coloring of Titian, and the shadowing of the Venetians, are but coarse and sorry daubing, when set in competition with what nature can exhibit by the rays of light passing through a single lens. The camera obscura is at the same time the painter's assistant and the painter's reproach. From the picture it forms he receives his best instructions, and he is shown what he should endeavor to attain; and hence, too, he learns the imperfections of his art, and what it is imposible for him to imitate. As a proof of this, the picture formed in the dark chamber will bear to be magnified to a great extent, without defacing its beauty or injuring the fineness of its parts; but the finest painted landscape, if viewed through a high magnifier, will appear only as a coarse daubing.

The following scheme will illustrate what has been now stated respecting the dark chamber: *E F* represents a darkened room, in the side of which, *I K*, is made the circular hole *V*, in which, on the inside, is fixed the scioptric ball. At some considerable distance from this hole is exhibited a landscape of houses, trees, and other objects, *A B C D*, which are opposite to the window. The rays which flow from the different objects which compose this landscape to the lens at *V*, and which pass through it, are converged to their respective foci on the opposite wall of the chamber, *H G*, or on a white movable screen placed in the focus of the lens, where they all combine to paint a lively and beautiful picture of the range of objects directly opposite, and on each side, so far as the lens can take in.

Fig. 37.



Though I have said that a scioptric ball and socket are expedient to be used in the above experiment, yet, where such an instrument is not at hand, the lens may be placed in a short tube, made of pasteboard or any other material, and fixed in the hole made in the window-shutter. The only imperfection attending this method is, that the lens can exhibit those objects only which lie directly opposite the window.

Some may be disposed to consider it as an imperfection in this picture, that all these objects appear in an *inverted* position; as they must necessarily do, according to what we formerly stated respecting the properties of convex lenses (p. 28). There are, however, different modes of viewing the picture as if it were erect; for if we stand before the picture, and hold a common mirror against our breast at an acute angle with the picture, and look down upon it, we shall see all the images of the objects as if restored to their erect position; and by the reflection of the mirror, the picture will receive such a luster as will make it still more delightful. Or, if a large concave mirror were placed before the picture at such a distance that its image may appear before the mirror, it will then appear erect and pendulous in the air in the front of the mirror. Or, if the image be received on a frame of paper, we may stand behind the frame, with our face toward the window, and look down upon the objects, when they will appear as if erect.

The experiment of the camera obscura may serve to explain and illustrate the nature of a common refracting telescope. Let us suppose that the lens in the window-shutter represents the object-glass of a refracting telescope. This glass forms an image in its focus, which is in every respect an exact picture or representation of the objects before it; and consequently the same idea is formed in the mind of the nature, form, magnitude, and color of the object, whether the eye at the center of the glass views the object itself, or the image formed in its focus; for, as formerly stated, the object and its image are both seen under the same angles by the eye placed at the center of the lens. Without such an image as is formed in the camera obscura—depicted either in the tube of a telescope or in the eye itself—no telescope could possibly be formed. If we now suppose that, behind the image formed in the dark chamber, we apply a convex lens of a short focal distance to view that image, then the image will be seen distinctly, in the same manner as we view common objects, such as a leaf or a flower, with a magnifying glass; consequently, the object itself will be seen distinct and magnified; and as the same image is nearer to one lens than the other, it will subtend a larger angle at the nearest lens, and, of course, will appear larger than through the other, and consequently the object will be seen magnified in proportion. For example, let us suppose the lens in the camera obscura, or the object lens of a telescope, to be five feet, or sixty inches focal distance: at this distance from the glass an image of the distant objects opposite to it will be formed. If, now, we place a small lens two inches focal distance beyond this point, or five feet two inches from the object-glass, the objects, when viewed through the small lens, will appear considerably magnified, and apparently much nearer than to the naked eye. The degree of magnifying power is in proportion to the focal distances of the two glasses; that is, in the present case, in the proportion of two inches, the focus of the small lens, to sixty inches, the focus of the object lens. Divide sixty by two, the quotient is thirty, which gives the magnifying power of such a telescope; that is, it represents objects thirty times nearer, or under an angle thirty times larger than to the naked eye. If the eyeglass, instead of being two inches, were only one and a half inch focus, the magnifying power would be in the proportion of one and a half to sixty, or forty times. If the eyeglass were three inches focus, the magnifying power would be twenty times; and so on with regard to other proportions. In all cases, where a telescope is composed of only two convex lenses, the magnifying power is determined *by dividing the focal distance of the object-glass by the focal distance of the eyeglass*, and the quotient expresses the number of times the object is magnified in length and breadth. This and various other particulars will be more fully illustrated in the sequel.

In performing experiments with the camera obscura in a darkened chamber, it is requisite that the following particulars be attended to: 1. That the lens be well figured, and free from any veins or blemishes that might distort the picture. 2. That it be placed *directly against* the object whose image we wish to see distinctly delineated. 3. The lens should be of a proper size, both as to its breadth and focal distance. It should not be less than three or four feet focal distance, otherwise the picture will be too small, and the parts of objects too minute to be distinctly perceived; nor should it exceed fifteen or eighteen feet, as in this case the picture will be faint, and of course not so pleasing. The best medium as to focal distance is from five to eight or ten feet. The aperture, too, or breadth of the glass, should not be too small, otherwise the image will be obscure, and the minute parts invisible for want of a sufficient quantity of light. A lens of six feet focal distance, for example, will require an aperture of at least two inches. Lenses of a shorter focal distance require less apertures, and those of a longer focal distance larger. But if the aperture be too large, the image will be confused and indistinct, by the admission of too much light. 4. We should never attempt to exhibit the images of objects, unless when the sun is shining and strongly illuminating the objects, except in the case of very near objects placed in a good light. As one of the greatest beauties in the phenomena of the dark chamber consists in the exquisite appearance and contrast of light and shadows, nothing of this kind can be perceived but from objects directly illuminated by the sun. 5. A south window should never be used in the forenoon, as the sun cannot then enlighten the north side of an object; and, beside, his rays would be apt to shine upon the lens, which would make the picture appear with a confused luster. An east window is best in the afternoon, and a western in the morning; but a north window is in most cases to be preferred, especially in the forenoon, when the sun is shining with his greatest strength and splendor. In general, that window ought to be used which looks to the quarter opposite to that in which the sun is shining.

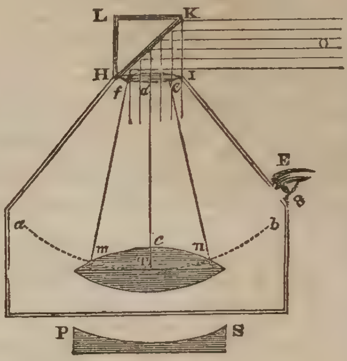
The picture should be received upon a very white surface, as the finest and whitest paper, or a painted cloth, bordered with black; as white bodies reflect most copiously the incumbent rays, while black surfaces absorb them. If the screen could be bent into the concave segment of a sphere, of which the focal distance of the double convex lens which is used is the radius, the parts of the picture adjacent to the extremities would appear most distinct. Sir D. Brewster informs us that, having tried a number of white substances of different degrees of smoothness, and several metallic surfaces on which to receive the image, he happened to receive the picture on the silvered back of a looking-glass, and was surprised at the brilliancy and distinctness with which external objects were represented. To remove the spherical protuberances of the tin foil, he ground the surface very carefully with a bed of hones which he had used for working the plane specula of Newtonian telescopes. By this operation, which may be performed without injuring the other side of the mirror, he obtained a surface finely adapted for the reception of images. The minute parts of the landscape were formed with so much precision, and the brilliancy of coloring was so uncommonly fine, as to equal, if not exceed, the images that are formed in the air by means of concave specula.

The following additional circumstances may be stated respecting the phenomena exhibited in the dark chamber: A more critical idea may be formed of any *movement* in the picture here presented than from observing the motion of the object itself. For instance, a man walking in a picture appears to have an undulating motion, or to rise up and down every step he takes, and the hands seem to move almost exactly like a pendulum; whereas scarcely anything of this kind is observed in the man himself, as viewed by the naked eye. Again, if an object be placed just twice the focal distance from the lens without the room, the image will be formed at the same distance from the lens within the room, and, consequently, will be equal in magnitude to the object itself. The recognition of this principle may be of use to those concerned in drawing, and who may wish at any time to form a picture of the exact size of the object. If the object be placed farther from the lens than twice its focal length, the image will be less than the object. If it be placed nearer, the image will be greater than the life. In regard to immovable objects, such as houses, gardens, trees, &c., we may form the images of so many different sizes by means of different lenses, the shorter focus making the lesser picture, and the longer focal distance the largest.

The experiments with the camera obscura may likewise serve to illustrate the nature of vision and the functions of the human eye. The frame or socket of the scioptric ball may represent the *orbit* of the natural eye. The ball, which turns every way, resembles the *globe* of the eye, movable in its orbit. The hole in the ball may represent the *pupil* of the eye; the convex lens corresponds to the *crystalline humor*, which is shaped like a lens, and contributes to form the images of objects on the inner part of the eye. The dark chamber itself is somewhat similar to the *internal part of the eye*, which is lined all around, and under the retina, with a membrane, over which is spread a mucus of a very black color. The white wall or frame of white paper to receive the picture of objects is a fair representation of the *retina* of the eye, on which all the images of external objects are depicted. Such are some of the general points of resemblance between the apparatus connected with the dark chamber and the organ of vision; but the human eye is an organ of such exquisite construction, and composed of such a number and variety of delicate parts, that it cannot be adequately represented by any artificial contrivance.

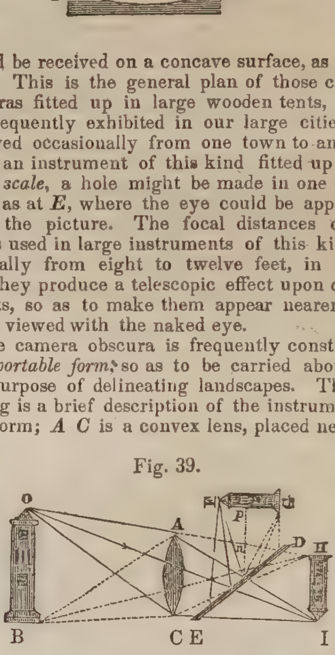
The darkened chamber is frequently exhibited in a manner somewhat different from what we have above described, as in the following scheme (fig. 38), which is termed the *revolving camera obscura*. In this construction, *K H* represents a plane mirror or metallic reflector, placed at half a right angle to the convex lens *H I*, by which rays proceeding from objects situated in the direction *O* are reflected to the lens, which forms an image of the objects on a round white table at *T*, around which several spectators may stand and view the picture as delineated on a horizontal plane. The reflector, along with its case, is capable of being turned round by means of a simple apparatus connected with it, so as to take in, in succession, all the objects which compose the surrounding scene. But as the image here is received on a flat surface, the rays, *f m*, *e n*, will have to diverge farther than the central rays, *d c*; and hence the representation of the object near the sides will be somewhat distorted; to remedy which, the view should be received on a concave surface, as *a b* or *P S*. This is the general plan of those camera obscuras fitted up in large wooden tents, which are frequently exhibited in our large cities, and removed occasionally from one town to another. Were an instrument of this kind fitted up on a *small scale*, a hole might be made in one of the sides, as at *E*, where the eye could be applied to view the picture. The focal distances of the lenses used in large instruments of this kind are generally from eight to twelve feet, in which case they produce a telescopic effect upon distant objects, so as to make them appear nearer than when viewed with the naked eye.

Fig. 38.



The camera obscura is frequently constructed in a *portable form*, so as to be carried about for the purpose of delineating landscapes. The following is a brief description of the instrument in this form; *A C* is a convex lens, placed near the end of a tube or drawer, which is movable in the side of a square box, within which is a plane mirror, *D E*, reclining backward in an angle of forty-five degrees from the perpendicular, *p n*.—The pencils of rays flowing from the object *O B*, and passing through the convex lens, instead of proceeding forward and forming the image *H I*, are reflected upward by the mirror, and meet in points, as *F G*, at the same distance at which they would have met at *H* and *I*, if they had not been intercepted by the mirror. At *F G*, the image of the object *O B*, is received either on a piece of oiled paper, or more frequently on a plane *unpolished* glass, placed in the horizontal situation *F G*, which receives the images of all objects opposite to the lens, and on which, or on an oiled paper placed upon it, their outlines may be traced by a pencil. The movable tube on which the lens is fixed serves to adjust the focus

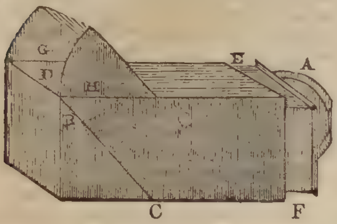
Fig. 39.



for near and distant objects, until their images appear distinctly painted on the horizontal glass at *F G*. The following is the most common form of the box of this kind of camera obscura. *A* is the position of the lens, *B C* the position of the mirror, *D* the plane unpolished glass on which the images are depicted, *G H* a movable top or screen to prevent the light from injuring the picture, and *E F* the movable tube.

The Daguerreotype.—An important and somewhat surprising discovery has lately been made in relation to the picture formed by the camera obscura. It is found that the images formed by this instrument are capable of being indelibly fixed on certain surfaces previously prepared for the purpose, so that the picture is rendered permanent. When a camera is presented to any object or landscape strongly illuminated by the sun, and the prepared ground for receiving the image is adjusted, and a certain time allowed to elapse until the rays of light produce their due effect, in a few minutes, or even seconds, a picture of the objects opposite to the lens is indelibly impressed upon the prepared plate, in all the accurate proportions and perspective which distinguish the images formed in a dark chamber, which representations may be hung up in apartments, along with other paintings and engravings, and will likely retain their beauty and luster for many years. These are pictures of nature's own workmanship, finished in an extremely short space of time, and with the most exquisite delicacy and accuracy.—The effect is evidently owing to certain chemical properties in the rays of light, and opens a new field for experiment and investigation to the philosopher. The only defect in the picture is, that it is not colored; but, in the progress of experiments, on this subject, it is not unlikely that even this object may be accomplished, in which case we should be able to obtain the most accurate landscapes and representations of all objects which can possibly be formed. This art or discovery goes by the name of the *Daguerreotype*, from M. Daguerre, a Frenchman, who is supposed to have been the first discoverer, and who received a large premium from the French government for disclosing the process, and making the discovery public. Several improvements and modifications, in reference to the preparation of the plates, have been made since the discovery was first announced, about the beginning of 1839; and the pictures formed on this principle are frequently distinguished by the name of *Photogenic* drawings, and are now exhibited at most of our public scientific institutions.

Fig. 40.



This new science or art has been distinguished by different names. It was first called *Photography*, from two Greek words, signifying *writing by light:* it was afterward called the art of *Photogenic Drawing*, or drawing produced by light. M. Daguerre gave it the name of *Heliography*, or *writing by the sun;* all which appellatives are derived from the Greek, and are expressive, in some degree, of the nature of the process. We shall, however, make use of the term Daguerreotype, derived from the name of the inventor.

As it does not fall within our plan to give any minute descriptions of the Daguerreotype process, we shall just give a few general hints in reference to it, referring those who wish for particular details to the separate treatises which have been published respecting it. The first thing necessary to be attended to in this art is the preparation of the plate on which the drawing is to be made. The plate consists of a thin leaf of copper, plated with silver, both metals together not being thicker than a card. The object of the copper is simply to support the silver, which must be the purest that can be procured. But, though the copper should be no thicker than to serve the purpose of support, it is necessary that it should be so thick as to prevent the plate from being warped, which would produce a distortion of the images traced upon it. This plate must be polished; and for this purpose the following articles are required: a vial of olive oil; some very fine cotton; pumice-powder ground, until it is almost impalpable, and tied up in a piece of fine muslin, thin enough to let the powder pass through without touching the plate when the bag is shaken; a little nitric acid, diluted with sixteen times, by measure, its own quantity of water; a frame of wire on which to place the plate when being heated; a spirit lamp to make the plate hot; a small box, with inclined sides within, and having a lid to shut it up close; and a square board large enough to hold the drawing, and having catches at the side to keep it steady.

To the above prerequisites, a good *camera obscura* is, of course, essentially necessary. This instrument should be large enough to admit the plate of the largest drawing intended to be taken. The lens which forms the image of the object should, if possible, be *achromatic*, and of a considerable diameter. In an excellent instrument of this description now before me, the lens is an achromatic about three inches diameter, but capable of being contracted to a smaller aperture.—Its focal distance is about 17 inches; and the box, exclusive of the tube which contains the lens, is 15 inches long, 13½ inches broad, and 11 inches deep. It forms a beautiful and well-defined picture of every well enlightened object to which it is directed.

Before the plate is placed in the camera, there are certain operations to be performed. 1. The surface of the plate should be made perfectly smooth or highly polished. For this purpose it must be laid flat, with the silver side upward, upon several folds of paper for a bedding; and having been well polished in the usual way, the surface must be powdered equally and carefully with fine pumice inclosed in the muslin bag.—Then taking a little cotton wool, dipped in olive oil, it must be rubbed over the plate with rounding strokes, and then crossing them by others which commence at right angles with the first.—This process must be repeated frequently, changing the cotton, and renewing the pumice-powder every time. A small portion of cotton must now be moistened with the diluted nitric acid, and applied equally to the whole surface. The next thing to be done is to make the plate thoroughly and equally hot, by holding the plate with a pair of pinchers by the corner over a charcoal fire, and when the plate is sufficiently hot, a white coating will be observed on the silver, which indicates that

that part of the operation is finished. An even cold surface is next wanted, such as a metallic plate cooled almost to the freezing point by muriate of soda, and to this the heated plate must be suddenly transferred.

2. The next operation is to give the plate a coating of *iodine.* This is accomplished by fixing the plate upon a board, and then putting it into a box containing a little dish with iodine divided into small pieces, with its face downward, and supported with small brackets at the corners. In this position the plate must remain until it assume *a full gold color,* through the condensation of the iodine on its surface, which process should be conducted in a darkened apartment. The requisite time for the condensation of the iodine varies from five minutes to half an hour. When this process is satisfactorily accomplished, the plate should be immediately fixed in a frame with catches and bands, and placed in the camera; and the transference from one receptacle to another should be made as quickly as possible, and with only so much light as will enable the operator to see what he is doing.

3. The next operation is to obtain the drawing. Having placed the camera in front of the scene to be represented, and the lens being adjusted to the proper focus, the ground glass of the camera is withdrawn, and the prepared plate is substituted for it, and the whole is left until the natural images are drawn by the natural light from the object. The time necessary to leave the plate for a complete delineation of the objects depends upon the intensity of the light. Objects in the shade will require more time for their delineation than those in the broad light. The full, clear light of the south of Europe, Spain, Italy, and particularly the more glowing brilliancy of tropical countries, will effect the object much more speedily than the duller luminosity of a northern clime. Some hours of the day are likewise more favorable than others. Daguerre states that "the most favorable is from 7, A. M., to 3 o'clock, P. M., and that a drawing could be effected in Paris in three or four minutes in June and July, which would require five or six in May and August, and seven or eight in April and September." In the progress of this art, at the present time, portraits and other objects are frequently delineated in the course of a few seconds. 4. Immediately after removing the plate from the camera, it is next placed over the vapor of mercury, which is placed in a cup at the bottom of a box, and a spirit lamp applied to its bottom until the temperature rise to 140° of Fahrenheit. This process is intended to bring out the image, which is not visible when withdrawn from the camera; but in the course of a few minutes, a faint tracery will begin to appear, and in a very short time the figure will be clearly developed.

5. The next operation is *to fix the impression.* In order to this, the coating on which the design was impressed must be removed, to preserve it from being decomposed by the rays of light. For this purpose, the plate is placed in a trough containing common water, plunging and withdrawing it immediately, and then plunging it into a solution of salt and water until the yellow coating has disappeared.

Such is a very brief sketch of the *photogenic* processes of Daguerre. Other substances, however, more easily prepared, have been recommended by Mr. Talbot, F.R.S., who appears, about the same time to have invented a process, somewhat similar to that of Daguerre. The following are his directions for the preparation of *photogenic paper:*

The paper is to be dipped into a solution of salt in water, in the proportion of half an ounce of salt to half a pint of water. Let the superfluous moisture drain off, and then laying the paper upon a clean cloth, *dab* it gently with a napkin, so as to prevent the salt collecting in one spot more than in another. The paper is then to be pinned down, by two of its corners, on a drawing board, by means of common pins, and one side washed or wetted with the photogenic fluid, using the brush prepared for that purpose, and taking care to distribute it equally. Next, dry the paper as rapidly as you can at the fire, and it will be fit for use for most purposes. If, when the paper is exposed to the sun's rays, it should assume an irregular tint, a very thin extra wash of the fluid will render the color uniform, and at the same time, somewhat darker. Should it be required to make a more sensitive description of paper, after the first application of the fluid the solution of salt should be applied, and the paper dried at the fire. Apply a second wash of the fluid, and dry it at the fire again: employ the salt a third time, dry it, and one application more of the fluid will, when dried, have made the paper extremely sensitive. When slips of such papers, differently prepared, are exposed to the action of daylight, those which are soonest affected by the light, by becoming dark, are the best prepared.

When photogenic drawings are finished in a perfect way, the designs then taken on the plate or paper are exceedingly beautiful and correct, and will bear to be inspected with a considerable magnifying power, so that the most minute portions of the objects delineated may be distinctly perceived. We have seen portraits finished in this way by a London artist with an accuracy which the best miniature painter could never attempt, every feature being so distinct as to bear being viewed with a deep magnifier. And in landscapes and buildings, such is the delicacy and accuracy of such representations, that the marks of the chisel and the crevices in the stones may frequently be seen by applying a magnifying lens to the picture; so that we may justly exclaim, in the words of the poet, "Who can paint like Nature!" That LIGHT—which is the first-born of Deity, which pervades all space, and illuminates all worlds —in the twinkling of an eye, and with an accuracy which no art can imitate, depicts every object in its exact form and proportions, superior to everything that human genius can produce.

The photogenic art, in its progress, will doubtless be productive of many highly interesting and beneficial effects. It affords us the power of representing, by an accurate and rapid process, all the grand and beautiful objects connected with our globe, the landscapes peculiar to every country, the lofty ranges of mountains which distinguish Alpine regions, the noble edifices which art has reared, the monumental remains of antiquity, and every other object which it would be interesting for human beings to contemplate; so that, in the course of time, the general scenery of our world, in its prominent parts, might be exhibited to almost every eye. The commission of the French Chambers, when referring to this art, has the following remark: "To copy the millions upon millions of hieroglyphics which cover even the exterior of the great monuments of Thebes and Memphis, of Carnac, &c., would require scores of years and legions of designers. By the assistance of the Daguerreotype, a single man could finish that immense work." This instrument lays down objects which the visual organs of man would overlook, or might be unable to perceive, with the same minuteness and nicety that it delineates the most prominent features of a landscape. The time-stained excrescences on a tree, the blades of grass, the leaf of a rose, the neglected weed, the moss on the summit of a lofty tower, and similar objects, are traced with the same accuracy as the larger objects in the surrounding scene.

It is not improbable, likewise, that this art (still in its infancy), when it approximates to perfection, may enable us to take representations of the sublime objects in the heavens. The sun affords sufficient light for this purpose; and there appears no insurmountable obstacle in taking, in this way, a highly magnified picture of that luminary, which shall be capable of being again magnified by a powerful microscope It is by no means improbable, from experiments that have hitherto been made, that we may obtain an accurate delineation of the lunar world from the moon herself. The plated discs prepared by Daguerre receive impressions from the action of the lunar rays to such an extent as permits the hope that photographic charts of the moon may soon be obtained; and, if so, they will excel in accuracy all the delineations of this orb that have hitherto been obtained; and if they should bear a microscopic power, objects may be perceived on the lunar surface which have hitherto been invisible. Nor is it impossible that the planets Venus, Mars, Jupiter, and Saturn may be delineated in this way, and objects discovered which cannot be descried by means of the telescope. It might, perhaps, be considered as beyond the bounds of probability to expect that even distant *nebulæ* might thus be fixed, and a delineation of their objects produced which shall be capable of being magnified by microscopes; but we ought to consider that the art is yet only in its infancy, that plates of a more delicate nature than those hitherto used may yet be prepared, and that other properties of light may yet be discovered which shall facilitate such designs. For we ought now to set no boundaries to the discoveries of science, and to the practical applications of scientific discovery which genius and art may accomplish.

In short, this invention leads to the conclusion that we have not yet discovered all the wonderful properties of that luminous agent which pervades the universe, and which unvails to us its beauties and sublimities; and that thousands of admirable objects and agencies may yet be disclosed to our view through the medium of light, as philosophical investigators advance in their researches and discoveries. In the present instance, as well as in many others, it evidently appears that the Creator intends, in the course of his providence, by means of scientific researches, gradually to open to the view of the inhabitants of our world the wonders, the beauties, and the sublimities of his vast creation; to manifest his infinite wisdom and his superabundant goodness, and to raise our souls to the contemplation and the love of him who is the original source of all that is glorious and beneficent in the scene of nature.

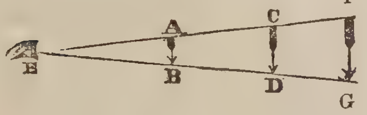
CHAPTER III.

ON THE OPTICAL ANGLE, AND THE APPARENT MAGNITUDE OF OBJECTS.

In order to understand the principle on which telescopes represent distant objects as magnified, it may be expedient to explain what is meant by the angle of vision, and the apparent magnitudes under which different objects appear, and the same object, when placed at different distances.

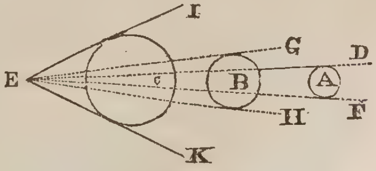
The optical angle is the angle contained under two right lines drawn from the extreme points of an object to the eye. Thus *A E B* or *C E D* (fig. 40*) is the optical or visual angle, or the angle under which the object *A B* or *C D* appears to the eye at *E*. These two objects, being at different distances, are seen under the same angle, although *C D* is evidently larger than *A B*. On the retina of the eye, their images are exactly of the same size, and so is the still larger object *F G*.

Fig. 40*



The *apparent magnitude* of objects denotes their magnitude as they appear to us, in contradistinction from their real or true magnitude, and it is measured by the visual angle; for, whatever objects are seen under the same, or equal angles, *appear* equal, however different their real magnitudes. If a half crown or half dollar be placed at about 120 yards from the eye, it is just perceptible as a visible point, and its apparent magnitude, or the angle under which it is seen, is very small. At the distance of thirty or forty yards, its bulk appears sensibly increased, and we perceive it to be a round body; at the distance of six or eight yards we can see the king or queen's head engraved upon it; and at the distance of eight or ten inches from the eye it will appear so large that it will seem to cover a large building placed within the distance of a quarter of a mile; in other words, the apparent magnitude of the half crown, held at such a distance, will more than equal that of such a building in the picture on the retina, owing to the increase of the optical angle. If we suppose *A* (fig. 41) to represent the apparent size of the half crown at nine yards' distance, then we say it is seen under the small angle *F E D*. *B* will represent its apparent magnitude at 4½ yards distant under the angle *H E G*, and the circle *C*, its apparent

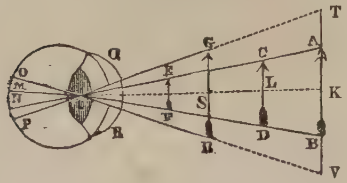
Fig. 41.



magnitude at 3 yards distant, under the large angle *K E I.*

This may be otherwise illustrated by the following figure: Let *A B* (fig. 42) be an object

Fig. 42.



viewed directly by the eye *Q R.* From each extremity *A* and *B* draw the lines *A N, B M,* intersecting each other in the crystalline humor in *I*: then is *A I B* the optical angle which is the measure of the apparent magnitude or length of the object *A B.* From an inspection of this figure, it will evidently appear that the apparent magnitudes of objects will vary according to their distances. Thus *A B, C D, E F,* the real magnitudes of which are unequal, may be situated at such distances from the eye as to have their *apparent* magnitudes all equal, and occupying the same space on the retina, *M N,* as here represented. In like manner, objects of equal magnitude, placed at unequal distances, will appear unequal. The objects *A B* and *G H,* which are equal, being situated at different distances from the eye, *G H* will appear under the large angle *T I V,* or as large as an object *T V,* situated at the same place as the object *A B,* while *A B* appears under the smaller angle *A I B.* Therefore the object *G H* is *apparently* greater than the object *A B,* though it is only equal to it. Hence it appears that we have no certain standard of the *true magnitude* of objects by our visual perception abstractly considered, but only of the *proportions* of magnitude.

In reference to apparent magnitudes, we scarcely ever judge any object to be so great or so small as it appears to be, or that there is so great a disparity in the visible magnitude of two equal bodies at different distances from the eye. Thus, for example, suppose two men, each six feet three inches high, to stand directly before us, one at the distance of a pole, or 5½ yards, and the other at the distance of 100 poles, or 550 yards: we should observe a considerable difference in their apparent size, but we should scarcely suppose, at first sight, that the one nearest the eye appeared a hundred times greater than the other, or that, while the nearest one appeared six feet three inches high, the remote one appeared only about *three-fourths of an inch.* Yet such is in reality the case; and not only so, but the visible bulk or area of the one is to that of the other as the square of these numbers, namely, as 10,000 to 1; the man nearest us presenting to the eye a magnitude or surface ten thousand times greater than that of the other. Again, suppose two chairs standing in a large room, the one twenty-one feet distance from us, and the other three feet; the one nearest us will appear seven times larger, both in length and breadth, than the more distant one, and, consequently, its visible area forty-nine times greater. If I hold up my finger at nine inches distance from my eye, it seems to cover a large town a mile and a half in extent, situated at three miles distance; consequently, the apparent magnitude of my finger, at nine inches distance from the organ of vision, is greater than that of the large town at three miles distance, and forms a larger picture on the retina of the eye. When I stand at the distance of a foot from my window and look through one of the panes to a village less than a quarter of a mile distant, I see, through that pane, nearly the whole extent of the village, comprehending two or three hundred houses; consequently the apparent magnitude of the pane is equal to nearly the extent of the village, and all the buildings it contains do not appear larger than the pane of glass in the window, otherwise the houses and other objects which compose the village could not be seen through that single pane. For, if we suppose a line drawn from one end of the village, passing through the one side of the pane, and another line drawn from the other end, and passing through the other side of the pane to the eye, these lines would form the optical angle under which the pane of glass and the village appears. If the pane of glass be fourteen inches broad, and the length of the village 2640 yards, or half a mile, this last lineal extent is 6788 times greater than the other, and yet they have the same *apparent* magnitude in the case supposed.

Hence we may learn the absurdity and futility of attempting to describe the extent of spaces in the heavens, by saying that a certain phenomenon was two or three feet or yards distant from another, or that the tail of a comet appeared several yards in length. Such representations can convey no definite ideas in relation to such magnitudes, unless it be specified at what distance from the eye the foot or yard is supposed to be placed. If a rod, a yard in length, be held at nine inches from the eye, it will subtend an angle, or cover a space in the heavens, equal to more than one-fourth of the circumference of the sky, or about one hundred degrees. If it be eighteen inches from the eye, it will cover a space equal to fifty degrees; if at three feet, twenty-five degrees, and so on in proportion to the distance from the eye; so that we can form no correct conceptions of apparent spaces or distances in the heavens, when we are merely told that two stars, for example, appear to be three yards distant from each other. The only definite measure we can use in such a case is that of degrees. The sun and moon are about half a degree in apparent diameter, and the distance between the extreme stars in *Orion's belt* three degrees, which measures, being made familiar to the eye, may be applied to other spaces of the heavens, and an approximate idea conveyed of the relative distances of objects in the sky.

From what has been stated above, it is evident that the magnitude of objects may be considered in different points of view. The true dimensions of an object, considered in itself, give what is called its *real* or *absolute magnitude;* and the opening of the visual angle determines the *apparent magnitude.* The real magnitude, therefore, is a constant quantity; but the apparent magnitude varies continually with the distance, real or imaginary; and, therefore, if we always judged of the dimensions of an object from its apparent magnitude, everything around us would, in this respect, be undergoing very sensible variations, which might lead us into strange and serious mistakes. A fly, near enough to the eye, might appear under an angle as great as an elephant at the distance of twenty feet, and the one be mistaken for the other. A giant eight feet high, seen at the distance of twenty-four feet, would not appear taller than a child two feet in hight at the distance of six feet; for both would be seen nearly under the same angle. But our experience generally prevents us from being deceived by such illusions. By the help of touch, and by making allowance for the different distances at which we see particular objects, we learn to correct the ideas we might otherwise form from attending to the optical angle alone, especially in the case of objects that are near us. By the sense of touch we acquire an impression of the distance of an object; this impression combines itself with that of the apparent magnitude, so that the impression which represents to us the real magnitude is the product of these two elements. When the objects, however, are at a great distance, it is more difficult to form a correct estimate of their true magnitudes. The visual angles are so small that they prevent comparison; and the estimated bulks of the objects depend, in a great measure, upon the *apparent* magnitudes; and thus an object situated at a great distance appears to us much smaller than it is in reality. We also estimate objects to be nearer or farther distant according as they are more or less clear, and our perception of them more or less distinct and well-defined; and likewise when several objects intervene between us and the object we are particularly observing. We make a sort of addition of all the estimated distances of intermediate objects, in order to form a total distance of the remote object, which, in this case, appears to be farther off than if the intervening space were unoccupied. It is generally estimated that no terrestrial object can be distinctly perceived if the visual angle it subtends be less than *one minute of a degree*, and that most objects become indistinct when the angle they subtend at the pupil of the eye is less than six minutes.

We have deemed it expedient to introduce the above remarks on the apparent magnitude of objects, because the principal use of a telescope is to increase the angle of vision, or to represent objects under a larger angle than that under which they appear to the naked eye, so as to render the view of distant objects more distinct, and to exhibit to the organ of vision those objects which would otherwise be invisible. A telescope may be said to enlarge an object just as many times as the angle under which the instrument represents it is greater than that under which it appears to the unassisted eye. Thus the moon appears to the naked eye under an angle of about half a degree; consequently, a telescope magnifies 60 times if it represents that orb under an angle of 30 degrees; and if it magnified 180 times, it would exhibit the moon under an angle of 90 degrees, which would make her appear to fill half of the visible heavens, or the space which intervenes from the horizon to the zenith.

CHAPTER IV.

ON THE DIFFERENT KINDS OF REFRACTING TELESCOPES.

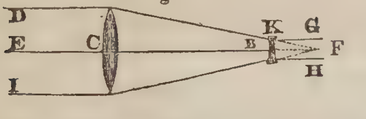
There are two kinds of telescopes, corresponding to two modes of vision, namely, those which perform their office by *refraction* through lenses, and those which magnify distant objects by *reflection* from mirrors. The telescope which is constructed with lenses produces its effects solely by refracted light, and is called a Dioptric, *or refracting telescope.* The other kind of telescope produces its effects partly by reflection, and partly by refraction, and is composed both of mirrors and lenses; but the mirrors form the principal part of the telescope, and therefore such instruments are denominated *reflecting telescopes.* In this chapter I shall describe the various kinds of *refracting* telescopes.

SECTION I.

The Galilean telescope.

This telescope is named after the celebrated Galileo, who first constructed, and probably *invented* it in the year 1609. It consists of only two glasses, a *convex* glass next the object, and a *concave* next the eye. The convex is called the *object-glass*, and the concave, to which the eye is applied, is called the *eye-glass.* Let *C* (fig. 43) represent the convex object-glass, presented to any object in the direction *D E I*, so that the rays fall parallel upon it; if these rays, after passing through it, were not intercepted by the concave lens *K*, they would pass on, and cross each other in the focus *F*, where an inverted image of the object would be formed. But the concave lens *K*, the virtual focus of which is at *F*, being interposed, the rays are not suffered to converge to that point, but are made less convergent,[*] and enter the pupil almost parallel, as *G H*, and are converged by the humors of the eye to their proper foci on the retina. The object, through this telescope, is seen upright, or in its natural position, because the rays are not suffered to come to a focus, so as to form an inverted picture. The concave eyeglass is placed as far within the focus of the object-glass as is equal to its own virtual focus; and the magnifying power is as the focal length of the object-glass to that of the eyeglass, that is, as *C F* to *B F*. Thus, suppose the focus of the object-glass to be ten inches, and the focus of the eyeglass to be one inch, the magnifying power will be ten times, which is always found by dividing the focal length of the object-glass by that of the eyeglass. The interval between the two glasses, in this case, will be nine inches, which is the length of the telescope, and the objects seen through it will appear under an angle ten times greater than they do to the naked eye. These propositions might be proved mathematically; but the process is somewhat tedious and intricate, and might not fully be understood by general readers. I shall therefore only mention some of the general properties of this telescope, which is now seldom used, except for the purpose of *opera-glasses.*

Fig. 43.



1. The focal distance of the object-glass must be greater than that of the eyeglass, otherwise it would not magnify an object: if the focal distance of the eyeglass were greater than that of

---

[*] It is one of the properties of concave lenses to render convergent rays less convergent, and when placed as here supposed, to render them parallel; and it is parallel rays that produce distinct vision.

the object-glass, it would diminish objects instead of magnifying them. 2 The visible area of the object is greater, the nearer the eye is to the glass; and it depends on the diameter of the pupil of the eye, and on the breadth of the object-glass; consequently, the field of view in this telescope is very small. 3. The distinctness of vision in this construction of a telescope exceeds that of almost any other. This arises from the rays of light proceeding from the object directly through the lenses, *without crossing* or intersecting each other; whereas, in the combination of convex lenses, they intersect one another to form an image in the focus of the object-glass, and this image is magnified by the eyeglass with all its imperfections and distortions. The thinness of the center of the concave lens also contributes to distinctness. 4. Although the field of view in this telescope is very small, yet, where no other telescope can be procured, it might be made of such a length as to show the spots on the sun, the crescent of Venus, the satellites of Jupiter, and the ring of Saturn; and, requiring only two glasses, it is the cheapest of all telescopes. It has been found that an object-lens five feet focal distance will bear a concave eyeglass of only one inch focal distance, and will consequently magnify the diameters of the planets sixty times, and their surfaces 3600 times, which is sufficient to show the phenomena now stated. And, although only a small portion of the sun and moon can be seen at once, yet Jupiter and all his satellites may sometimes be seen at one view; but there is some difficulty in finding objects with such telescopes. 5. Opera-glasses, which are always of this construction, have the object-lens generally about six inches focus and one inch diameter, with a concave eyeglass of about two inches focus. These glasses magnify about three times in diameter, have a pretty large field, and produce very distinct vision. When adjusted to the eye they are about four inches in length. To the object-end of an opera-glass there is sometimes attached a plane mirror, placed at an angle of forty-five degrees, for the purpose of viewing objects on either side of us. By this means, in a theater or assembly, we can take a view of any person without his having the least suspicion of it, as the glass is directed in quite a different direction. The instrument with this appendage is sometimes called a *Polemoscope*.

SECTION II.

THE COMMON ASTRONOMICAL REFRACTING TELESCOPE.

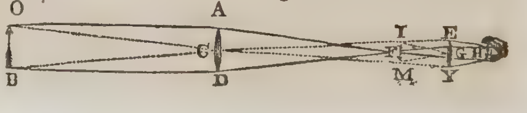
THE astronomical telescope is the most simple construction of a telescope, composed of convex lenses only, of which there are but two essentially necessary, though a third is sometimes added to the eyepiece for the purpose of enlarging the field of view. Its construction will be easily understood from a description of the following figure: Its two essential parts are an object-glass, $A D$, and an eyeglass $E Y$, so combined in a tube that the focus F of the object-glass is exactly coincident with the focus of the eyeglass. Let $O B$ (fig. 44) represent a distinct object, from which rays nearly parallel proceed to the object-lens $A D$. The rays passing through this lens will cross at F, and form an image of the object at $I M$. This image forms, as it were, an object to the eyeglass $E Y$, which is of a short focal distance, and the eye is thus enabled to contemplate the object as if it were brought much nearer than it is in reality; for the rays, which, after crossing, proceed in a divergent state, fall upon the lens $E Y$ as if they proceeded from a real object situated at F. All that is effected, therefore, by such a telescope is to form an image of a distant object by means of the object-lens, and then to give the eye such assistance as is necessary for viewing that image as near as possible, so that the angle it shall subtend at the eye shall be very large compared with the angle which the object itself would subtend in the same situation.

Here it may be expedient to explain, 1. How this arrangement of glasses shows distant objects distinctly; and 2. The reason why objects appear magnified when seen through it. As to the first particular, it may be proved as follows: The rays $O A$ and $B D$, which are parallel before they fall upon the object-glass, are by this glass refracted and united at its focus. In order, then, to distinct vision, the eyeglass must re-establish the parallelism of the rays, which is effected by placing the eyeglass so that its focus may be at F, and, consequently, the rays will proceed from it parallel to each other, and fall upon the eye in that direction; for distinct vision is produced by parallel rays. 2. The reason why the object appears magnified will appear, if we consider that, if the eye viewed the object from the center of the object glass, it would see it under the angle $O C B$; let $O C$ and $B C$ then be produced to the focus of the glass, they will then limit the image, $I M$, formed in the focus. If, then, two parallel rays are supposed to proceed to the eyeglass $E Y$, they will be converged to its focus H, and the eye will see the image under the angle $E H Y$. The apparent magnitude of the object, therefore, as seen by the naked eye, is to the magnitude of the image as seen through the telescope, as $O C B$ to $E H Y$, or as the distance $C F$ to the distance $F G$; in other words, *as the focal length of the object-glass to that of the eyeglass.*

It is obvious from the figure, that, through this telescope, all objects will appear *inverted*; since the object $O B$ is depicted by the object-glass in an inverted position at $I M$, and in this position is viewed by the eyeglass $E Y$; and, therefore, this kind of telescope is not well adapted for viewing terrestrial objects, since it exhibits the tops of trees, houses, and other objects as undermost, and the heads of people as pointing downward. But this circumstance is of no consequence with respect to the heavenly bodies, since they are round, and it can make little difference to an observer which side of a globular body appears uppermost or undermost. All astronomical refracting telescopes invert objects; but they are preferred to any other telescopes, because they have few glasses, and, consequently, more light. This telescope, however, can be transformed into a common day telescope for land objects by the addition of two other eyeglasses, as we shall afterward explain; but in this case a quantity of light is lost by refraction at each lens, for there is scarcely any transparent substance that transmits all the rays of light that fall upon it.

The *magnifying power* of this telescope is found *by dividing the focal distance of the object-glass by the focal distance of the eyeglass;* the quotient

Fig. 44.



gives the magnifying power, or the number of times that the object seen through the telescope appears larger or nearer than to the naked eye. Thus, for example, if the focal distance of the object-glass be 28 inches, and the focal distance of the eyeglass 1 inch, the magnifying power will be 28 times. If we would enlarge the telescope, and select an object-glass 10 feet, or 120 inches focus, an eyeglass of 2 inches focal length might be applied, and then the diameter of objects would be magnified 60 times, and their surfaces 3600 times. If we would use an object-glass of 100 feet, it would be necessary to select an eyeglass about 6 inches focus, and the magnifying power would be 200 times, equal to 1200 inches divided by 6. Since, then, the power of magnifying depends on the proportion of the focal length of the object and eyeglasses, and this proportion may be varied to any degree, it may seem strange to some that a short telescope of this kind will not answer that purpose as well as a long one. For instance, it may be asked why an object glass of 10 feet focus may not be made to magnify as much as one of 100 feet focal length, by using an eyeglass of half an inch focus, in which case the magnifying power would be 240 times? But it is to be considered that, if the power of magnifying be increased while the length of the telescope remains the same, it is necessary to diminish the focal length of the eyeglass in the same proportion, and this cannot be done, on account of the great distortion and coloring which would then appear in the image, arising both from the deep convexity of the lens and the different refrangibility of the rays of light. It is found that the length of common refracting telescopes must be increased in proportion to the square of the increase of their magnifying power; so that, in order to magnify twice as much as before with the same light and distinctness, the telescope must be lengthened four times; to magnify 3 times as much, 9 times; and to magnify 4 times as much, 16 times; that is—suppose a telescope of 3 feet to magnify 33 times—in order to procure a power four times as great, or 132 times, we must extend the telescope to the length of 48 feet, or 16 times the length of the other. Much, likewise, depends upon the breadth or aperture of the object-glass. If it be too small, there will not be sufficient light to illuminate the object; and if it be too large, the redundance of light will produce confusion in the image.

The foregoing table, constructed originally by Huygens, and which I have recalculated and corrected, shows the linear aperture, the focal distance of the eyeglass, and the magnifying power of astronomical telescopes of different lengths, which may serve as a guide to those who wish to construct telescopes of this description.

In the above table the first column expresses the focal length of the object-glass in feet, the second column the diameter of the aperture[*] of the object-glass, the third column the focal distance of the eyeglass, and the fourth the magnifying power, which is found by reducing the feet in the first column to inches, and dividing by the numbers in the third column. From this table it appears that, in order to obtain a magnifying power of 168 times by this kind of telescope, it is requisite to have an object-glass of 70 feet focal distance, and an eyeglass five inches focus, and that the aperture of the object-glass ought not to be more than about 4½ inches diameter. To obtain a power of 220 times requires a length of 120 feet.

The following is a summary view of the properties of this telescope: 1. The object is always inverted. 2. The magnifying power is always in the proportion of the focal distance of the object-glass to the eyeglass. 3. As the rays emerging from the eyeglass should be rendered parallel for every eye, there is a small sliding tube next the eye, which should be pushed out or in until the object appears distinct. When objects are pretty near, this tube requires to be pulled out a little. These circumstances require to be attended to in all telescopes. 4. The apparent magnitude of an object is the same wherever the eye be placed, but the visible area, or field of view, is the greatest when the eye is nearly at the focal distance of the eyeglass. 5. The visual angle depends on the breadth of the eyeglass, for it is equal to the angle which the eyeglass subtends at the object-glass; but the breadth of the eyeglass cannot be increased beyond a certain limit without producing coloring and distortion.

If the general principles on which this telescope is constructed be thoroughly understood, it will be quite easy for the reader to understand the construction of all the other kinds of telescopes, whether refracting or reflecting. A small astronomical telescope can be constructed in a few moments, provided one has at hand the following lenses: 1. A common reading-glass, eight or ten inches focal distance: 2. A common magnifying lens, such as watchmakers or botanists use, of about 1½ or 2 inches focus. Hold the reading-glass—suppose of ten inches focus—in the left hand opposite any object, and the magnifying lens of two inches focus in the right hand near the eye, at twelve inches distance from the other in a direct line, and a telescope is formed which magnifies five times. I have frequently used this plan, when traveling, when no other telescope was at hand.

---

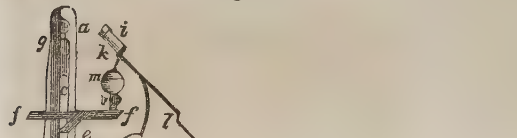
[*] The word *aperture*, as applied to object-glasses, signifies the opening to let in the light, or that part of the object-glass which is left uncovered. An object-glass may be 3 inches in diameter, but if one inch of this diameter be covered, its aperture is said to be only 2 inches.

SECTION III.

THE AERIAL TELESCOPE.

The aerial is a refracting telescope of the kind we have now described, intended to be used without a tube in a dark night; for the use of a tube is not only to direct the glasses, but to make the place dark where the images are formed. It appears, from the preceding table, that we cannot obtain a high magnifying power with the common astronomical telescope without making it of an extreme length, in which case the glasses are not manageable in tubes—which are either too slight and apt to bend, or too heavy and unwieldy if made of wood, iron, or other strong materials. The astronomers of the seventeenth century, feeling some inconveniences in making celestial observations with long tubes, contrived a method of using the glasses without tubes. Hartsocker, an eminent optician, contrived to fix them at the top of a tree, a high wall, or the roof of a house; but the celebrated Huygens, who was not only an astronomer, but also an excellent mechanic, made considerable improvements in the method of using an object-glass without a tube. He placed it at the top of a very long pole, having previously inclosed it in a short tube, which was made to turn in all directions by means of a ball and socket.—The axis of this tube he could command with a fine silken string, so as to bring it into a line with the axis of another short tube which he held in his hand, and which contained the eyeglass.—

Fig. 45.



The following is a more particular description of one of these telescopes: On the top of a long pole or mast *a b* (fig. 45), is fixed a board movable up and down in the channel *c d*; *e* is a perpendicular arm fixed to it, and *f f* is a transverse board that supports the object-glass inclosed in the tube *i*, which is raised or lowered by means of the silk cord *r l*; *g g* is an endless rope with a weight *h*, by which the apparatus of the object-glass is counterpoised; *k l* is a stick fastened to the tube *i*; *m* the ball and socket, by means of which the object-glass is movable every way; and, to keep it steady, there is a weight, *n*, suspended by a wire; *l* is a short wire to which the thread *r l* is tied; *o* is the tube which holds the eyeglass; *q* the stick fixed to this tube, *s* a leaden bullet, and *t* a spool to wind the thread on; *u* is pins for the thread to pass through; *x* the rest for the observer to lean upon, and *y* the lantern. Fig. 46 is an apparatus contrived by M. de la Hire for managing the object-glass, but which it would be too tedious particularly to describe. To keep off the dew from the object-glass, it was sometimes included in a pasteboard tube, made of spongy paper, to absorb the humidity of the air. And, to find an object more readily, a broad annulus of white pasteboard was put over the tube that carried the eyeglass, upon which the image of the object being painted, an assistant who perceived it might direct the tube of the eyeglass into its place.

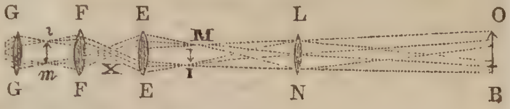
Such was the construction of the telescopes with which Hevelius, Huygens, Cassini, and other eminent astronomers of the seventeenth century made their principal discoveries. With such telescopes Huygens discovered the fourth satellite of Saturn, and determined that this planet was surrounded with a ring; and with the same kind of instrument Cassini detected the first, second, third, and fifth satellites of Saturn, and made his other discoveries. When the night was very dark, they were obliged to make the object-glass visible by means of a lantern so constructed as to throw the rays of light up to it in a parallel direction.—In making such observations they must have taken incredible pains, endured much cold and fatigue and subjected themselves to very great labor and expense—which almost makes us wonder at the discoveries they were instrumental in bringing to light—and should make modern philosophers sensible of the obligations they are under to such men as Newton and Dollond, through whose inventions such unwieldy instruments are no longer necessary. Telescopes of the description now stated were made of all sizes, from 30 to above 120 feet in length. Divini at Rome, and Campani at Bologna, were famed as makers of the object-glasses of the long focal distance to which we have alluded, who sold them for a great price, and took every method to keep the art of making them a secret. It was with telescopes made by Campani that Cassini made his discoveries. They were made by the express order of Louis XIV, and were of 86, 100, and 136 Paris feet in focal length. M. Azout made one object-glass of 600 feet focus; but he was never able to manage it so as to make any practical observations with it. Hartsocker is said to have made some of a still greater focal length. The famous aerial telescope of Huygens was 123 feet in focal length, with six inches of aperture. At his death he bequeathed it to the Royal Society of London, in whose possession it still remains. It required a pole of more than a hundred feet high on which to place the object-glass for general observations. It was with this glass that Dr. Derham made the observations to which he alludes in his preface to his "Astro-Theology." When this glass was in the possession of Mr. Cavendish, it was compared with one of Mr. Dollond's forty-six inch treble object-glass achromatics, and the gentlemen who were present at the trial, said that "the Dwarf was fairly a match for the Giant." It magnified 218 times, and the trouble of managing it was said to be extremely tiresome and laborious.

SECTION IV.

THE COMMON REFRACTING TELESCOPE FOR TERRESTRIAL OBJECTS.

THIS telescope is constructed on the same principle as the astronomical telescope already described, with the addition of two or three glasses. In fig. 47, *O B* represents a distant object, *L N* the object-glass, which forms the image *I M* in its focus, which is, of course, in an inverted position, and, if the eye were applied to the lens *E E*, the object would appear exactly as through the astronomical telescope, every object being apparently turned upside down. To remedy this inconvenience, there are added two other glasses, *F F* and *G G*, by which a second image is formed from the first, in the same position as the object. In order to effect this, the first of these two glasses, namely, *F F*, is placed at twice its focal distance from the former glass, *E E*, and the other lens, *G G*, next the eye, is placed at the same distance from *F F;* for all the three glasses are supposed to be of the same focal distance.—Now the lens *F F*, being placed at twice the focal distance for parallel rays from *E E*, receives the pencils of parallel rays after they have crossed each other at *X*, and forms an image at *i m* similar to that at *I M*, and equal to it, but contrary in position, and consequently erect; which last image is viewed by the lens *G G*, in the same manner as the first image, *I M*, would be viewed by the lens *E E*. In this case the image *I M* is considered as an object to the lens *F F*, of which it forms a picture in its focus, in a reverse position from that of the first image, and, of course, in the same position as the object.

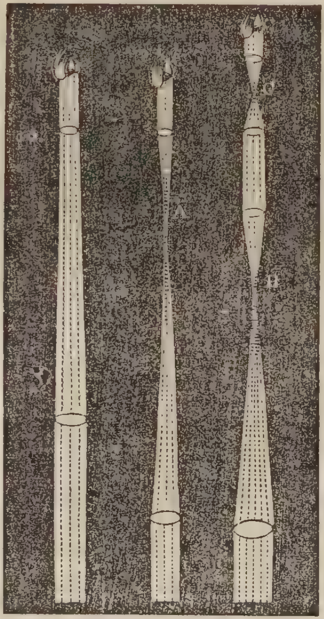
Fig. 47.



The magnifying power of this telescope is determined precisely in the same way as that of the astronomical telescope. Suppose the object-glass to be thirty inches focal distance, and each of the eye-glasses 1½ inch focal distance, the magnifying power is in the proportion of 30 to 1½, or 20 times, and the instrument is, of course, considerably longer than an astronomical telescope of the same power. The distance, in this case, betweeen the object-glass and the first eyeglass, *E E*, is 31½ inches; the distance between *E E* and the second glass, *F F*, is 3 inches, and the distance between *F F* and the glass *G G*, next the eye, 3 inches; in all, 37½ inches, the whole length of the telescope. Although it is usual to make use of three eyeglasses in this telescope, yet two will cause the object to appear erect, and of the same magnitude. For, suppose the middle lens, *F F*, taken away, if the first lens, *E E*, be placed at *X*, which is double its focal distance from the image, *I M*, it will, at the same distance, *X m*, on the other side, form a secondary image, *i m*, equal to the primary image *I M*, and also in a contrary position. But such a combination of eyeglasses produces a great degree of coloring in the image, and therefore is seldom used. Even the combination now described, consisting of three lenses of equal focal distances, is now almost obsolete, and has given place to a much better arrangement, consisting of *four* glasses of different focal distances, which shall be afterward described.

The following figures, 48, 49, 50, represent the manner in which the rays of light are refracted through the glasses of the telescopes we have now described. Fig. 48 represents the rays of light as they pass from the object to the eye in the Galilean telescope. After passing in a parallel direction to the object-glass, they are refracted by that glass, and undergo a slight convergence in passing toward the concave eyeglass, where they enter the eye in a parallel direction, but no image is formed previous to their entering the eye until they arrive at the retina. Fig. 49 represents the rays as they pass through the glasses of the astronomical telescope. The rays, after entering the object-glass, proceed in a converging direction until they arrive at its focus about *A*, where an image of the object is formed; they then proceed diverging to the eyeglass, where they are rendered parallel, and enter the eye in that direction. Fig. 50 represents the rays as they converge and diverge in passing through the four glasses of the common day telescope, described above. After passing through the object-glass, they converge toward *B*, where the first image is formed. They then diverge toward the first eyeglass, where they are rendered parallel, and, passing through the second eyeglass, they again converge and form a second image at *C*, from which point they again diverge, and, passing through the first eyeglass, enter the eye in a parallel direction If the glasses of these telescopes were fixed on long pieces of wood, at their proper distances from each other, and placed in a darkened room, when

Fig 48. Fig. 49. Fig. 50.



the sun is shining, the beam of the sun's light would pass through them in the same manner as here represented.

SECTION V.

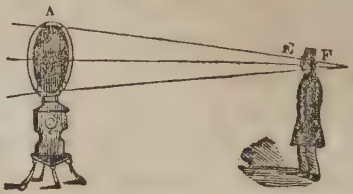
TELESCOPE FORMED BY A SINGLE LENS.

THIS is a species of telescope altogether unnoticed by optical writers, so far as I know; nor has the property of a single lens, in magnifying distant objects, been generally adverted to or recognized. It may not, therefore, be inexpedient to state a few experiments which I have made in relation to this point. When we hold a spectacle-glass of a pretty long focal distance—say from 20 to 24 inches—close to the eye, and direct it to distant objects, they do not appear sensibly magnified.—But if we hold the glass about 12 or 16 inches from our eye, we shall perceive a sensible degree of magnifying power, as if distant objects were seen at less than half the distance at which they are placed. This property of a spectacle-glass I happened to notice when a boy, and on different occasions since that period have made several experiments on the subject, some of which I shall here relate.

With the object-glass of a common refracting telescope, 4½ feet focal distance, and 2½ inches diameter, I looked at distant objects—my eye being at about 3½ feet from the lens, or about 10 or 12 inches within its focus—and it produced nearly the same effect as a telescope which magnifies the diameters of objects 5 or 6 times. With another lens, 11 feet focal distance and 4 inches diameter, standing from it at the distance of about ten feet, I obtained a magnifying power of about 12 or 14 times, which enabled me to read the letters on the signposts of a village half a mile distant.—Having some time ago procured a very large lens, 26 feet focal distance and 11½ inches diameter, I have tried with it various experiments of this kind upon different objects. Standing at the distance of about 25 feet from it, I can see distant objects through it magnified about 26 times in diameter, and consequently 676 times in surface, and remarkably clear and distinct, so that I can distinguish the hour and minute hands of a public clock in a village two miles distant. This single lens, therefore, answers the purpose of an ordinary telescope with a power of 26 times. In making such experiments, our eye must always be *within* the focus of the lens, at least 8 or 10 inches. The object will, indeed, be seen at any distance from the glass within this limit, but the magnifying power is diminished in proportion as we approach nearer to the glass. Different eyes, too, will require to place themselves at different distances, so as to obtain the greatest degree of magnifying power with distinctness, according as individuals are long or shortsighted.

This kind of telescope stands in no need of a tube, but only of a small pedestal on which it may be placed on a table, nearly at the hight of the eye, and that it be capable of a motion in a perpendicular or parallel direction, to bring it in a line with the eye and the object. The principle on which the magnifying power in this case is produced, is materially the same as that on which the Galilean telescope depends. The eye of the observer serves instead of the concave lens in that instrument; and as the concave lens is placed as much within the focus of the object-glass as is equal to its own focal distance, so the eye, in these experiments, must be placed at least its focal distance within the focus of the lens with which we are experimenting; and the magnifying power will be nearly in the proportion of the focal distance of the lens to the focal distance of the eye. If, for example, the focal distance of the eye, or the distance at which we see to read distinctly, be 10 inches, and the focal distance of the lens 11 feet, the magnifying power will be as 11 feet, or 132 inches to 10, that is, about 13 times. Let *A* (fig. 51) represent the lens placed on a pedestal; the rays of light passing through this lens from distant objects will converge toward a focus at *F*.—If a person then place his eye at *E*, a certain distance within the focal point, he will see distant objects magnified nearly in the proportion of the focal distance of the lens to that of the eye; and when the lens is very broad—such as the 26 feet lens mentioned above—two or three persons may look through it at once, though they will not all see the same object. I have alluded above to a lens made by M. Azout of 600 feet focal distance. Were it possible to use such a lens for distant objects, it might represent them as magnified 5 or 600 times, without the application of any eyeglass. In this way the aerial telescope of Huygens would magnify objects above 100 times, which is about half the magnifying power it produced with its eyepiece. Suppose Azout's lens had been fitted up as a telescope, it would not have magnified above 480 times, as it would have required an eyeglass of 14 or 15 inches focal distance, whereas, without an eyeglass, it would have magnified objects considerably above 500 times. It is not unlikely that the species of telescope to which I have now adverted constituted one of those instruments for magnifying distant objects which were said to have been in the possession of certain persons long before their invention in Holland, and by Galileo in Italy, to which I have referred in p. 55. Were this kind of telescope to be applied to the celestial bodies, it would require to be elevated upon a pole in the manner represented in fig. 45, p. 66.

Fig. 51.



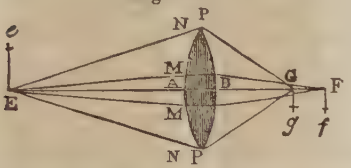
SECTION VI.

THE ACHROMATIC TELESCOPE.

THIS telescope constitutes the most important and useful improvement ever made upon telescopic instruments, and it is probable it will, ere long, supersede the use of all other telescopes. Its importance and utility will at once appear when we consider that a good achromatic telescope of only 4 or 5 feet in length will bear a magnifying power as great as that of a common astronomical telescope 100 feet long, and even with a greater degree of distinctness, so that they are now come into general use both for terrestrial and celestial observations. There are, indeed, certain obstructions which prevent their being made of a very large size; but from the improvement in the manufacture of achromatic glass which is now going forward, it is to be hoped that the difficulties which have hitherto impeded the progress of opticians will soon be removed. In order to understand the nature of this telescope, it will be necessary to advert a little to the *imperfections* connected with the common refracting telescopes.

The first imperfection to which I allude is this, that *spherical surfaces do not refract the rays of light accurately to a point;* and hence the image formed by a single convex lens is not perfectly accurate and distinct. The rays which pass near the extremities of such a lens meet in foci nearer to the lens than those which pass nearly through the center, which may be illustrated by the following figure: Let *P P* (fig. 52) be a convex lens, and *E e*, an object, the point *E* of which corresponds with the axis, and sends forth the rays *E M*, *E N*, *E A*, &c., all of which reach the surface of the glass, but in different parts. It is manifest that the ray *E A*, which passes through the middle of the glass, suffers no refraction. The rays *E M*, *E M*, likewise, which pass through near to *E A*, will be converged to a focus at *F*, which we generally consider as the focus of the lens. But the rays *E N*, *E N*, which are nearer to the edge of the glass, will be differently refracted, and will meet about *G*, nearer to the lens, where they will form another image *G g*. Hence it is evident that the first image, *F f*, is formed only by the union of those rays which pass very near the center of the lens; but as the rays of light proceeding from every point of an object are very numerous, there is a succession of images formed, according to the parts of the lens where they penetrate, which necessarily produces indistinctness and confusion. This is the imperfection which is distinguished by the name of *spherical aberration*, or the error arising from the spherical form of lenses.

Fig. 52.



The second and most important imperfection of single lenses, when used for the object-glasses of telescopes, is, that the rays of compounded light being differently refrangible, come to their respective foci at different distances from the glass; the more refrangible rays, as the *violet*, converging sooner than those which are less refrangible, as the *red*. I have had occasion to illustrate this circumstance, when treating on the colors produced by the prism (see p. 42, and figures 32 and 33), and it is confirmed by the experiment of a paper painted red, throwing its image, by means of a lens, at a greater distance than another paper painted blue. From such facts and experiments, it appears that the image of a white object consists in an indefinite number of colored images, the violet being nearest, and the red farthest from the lens, and the images of intermediate colors at intermediate distances. The aggregate, or image itself, must therefore be in some degree confused; and this confusion being much increased by the magnifying power, it is found necessary to use an eyeglass of a certain limited convexity to a given object-glass. Thus, an object-glass of 34 inches focal length will bear an eyeglass of only one inch focus, and will magnify the diameters of objects 34 times; one of 50 feet focal distance will require an eyeglass of 4½ inches focus, and will magnify only 142 times; whereas, could we apply to it an eyeglass of only one inch focus, as in the former case, it would magnify no less than 600 times. And were we to construct an object-glass of 100 feet focal length, we should require to apply an eyeglass not less than six inches focus, which would produce a power of about 200 times; so that there is no possibility of producing a great power by single lenses without extending the telescope to an immoderate length.

Sir Isaac Newton, after having made his discoveries respecting the colors of light, considered the circumstance we have now stated as an insuperable barrier to the improvement of refracting telescopes, and therefore turned his attention to the improvement of telescopes by *reflection*. In the telescopes which he constructed and partly invented, the images of objects are formed by reflection from speculums or mirrors; and being free from the irregular convergency of the various colored rays of light, will admit of a much larger aperture and the application of a much greater degree of magnifying power. The reflector which Newton constructed was only six inches long, but it was capable of bearing a power equal to that of a six feet refractor. It was a long time, however, after the invention of these telescopes, before they were made of a size fitted for making celestial observations. After reflecting telescopes had been some time in use, Dollond made his famous discovery of the principle which led him to the construction of the *achromatic* telescope. This invention consists of a compound object-glass formed of two different kinds of glass, by which both the spherical aberration and the errors arising from the different refrangibility of the rays of light are in a great measure corrected. For the explanation of the nature of this compound object-glass and the effects it produces, it may be expedient to offer the following remarks respecting the dispersion of light and its refraction by different substances.

The *dispersion* of light is estimated by the variable angle formed by the red and violet rays which bound the solar spectrum, or, rather, it is the excess of the refraction of the most refrangible ray above that of the least refrangible ray. The dispersion is not proportional to the refraction, that is, the substances which have an equal mean refraction do not *disperse* light in the same ratio. For example, if we make a prism with plates of glass, and fill it with oil of cassia, and adjust its refracting angle, *A C B* (fig. 31, p. 42), so that the middle of the spectrum which it forms falls exactly at the same place where the green rays of a spectrum formed by a glass prism would fall, then we shall find that the spectrum formed by the *oil of cassia* prism will be two or three times *longer* than that of the *glass* prism. The oil of cassia, therefore, is said to *disperse* the rays of light more than the glass, that is, to separate the extreme red and violet rays at *O* and *P* more than the mean ray at *green*, and to have a greater *dispersive power*. Sir I. Newton appears to have made use of prisms composed of different substances, yet, strange to tell, he never observed that they formed spectrums whose lengths were different when the refraction of the green ray was the same, but thought that the dispersion was proportional to the refraction. This error continued to be overlooked by philosophers for a considerable time, and was the cause of retarding the invention of the achromatic telescope for more than 50 years.

Dollond was among the first who detected this error. By his experiments it appears that the different kinds of glass differ extremely with respect to the divergency of colors produced by equal refractions. He found that two prisms, one of white flint glass, whose refracting angle was about 25 degrees, and another of crown glass, whose refracting angle was about 29 degrees, refracted the beam of light nearly alike, but that the divergency of color in the white flint was considerably more than in the crown glass; so that when they were applied together, to refract contrary ways, and a beam of light transmitted through them, though the emergent continued parallel to the incident part, it was, notwithstanding, separated into component colors. From this he inferred that, in order to render the emergent beam white, it is necessary that the refracting angle of the prism of crown glass should be *increased*, and by repeated experiments he discovered the exact quantity. By these means he obtained a theory in which refraction was performed without any separation or divergency of color, and thus the way was prepared for applying the principle he had ascertained to the construction of the object-glasses of refracting telescopes. For the edges of a convex and concave lens, when placed in contact with each other, may be considered as two prisms which refract contrary ways; and if the excess of refraction in the one be such as precisely to destroy the divergency of color in the other, a colorless image will be formed. Thus, if two lenses are made of the same focal length, the one of flint glass and the other of crown, the length or diameter of the colored image in the first will be to that produced by the crown glass as three to two nearly. Now if we make the focal lengths of the lenses in this proportion, that is, as three to two, the colored spectrum produced by each will be equal. But if the flint lens be concave, and the crown convex, when placed in contact they will mutually correct each other, and a pencil of white light refracted by the compound lens will remain colorless.

The following figure may perhaps illustrate what has been now stated. Let *L L* (fig. 53) represent a convex lens of *crown glass*, and *l l* a concave lens of *flint glass*. A ray of the sun, *S*, falls at *F* on the convex lens, which will refract it exactly as the prism *A B C*, whose faces touch the two surfaces of the lens at the points where the ray enters and quits it. The solar ray, *S F*, thus refracted by the lens *L L*, or prism *A B C*, would have formed a spectrum, *P T*, on the wall, had there been no other lens, the violet ray, *F*, crossing the axis of the lens at *V*, and going to the upper end, *P*, of the spectrum; and the red ray, *F R*, going to the lower end, *T*. But as the flint glass lens *l l*, or the prism *A a C*, which receives the rays *F V*, *F R*, at the same points, is interposed, these rays will be united at *f*, and form a small circle of white light; the ray *S F* of the sun being now refracted without color from its primitive direction *S F Y* into the new direction *F f*. In like manner, the corresponding ray *S M* will be refracted to *f*, and a white and colorless image of the sun will be there formed by the two lenses. In this combination of lenses, it is obvious that the spherical aberration of the flint lens corrects to a considerable degree that of the crown glass, and by a proper adjustment of the radii of the surfaces, it may be almost wholly removed. This error is still more completely corrected in the *triple* achromatic object-glass, which consists of three lenses—a concave flint lens placed between convexes of crown glass. Fig. 54 shows the *double* achromatic lens, and fig. 55 the *triple* object-glass, as they are fitted up in their cells, and placed at the object end of the telescope. In consequence of their producing a focal image free of color, they will bear a much larger aperture and a much greater magnifying power than common refracting telescopes of the same length. While a common telescope whose object-glass is 3½ feet focal distance will bear an aperture of scarcely one inch, the 3½ feet achromatic will bear an aperture of 3¼ inches, and consequently transmits 10½ times the quantity of light. While the one can bear a magnifying power of only about 36 times, the other will bear a magnifying power for celestial objects of more than 200 times.

Fig. 53.

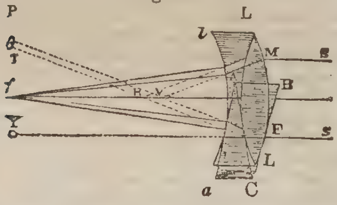


Fig. 54.

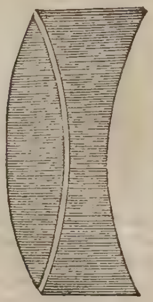

Fig. 55.

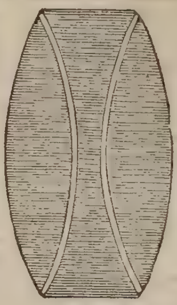

The theory of the achromatic telescope is somewhat complicated and abstruse, and would require a more lengthened investigation than my limits will permit. But what has been already stated may serve to give the reader a general idea of the *principle* on which it is constructed, which is all I intended. The term *achromatic*, by which such instruments are now distinguished, was first given to them by Dr. Bevis. It is compounded of two Greek words which signify "free of color." And were it not that even philosophers are not altogether free of that pedantry which induces us to select Greek words which are unintelligible to the mass of mankind, they might have been contented with selecting the plain English word *colorless*, which is as significant and expressive as the Greek word *achromatic*. The *crown glass*, of which the convex lenses of this telescope are made, is the same as good common window glass; and the *flint glass* is that species of glass of which wine-glasses, tumblers, decanters, and similar articles are formed, and is sometimes distinguished by the name of crystal glass. Some opticians have occasionally formed the concave lens of an achromatic object-glass from the bottom of a broken tumbler.

This telescope was invented and constructed by Mr. John Dollond, about the year 1758. When he began his researches into this subject, he was a silk weaver in Spitalfields, London The attempt of the celebrated Euler to form a colorless telescope, by including water between two meniscus glasses, attracted his attention, and in the year 1753 he addressed a letter to Mr. Short, the optician, which was published in the Philosophical Transactions of London, "concerning a mistake in Euler's theorem for correcting the aberrations in the object-glasses of refracting telescopes." After a great variety of experiments on the refractive and dispersive powers of different substances, he at last constructed a telescope in which an exact balance of the opposite dispersive powers of the crown and flint lenses made the colors disappear, while the predominating refraction of the crown lens disposed the achromatic rays to meet at a distant focus. In constructing such object-glasses, however, he had several difficulties to encounter. In the first place, the focal distance as well as the particular surfaces must be very nicely proportioned to the densities or refractive powers of the glasses, which are very apt to vary in the same sort of glass made at different times. In the next place, the centers of the two glasses must be placed truly in the common axis of the telescope, otherwise the desired effect will be in a great measure destroyed. To these difficulties is to be added, that there are four surfaces (even in double achromatic object-glasses) to be wrought perfectly spherical; and every person practiced in optical operations will allow that there must be the greatest accuracy throughout the whole work. But these and other difficulties were at length overcome by the judgment and perseverance of this ingenious artist.

It appears, however, that Dollond was not the only person who had the merit of making this discovery—a private gentleman, Mr. Chest, of Chest Hall, a considerable number of years before, having made a similar discovery, and applied it to the same purpose. This fact was ascertained in the course of a process raised against Dollond, at the instance of Watkins, optician at Charing Cross, when applying for a patent. But as the other gentleman had kept his invention a secret, and Dollond had brought it forth for the benefit of the public, the decision was given in his favor. There was no evidence that Dollond borrowed the idea from his competitor, and both were, to a certain extent, entitled to the merits of the invention.

One of the greatest obstructions to the construction of large achromatic telescopes is the difficulty of procuring large discs of flint glass of a uniform refractive density, of good color, and free from veins. It is said that fortunately for Mr. Dollond, this kind of glass was procurable when he began to make achromatic telescopes, though the attempts of ingenious chemists have since been exerted to make it without much success. It is also said that the glass employed by Dollond in the fabrication of his best telescopes was of the same melting, or made at the same time, and that, excepting this particular treasure, casually obtained, good dense glass for achromatic purposes was always as difficult to be procured as it is now. The dispersion of the flint glass, too, is so variable, that, in forming an achromatic lens, trials on each specimen require to be made before the absolute proportional dispersion of the substances can be ascertained. It is owing, in a great measure, to these circumstances that a large and good achromatic telescope cannot be procured unless at a very high price. Mr. Tulley, of Islington—who has been long distinguished as a maker of excellent achromatic instruments—showed me, about six years ago, a rude piece of flint glass about five inches diameter, intended for the concave lens of an achromatic object-glass, for which he paid eight guineas. This was before the piece of glass was either figured or polished, and, consequently, he had still to perform the delicate operation of figuring, polishing, and adjusting this concave to the convex lenses with which it was to be combined; and, during the process, some veins or irregularities might be detected in the flint glass which did not then appear. Some years before, he procured a disc of glass from the Continent, about seven or eight inches diameter, for which he paid about thirty guineas, with which an excellent telescope, twelve feet focal length, was constructed for the Astronomical Society of London. It is obvious, therefore, that large achromatic telescopes must be charged at a pretty high price.

In order to stimulate ingenious chemists and opticians to make experiments on this subject, the Board of Longitude, more than half a century ago, offered a considerable reward for bringing the art of making good flint glass for optical purposes to the requisite perfection. But considerable difficulties arise in attempting improvements of this kind, as the experiments must all be tried on a very large scale, and are necessarily attended with a heavy expense; and, although government has been extremely liberal in voting money for warlike purposes, and in bestowing pensions on those who stood in no need of them, it has thrown an obstruction in the way of such experiments, by the heavy duty of excise, which is rigorously exacted, whether the glass be manufactured into saleable articles or not, and has thus been instrumental in retarding the progress of improvement and discovery. It would appear that experiments of this kind have been attended with more sucess in France, Germany, and other places on the Continent than in Britain, as several very large achromatic telescopes have been constructed in those countries by means of flint glass, which was cast for the purpose in different manufactories, and to which British artists have been considerably indebted, as the London opticians frequently purchase their largest discs of flint glass from Parisian agents. Guinaud, a Continental experimenter, and who was originally a cabinetmaker, appears to have had his labors in this department of art crowned with great success. Many years were employed in his experiments, and he too frequently, notwithstanding all his attention, discovered his metal to be vitiated by striæ, specks, or grains, with cometic tails. He constructed a furnace capable of melting two *cwt.* of glass in one mass, which he sawed vertically, and polished one of the sections, in order to observe what had taken place during the fusion. From time to time, as he obtained blocks including portions of good glass, his practice was to separate them by sawing the blocks into horizontal sections, or perpendicular to their axes. A fortunate accident conducted him to a better process. While his men were one day carrying a block of this glass on a handbarrow to a sawmill which he had erected at the Fall of the Doubs, the mass slipped from its bearers, and rolling to the bottom of a steep and rocky declivity, was broken to pieces. Guinaud having selected those fragments which appeared perfectly homogeneous, softened them in circular molds in such a manner, that, on cooling, he obtained discs that were afterward fit for working. To this method he adhered, and contrived a way for clearing his glass while cooling, so that the fractures should follow the most faulty parts. When flaws occurred in the large masses, they were removed by cleaving the pieces with wedges; then smelting them again in molds, which gave them the form of discs. The Astronomical Society of London have made trial of discs made by Guinaud, and have found them entirely homogeneous and free from fault. Of this ingenious artist's flint glass some of the largest achromatic telescopes on the Continent have been constructed. But it is more than twenty years since this experimenter took his flight from this terrestrial scene, and it is uncertain whether his process [illegible] carried on with equal success.

NOTICES OF SOME LARGE ACHROMATIC TELESCOPES ON THE CONTINENT AND IN GREAT BRITAIN.

1. *The Dorpat Telescope.*—This is one of the largest and most expensive refracting telescopes ever constructed. It was made by the celebrated Fraunhofer, of Munich, for the observatory of the Imperial University of Dorpat, and was received into the observatory by Professor Strüve, in the year 1825. The aperture of the object-glass of this telescope is 9½ English inches, and its solar focal length about 14 feet, the main tube being 13 French feet, exclusive of the tube which holds the eyepieces. The smallest of the four magnifying powers it possesses is 175, and the largest 700, which, in favorable weather, is said to present the object with the utmost precision. "This instrument," says Strüve, "was sold to us by Privy-counsellor Von Utzchneider, the chief of the optical establishment at Munich, for 10,500 florins (about £950 sterling), a price which only covers the expenses which the establishment incurred in making it." The framework of the stand of this telescope is of oak, inlaid with pieces of mahogany in an ornamental manner, and the tube is of deal veneered with mahogany and highly polished. The whole weight of the telescope and its counterpoises is supported at one point, at the common center of gravity of all its parts; and though these weigh 3000 Russian pounds, yet we are told that this enormous telescope may be turned in every direction toward the heavens with more ease and certainty than other hitherto in use. When the object-end of the telescope is elevated to the zenith, it is sixteen feet four inches, Paris measure, above the floor, and its eye-end in this position is two feet nine inches high. This instrument is mounted on an equatorial stand, and clockwork is applied to the equatorial axis, which gives it a smooth and regular sidereal motion, which, it is said, keeps a star in the exact center of the field of view, and produces the appearance of a state of rest in the starry regions, which motion can be made solar, or even lunar, by a little change given to the place of a pointer that is placed as an index on the dial plate. Professor Strüve considers the optical powers of this telescope superior to those of Schroeter's twenty-five feet reflector, from having observed σ Orionis with fifteen companions, though Schroeter observed only twelve that he could count with certainty. Nay, he seems disposed to place it in competition with the late Sir W. Herschel's forty-feet reflector. The *finder* of this telescope has a focal distance of 30 French inches, and 2-42 aperture.

2. *Sir James South's Telescope.*—About the year 1829, Sir J. South, President of the London Astronomical Society, procured of M. Cauchoix, of Paris, an achromatic object-glass of 11 2-10 inches clear aperture, and of 19 feet focal length. The flint glass employed in its construction was the manufacture of the late Guinaud le Pere, and was found to be absolutely perfect. The first observation was made with this telescope while on a temporary stand, on Feb. 13, 1830, when Sir J. Herschel discovered with it a *sixth* star in the trapezium in the nebula of Orion, whose brightness was about one-third of that of the fifth star discovered by Strüve, which is as distinctly seen as the companion to Polaris is in a five feet achromatic. Sir James gives the following notices of the performance of this instrument on the morning of May 14, 1830. "At half past two placed the 20 feet achromatic on the Georgium Sidus, saw it with a power of 346, a beautiful planetary disc; not the slightest suspicion of any ring, either perpendicular or horizontal; but the planet three hours east of the meridian, and the moon within three degrees of the planet. At a quarter before three, viewed *Jupiter* with 252 and 346, literally covered with belts, and the diameters of his satellites might have been as easily measured as himself. One came from behind the body, and the contrast of the color with that of the planet's limb was striking. At three o'clock viewed *Mars.* The contrast of light in the vicinity of the poles very decided. Several spots on his body well and strongly marked; that about the south pole seems to overtake the body of the planet, and gives an appearance not unlike that afforded by the new moon, familiarly known as 'the old moon in the moon's arms.'" *Saturn* has been repeatedly seen with powers from 130 to 928, under circumstances the most favorable; but not anything anomalous about the planet or its ring could even be suspected. This telescope is erected on an equatorial stand, at Sir J. South's observatory, Kensington.

3. *Captain Smith's Telescope in his private observatory at Bedford.*—This achromatic telescope is 8½ feet focal length, with a clear aperture of 5 9-10 inches, worked by the late Mr. Tulley, senior, from a disc purchased by Sir James South at Paris. It is considered by Captain Smith to be the finest specimen of that eminent optician's skill, and, it is said, will bear with distinctness a magnifying power of 1200. Its distinctness has been proved by the clear vision it gives of the obscure nebulæ, and of the companions of Polaris, Rigel, α Lyræ, and the most minute double stars—the lunar mountains, craters, and shadows under all powers—the lucid polar regions of Mars—the sharpness of the double ring of Saturn—the gibbous aspect of Venus—the shadows of Jupiter's satellites across his body, and the splendid contrast of colors in α Hercules, γ Andromedæ, and other superb double stars.

Other large Achromatics.—Beside the above, the following, belonging to public observatories and private individuals, may be mentioned. In the Royal Observatory at Greenwich there is an achromatic of 10 feet focal distance, having a double object-glass 5 inches diameter, which was made by Mr. Peter Dollond, and the only one of that size he ever constructed. There is also a 46 inch achromatic, with a triple object-glass 3¾ inches aperture, which is said to be the most perfect instrument of the kind ever produced. It was the favorite instrument of Dr. Maskelyne, late astronomer royal, who had a small room fitted up in the observatory for this telescope. The observatory some years ago erected near Cambridge is, perhaps the most splendid structure of the kind in Great Britain. It is furnished with several very large achromatic telescopes on equatorial machinery; but the achromatic telescope lately presented to it by the Duke of Northumberland is undoubtedly the largest instrument of this description which is to be found in this country. The object-glass is said to be twenty-five feet focal distance, and of a corresponding diameter;

but as there was no access to this instrument at the time I visited the observatory, nearly six years ago, I am unable to give a particular description of it. In the Royal Observatory at Paris, which I visited in 1837, I noticed, among other instruments, two very large achromatic telescopes, which, measuring them rudely by the eye, I estimated to be from 15 to 18 feet long, and the aperture at the object-end from 12 to 15 inches diameter. They were the largest achromatics I had previously seen; but I could find no person in the Observatory at that time who could give me any information as to their history, or to their exact dimensions or powers of magnifying.*

The Rev. Dr. Pearson, treasurer to the Astronomical Society of London, is in possession of the telescope formerly alluded to made by Mr. Tulley, of twelve feet focal distance and seven inches aperture, which is said to be a very fine one. The small star which accompanies the pole-star, with a power of 100, appears through this telescope as distinct and steady as one of Jupiter's satellites. With a single lens of 6 inches focus, which produced a power of 24 times, according to the testimony of an observer who noticed it, the small star appeared as it does in an achromatic of three inches aperture, which shows the great effect of illuminating power in such instruments. Mr. Lawson a diligent astronomical observer in Hereford, possesses a most beautiful achromatic telescope of about 7 inches aperture and 12 feet focal distance, which was made by one of the Dollands, who considered it his *chef d'œuvre*. It is said to bear powers as high as 1100 or 1400, and has been fitted up with mechanism, devised by Mr. Lawson himself, so as to be perfectly easy and manageable to the observer, and which displays this gentleman's inventive talent. In several of his observations with this instrument, he is said to have had a view of some of the more minute subdivisions of the ring of Saturn. A very excellent achromatic telescope was fitted up some years ago by my worthy friend William Bridges, Esq., Blackheath. Its object-glass is 5½ inches diameter, and about 5½ feet focal length. It is erected upon equatorial machinery, and placed in a circular observatory which moves round with a slight touch of the hand. The object-glass of this instrument cost about 200 guineas; the equatorial machinery on which it is mounted cost 150 guineas; and the circular observatory in which it is placed about 100 guineas, in all 450 guineas. Its powers vary from 50 to 300 times.†

ACHROMATIC TELESCOPES OF A MODERATE SIZE.

Such telescopes as I have alluded to above are among the largest which have yet been made on the achromatic principle; they are, of course, comparatively rare, and can be afforded only at a very high price. Few of the *object-glasses* in the telescopes to which I have referred would be valued at less than 200 guineas, independently of the tubes, eyepieces, and other apparatus with which they are fitted up. It is so difficult to procure large discs of flint glass for optical purposes, to produce the requisite curves of the different lenses, and to combine them together with that extreme accuracy which is requisite, that, when a good compound lens of this description is found perfectly achromatic, the optician must necessarily set a high value upon it, since it may happen that he may have finished half a dozen before he has got one that is nearly perfect. The more common sizes of achromatic telescopes for astronomical purposes, which are regularly sold by the London opticians, are the following:

1. *The 2½ feet Achromatic.*—This telescope has an object-glass 30 inches in focal length, and 2 inches clear aperture. It is generally furnished with two eyepieces, one, for terrestrial objects, magnifying about 30 or 35 times, and one for celestial objects, with a power of 70 or 75 times. It might be furnished with an additional astronomical eyepiece, if the object-glass be a good one, so as to produce a power of 90 or 95 times. With such a telescope the belts and satellites of Jupiter, the phases of Venus, and the ring of Saturn may be perceived, but not to so much advantage as with larger telescopes. It is generally fitted up either with a mahogany or a brass tube, and is placed upon a tripod brass stand, with a universal joint which produces a horizontal and vertical motion. It is packed, along with the eyepieces and whatever else belongs to it, in a neat mahogany box. Its price varies according as it is furnished with an elevating rack or other apparatus.

The following are the prices of this instrument, as marked in the catalogue of Mr. Tulley, Terrett's Court, Islington, London.

	£	s.	d.
2½ feet telescopes, brass mounted on plain pillar and claw stand, with 1 eyepiece for astronomical purposes and 1 for land objects, to vary the magnifying power, packed in a mahogany box	10	10	0
Ditto, ditto, brass mounted on pillar and claw stand, with elevating rack, 1 eyepiece for astronomical purposes, and 1 for land objects, to vary the magnifyiny power, packed in a mahogany box	12	12	0

The following prices of the same kind of telescope are from the catalogue of Messrs. W. and S. Jones, 30 Lower Holborn, London.

	£	d.	s.
The improved 2½ feet achromatic refractor, on a brass stand, mahogany tube, with three eyepieces, two magnifying about 40 and 50 times for terrestrial objects, and the other about 75 times for astronomical purposes, in a mahogany case	10	10	0
Ditto, ditto, the tube all brass, with three eyepieces . .	11	11	
Ditto, ditto, with vertical and horizontal rack-work motions .	15	15	

2. *The 3½ feet Achromatic Telescope.*—The object-glass of this telescope is from 44 to 46 inches focal length, and 2¾ inches diameter. It is generally furnished with four eyepieces, two for terrestrial and two for celestial objects. The lowest power for land objects is generally about 45, which affords a large field of view, and exhibits the objects with great brilliancy. The other terrestrial power is usually from 65 to 70 The astronomical powers are about 80 and 130, but such a telescope should always have another

---

* An achromatic telescope is said to be in possession of Mr. Cooper, M. P. for Sligo, which is 26 feet long, and the diameter of the object-glass 14 inches.

† This telescope, which was made by Dolland, with a power of 240 times, gives a beautiful view of the belts of Jupiter, and the double ring of Saturn, and with a power of 50 the stars in the Milky Way and some of the nebulæ appear very numerous and brilliant. Its owner is a gentleman who unites science with Christianity.

eyepiece, to produce a power of 180 or 200 times, which it will bear with distinctness, in a serene state of the atmosphere, if the object-glass be truly achromatic. The *illuminating power* in this telescope is nearly double that of the 2½ feet telescope, or in the proportion of 7.56 to 4, and therefore it will bear about double the magnifying power with nearly equal distinctness. This telescope is fitted up in a manner somewhat similar to the former, with a tripod stand which is placed upon a table. Sometimes, however, it is mounted on a long mahogany stand which rests upon the floor (as in fig. 56,) and is fitted with an equatorial motion; and has generally a small telescope fixed near the eye end of the large tube, called a *finder*, which serves to direct the telescope to a particular object in the heavens when the higher powers are applied. It is likewise eligible that it should have an elevating rack and sliding tubes, for supporting the eye end of the instrument, to keep it steady during astronomical observations, and it would be an advantage, for various purposes which shall be afterward described, to have fitted to it a *diagonal eyepiece* magnifying 40 times or upward.

The prices of this instrument, as marked in Mr. Tulley's catalogue, are as follows:

	£	s.	d.
The 3½ feet achromatic telescope, 2¾ inches aperture, on plain pillar and claw stand, 2 eyepieces for astronomical purposes and 1 for land objects, to vary the magnifying power, packed in a mahogany box	21	0	0
Ditto, ditto, with elevating rack and achromatic finder, 2 eyepieces for astronomical purposes and 1 for day objects, to vary the magnifying power, packed in a mahogany box	26	5	0

The following are the prices as marked in Messrs. W. and S. Jones's catalogue:

	£	s.	d.
The 3½ feet achromatic, plain mahogany tube	18	18	0
Ditto, ditto, brass tube	21	0	0
Ditto, all in brass, with rack-work motions, &c.	26	5	0
Ditto, the object-glass of the largest aperture, and the rack-work motions on an improved principle, *from* £37 16*s.* to	42	0	0
Ditto, fitted up with equatorial motion, framed mahogany stand, divided altitude and azimuth arches, or declination and right ascension circles, &c., &c., *from* £60 to	80	0	0

This is the telescope which I would particularly recommend to astronomical amateurs, whose pecuniary resources do not permit them to purchase more expensive instruments. When fitted up with the eyepieces and powers already mentioned, and with a finder and elevating rack—price 25 guineas—it will serve all the purposes of general observation. By this telescope satisfactory views may be obtained of most of the interesting phenomena of the heavens—such as the spots on the sun—the mountains, vales, and caverns on the lunar surface—the phases of Mercury and Venus —the spots on Mars—the satellites and belts of Jupiter—the ring of Saturn—many of the more interesting nebulæ, and most of the double stars of the second and third classes. When the object-glass of this telescope is accurately figured and perfectly achromatic, a power of from 200 to 230 may be put upon it, by which the division of Saturn's ring might occasionally be perceived. It is more easily managed, and represents objects considerably brighter than reflecting telescopes of the same price and magnifying power, and it is not so apt to be deranged as reflectors generally are. A telescope of a less size would not, in general, be found satisfactory for viewing the objects I have now specified, and for general astronomical purposes. It may not be improper, for the information of some readers, to explain what is meant in Mr. Tulley's catalogue, when it is stated that this instrument "has one eyepiece for day objects, *to vary the magnifying power.*" The eyepiece alluded to is so constructed, that by drawing out a tube next the eye you may increase the power at pleasure, and make it to vary say from 40 to 80 or 100 times; so that such a construction of the terrestrial eyepiece (to be afterward explained) serves, in a great measure, the purpose of separate eyepieces. The whole length of the 3½ feet telescope, when the terrestrial eyepiece is applied, is about 4½ feet from the object-glass to the first eyeglass.

When the aperture of the object-glass of this telescope exceeds 2¾ inches, its price rapidly advances.

The following is Mr. Tulley's scale of prices, proportionate to the increase of aperture:

	£	s.	d
3½ feet telescopes, 3¼ inches aperture, with vertical and horizontal rack-work motions, achromatic finder, 3 eyepieces for astronomical purposes, and one for day objects, to vary the magnifying power, packed in a mahogany box	42	0	0
Ditto, ditto, 3¾ inches diameter, mounted as above	68	5	0
Ditto, with universal equatorial instead of pillar and claw stand	84	0	0

Here, in the one case, the increase of half an inch in the diameter of the object-glass adds about £16 to the expense, and in the other case no less than £26 5s. The proportion of light in those two telescopes, compared with that of 2¾ inches aperture, is as follows: The square of the 2¾ object-glass is 7.56; that of 3¼, 10.56; and that of the 3¾, 14.06; so that the light admitted by the 3¼ compared with the 2¾ aperture is nearly as 10 to 7; and the light admitted by the 3¾ object-glass is nearly double that of the 2¾ aperture, and will bear nearly a proportional increase of magnifying power.

3. *The 5 feet Achromatic Telescope.*—The focal length of the object-glass of this telescope is 5 feet 3 inches, and the diameter of its aperture 3 8-10 inches. The usual magnifying powers applied to it are, for land objects 65 times, and for celestial objects 110, 190, 250, and sometimes one or two higher powers. The quantity of light it possesses is not much larger than that of the 3½ feet telescope, with 3¾ inches aperture; but the larger focal length of this telescope is considered to be an advantage, since the longer the focus of the object-glass, the less will be its chromatic and spherical aberrations, and the larger may be the eyeglasses, and the flatter the field of view.

The following are the prices of these telescopes, as marked in Mr. Tulley's catalogue:

5 feet telescopes, 3¾ inches aperture, on a universal equatorial stand, with achromatic finder 4 eyepieces for astronomical purposes and 1 for

	£	s.	d.
day objects, to vary the magnifying power, packed in a mahogany box, 100 guineas to	157	10	0
7 feet ditto, 5 inches aperture, on a newly improved universal equatorial stand, 6 eyepieces for astronomical purposes and 1 for day objects, to vary the magnifying power, with achromatic finder and Troughton's micrometer,	207	5	0

The above are all the kinds of achromatic telescopes *generally* made by the London opticians. Those of the larger kind, as 5 and 7 feet telescopes, and the 3½ feet with 3¾ inches aperture, are generally made to order, and are not always to be procured. But the 2½ and 3½ feet achromatics of 2¾ inches aperture are generally to be found ready made at most of the opticians' shops in the metropolis. The prices of these instruments are nearly the same in most of the opticians' shops in London. Some of them demand a higer price, but few of them are ever sold lower than what has been stated, unless in certain cases where a discount is allowed.

The stands for these telescopes, and the manner in which they are fitted up for observation, is represented in figures 57, 58, and 59. Fig. 57 represents either the 2½ or the 3½ feet telescopes, mounted on a plain brass stand, to be placed on a table. *A* is the long eyepiece for land objects, and *B* the small eyepiece for astronomical observation, which is composed of two lenses, and represents the object in an inverted position. These eyepieces are screwed on, as occasion requires, at *E*, the eye end of the telescope. The shorter of the two astronomical eyetubes which accompany this telescope produces the highest magnifying power. For adjusting the telescope to distinct vision, there is a brass knob or button at *a*, which moves a piece of rack-work connected with the eyetube, which must be turned either one way or the other until the object appears distinctly, and different eyes frequently require a different adjustment.

Fig. 57.

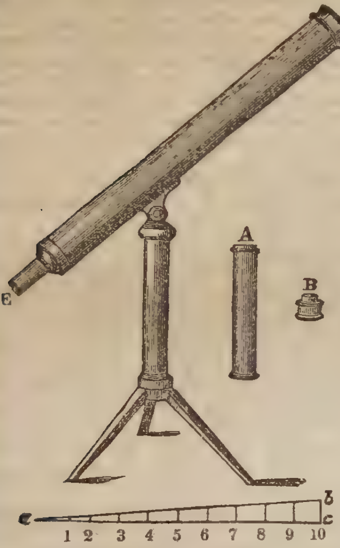

Fig. 58 represents a 5 feet telescope fitted up for astronomical observations. It is mounted on a mahogany stand, the three legs of which are made to close up together by means of the brass frame *a a a*, which is composed of three bars, connected with three joints in the center, and three other joints, connected with the three mahogany bars. It is furnished with an apparatus for equatorial motions. The brass pin is made to move round in the brass socket *b*, and may be tightened by means of the finger screw *d*, when the telescope is directed nearly to the object intended to be viewed. This socket may be set perpendicular to the horizon, or to any other required angle; and the quantity of the angle is ascertained by the divided arc, and the instrument made fast in that position by the screw *e*. If this socket be set to the latitude of the place of observation, and the plane of this arc be turned so as to be in the plane of the meridian, the socket *b* being fixed to the inclination of the pole of the earth, the telescope, when turned in this socket, will have an equatorial motion, so that celestial objects may be always kept in view when this equatorial motion is performed. The two handles at *k*, are connected with rack-work, intended to move the telescope in any required direction. The two sets of brass sliding rods, *i i*, are intended to render the telescope as steady as possible, and to elevate and depress it at pleasure, and are so constructed as to slide into each other with the utmost ease.

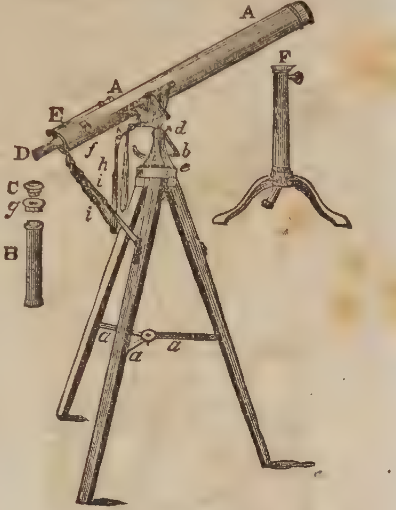
Fig. 58.



The *finder* is placed at *A E*, either on the top or the left side of the tube of the telescope. When high magnifying powers are applied to any telescope, it is sometimes difficult, on account of the smallness of the field of view, to direct the main tube of the telescope to the object. But by the finder, which is a telescope with a small power, and consequently has a large field of view, when directed to any object, it is easily found, and being brought to the center of the field, where two cross-hairs intersect each other, it will then be seen in the larger telescope. *B* is the eyetube for terrestrial objects, containing four glasses, and *C* one of the astronomical eyepieces. A socket is represented at *g*, containing a stained glass, which is screwed to any of the eyepieces, to protect the eye from the glare of light, when viewing the spots of the sun. The brass nut above *f* is intended for the adjustment of the eyepiece to distinct vision. The 3½ feet telescope is sometimes mounted in this form.

Fig. 59.

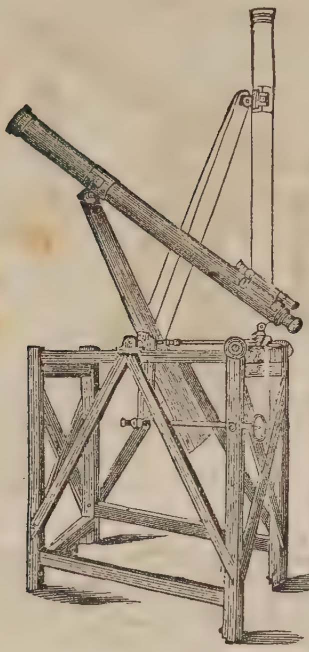


Fig. 59 represents a 5 or 6 feet telescope, mounted on a stand of a new construction by Dollond. It possesses the advantage of supporting the telescope in two places, which renders it extremely steady, a property of great importance when viewing celestial objects with high magnifying powers. It possesses, likewise, the advantage of enabling the observer to continue seated at the same hight from the floor, although the telescope be raised to any altitude, *the elevation being entirely at the object end*, although it may be changed from the horizon to the zenith. The framework is composed of bars of mahogany, and rests on three castors, two of which are made fast to their respective legs in the usual way, and the third stands under the middle of the lower horizontal bar that connects the two opposite legs, so that the frame has all the advantages of a tripod. As it becomes very inconvenient to stoop to the eye end of a telescope when the altitude of an object is considerable, and the center of motion at the middle of the tube, this construction of a stand serves to remedy such inconvenience.

PROPORTIONS OF CURVATURE OF THE LENSES WHICH FORM AN ACHROMATIC OBJECT-GLASS.

As some ingenious mechanics may feel a desire to attempt the construction of a compound achromatic object-glass, I shall here state some of the proportions of curvature of the concave and convex lenses which serve to guide opticians in their construction of achromatic instruments. These proportions are various; and even when demonstrated to be mathematically correct, it is sometimes difficult to reduce them to practice, on account of the different powers of refraction and dispersion possessed by different discs of crown and flint glass, and of the difficulty of producing, by mechanical means, the exact curves which theory requires. The following table shows the radii of curvature of the different surfaces of the lenses necessary to form *a double achromatic object-glass*, it being supposed that the sine of refraction in the crown-glass is as 1.528 to 1, and in the flint as 1.5735 to one, the ratio of their dispersive powers being as 1 to 1.524. It is also assumed that the curvatures of the concave lens are as 1 to 2, that is, that the one side of this lens is ground on a tool, the radius of which is double that of the other. The 1st column expresses the compound focus of the object-glass in *inches;* the 2d column states the radius of the *anterior* surface of the *crown*, and column 3d its *posterior* side. Column 4th expresses the radius of the anterior surface of the *concave* lens, and column 5th its posterior surface, which, it will be observed, is exactly double that of the other.

Focus in inches.	Radius of anterior surface, convex.		Radius of posterior surface.		Rad. of anterior surface, concave.		Radius of posterior surface.	
	Inc.	Dec.	Inc.	Dec.	Inc.	Dec.	Inc.	Dec.
12	3		4.	652	4.	171	8.	342
24	6		9.	304	8.	342	16.	684
30	7.	5	11.	63	10.	428	20.	856
36	9		13.	956	12.	513	25.	027
48	12		18.	608	16.	684	33.	369
60	15		23.	260	20.	856	41.	712
120	30		46.	520	41.	712	83.	424

Focal length.	Convex lens of Crown glass.				Concave lens of flint glass.				Convex lens of crown glass.			
Inches.	Inc.	Dec.	Inc.	Dec.	Inc.	Dec.	Inc.	Dec.	Inc.	Dec.	Inc.	Dec.
6	4.	54	3.	03	3.	03	6.	36	6.	36	.	64
9	6.	83	4.	56	4.	56	9.	54	9.	54	.	92
12	9.	25	6.	17	6.	17	12.	75	12.	75	1.	28
18	13.	67	9.	12	9.	12	19.	08	19.	08	1.	92
24	18.	33	12.	25	12.	25	25.	50	25.	50	2.	56
30	22.	71	15.	16	15.	16	31.	79	31.	79	3.	20
36	27.	33	18.	25	18.	25	38.	17	38.	17	3.	84
42	31.	87	21.	28	21.	28	44.	53	44.	53	4.	48
48	36.	42	24.	33	24.	33	50.	92	50.	92	6.	12
54	40.	96	27.	36	27.	36	57.	28	57.	28	5.	76
60	45.	42	30.	33	30.	33	63.	58	63.	58	6.	4

From the preceding table it will be seen that, to construct, for example, a 30 inch compound object-glass, the radius of the anterior side of the crown must be 7½ inches, and that of the posterior side 11.63 inches; the radius of the anterior surface of the concave 10.428, and that of the posterior 20.856 inches. It may be proper to observe, that in these computations, the radius of the anterior surface of the concave is less than the posterior side of the convex, and consequently admits of its approach, without touching in the center—a circumstance which always requires to be guarded against in the combination of achromatic glasses. The preceding table shows the radii of curvature of the lenses of a *triple* object-glass, calculated from formula deduced by Dr. Robison of Edinburgh.

The following table contains the proportions of curvature said to be employed by the London opticians:

Focal length.	Convex lens of crown glass.				Radius of both the surfaces of the concave of flint glass.		Convex lens of crown glass.			
Inches.	Inc.	Dec.	Inc.	Dec.	Inc.	Dec.	Inc.	Dec.	Inc.	Dec.
6	3.	77	4.	49	3.	47	3.	77	4.	49
9	5.	65	6.	74	5.	21	5.	65	6.	74
12	7.	54	8.	99	6.	95	7.	54	8.	99
18	11.	30	13.	48	10.	42	11.	30	13.	48
24	15.	08	17.	98	13.	90	15.	08	17.	98
36	22.	61	26.	96	20.	84	22.	61	26.	96
42	26.	38	31.	45	24.	31	26.	38	31.	45
48	30.	16	35.	96	27.	80	30.	16	35.	96
54	33.	91	40.	45	31.	27	33.	91	40.	45
60	37.	68	44.	94	34.	74	37.	68	44.	94

From this table it appears that the two convex lenses have the same radii of their respective sides, and that the concave flint lens has its two surfaces equally concave, so that a triple object-glass formed according to these proportions would require only three pair of grinding tools. The following are the curves of the lenses of one of the best of Dollond's achromatic telescopes, the focal length of the compound object-glass being 46 inches. Reckoning from the surface next the object, the radii of the crown glass were 28 and 40 inches; the concave lens 20.9 inches, and the inner crown glass lens 28.4 and 28.4 inches. This telescope carried magnifying powers of from 100 to 200 times.

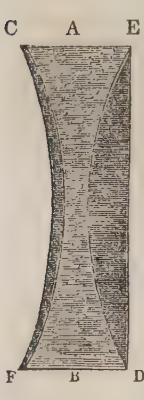
Although I have inserted the above tables, which might, in some measure, guide an ingenious artist, yet, on the whole, a private amateur has little chance in succeeding in such attempts. The diversity of glasses, and the uncertainty of an unpracticed workman's producing the precise curvature he intends, is so great, that the object-glass, for the most part, turns out different from his expectations. The great difficulty in the construction is to find the exact proportion of the dispersive powers of the crown and flint glass. The crown is pretty constant, but there are hardly two pots of flint glass which have the same dispersive power. Even if constant, it is difficult to measure it accurately; and an error in this greatly affects the instrument, because the focal distances of the lenses must be nearly as their dispersive powers. In the two preceding tables, the sine of incidence in the crown glass is supposed to be to the sine of refraction as 1.526 to 1; and in the flint glass, as 1.604 to one. Opticians who make great numbers of lenses, both of flint and crown glass, acquire, in time, a pretty good guess of the nature of the errors which may remain after they have finished an object-glass; and having many lenses intended to be of the same form, but unavoidably differing a little from it, they try several of the concaves with the two convexes, and finding one better than the rest, they make use of it to complete the set. In this way some of the best achromatic telescopes are frequently formed I have sometimes found, when supplying a concave flint glass to a telescope where it happened to be wanting, that, of four or five concave lenses which appeared to be the same as to curvature and other properties, only one was found to produce a distinct and colorless image. Should any one, however, wish to attempt the construction of an achromatic telescope, the best way for preventing disappointments in the result is to procure a *variety* of tables of the respective curvatures founded on *different conditions*, and which, of course, require the surfaces of the several lenses to be of different curves. Having lenses of different radii at his command, and having glass of different refractive or dispersive powers, when one combination does not exactly suit, he may try another, and ultimately may succeed in constructing a good achromatic telescope; for, in many cases, it has been found that chance, or a happy combination of lenses by trial, has led to the formation of an excellent object-glass.

ACHROMATIC TELESCOPES COMPOSED OF FLUID LENSES.

The best achromatic telescopes, when minutely examined, are found to be in some respects defective, on account of that slight degree of color which, by the aberration of the rays, they give to objects, unless the object-glass be of small diameter. When we examine with attention a good achromatic telescope, we find that it does not show white or luminous objects perfectly free from color, their edges being tinged on one side with a claret colored fringe, and on the other with a green fringe. This telescope, therefore, required further improvement, to get rid of these secondary colors, and Father Boscovich, to whom every branch of optics is much indebted, displayed much ingenuity in his attempts to attain this object. But it is to Dr. Blair, professor of astronomy in Edinburgh, that we are chiefly indebted for the first successful experiments by which this end was accomplished. By a judicious set of experiments, he proved that the quality of dispersing the rays in a greater degree than crown glass is not confined to a few mediums, but is possessed by a great variety of fluids, and by some of these in a most extraordinary degree. Having observed that when the extreme red and violet rays were perfectly united, the green were left out, he conceived the idea of making an achromatic concave lens which should refract the green less than the united red and violet, and an achromatic convex lens which should do the same; and as the concave lens refracted the outstanding green to the axis, while the concave one refracted them from the axis, it followed that, by a combination of these two opposite effects, the green would be united with the red and violet.

By means of an ingenious prismatic apparatus, he examined the optical properties of a great variety of fluids. The solutions of metals and semi-metals proved in all cases more dispersive than crown glass. Some of the salts, such as sal ammoniac, greatly increased the dispersive power of water. The marine acid disperses very considerably, and this quality increases with its strength. The most dispersive fluids were accordingly found to be those in which this acid and the metals were combined. The chemical preparation called *causticum antimoniale*, or butter of antimony, in its most concentrated state, when it has just attracted sufficient humidity to render it fluid, possesses the quality of dispersing the rays in an astonishing degree. The great quantity of the semi-metal retained in solution, and the highly concentrated state of the marine acid, are considered as the cause of this striking effect. Corrosive sublimate of mercury, added to a solution of *sal ammoniacum* in water, possesses the next place to the butter of antimony among the dispersive fluids which Dr. Blair examined. The essential oils were found to hold the next rank to metallic solutions among fluids which possess the dispersive quality, particularly those obtained from bituminous minerals, as native petrolea, pit-coal, and amber. The dispersive power of the essential oil of sassafras, and the essential oil of lemons, when genuine, were found to be not much inferior to any of these. But of all the fluids fitted for optical purposes, Dr. Blair found that *the muriatic acid mixed with a metallic solution*, or, in other words, a fluid in which the marine acid and metalline particles hold a due proportion, most accurately suited his purpose. In a spectrum formed by this fluid, the green were among the most refrangible rays; and when its dispersion was corrected by that of glass, there was produced an inverted secondary spectrum, that is, one in which the green was above, when it would have been below with a common medium. He therefore placed a concave lens of muriatic acid with a metallic solution between the two lenses, as in fig. 60, where *A B* is the concave fluid lens, *C F* a plano-convex lens, with its plane side next the object, and *E D* a meniscus. With this object-glass the rays of different colors were bent from their rectilineal course with the same equality and regularity as in reflection.

Fig. 60.



Telescopes constructed with such object-glasses were examined by the late Dr. Robison and Professor Playfair. The focal distance of the object-glass of one of these did not exceed 17 inches, and yet it bore an aperture of 3½ inches. They viewed some single and double stars and some common objects with this telescope, and found that in magnifying power, brightness, and distinctness, it was manifestly superior to one of Mr. Dollond's of 42 inches focal length. They had most distinct vision of a star, *when using an erecting eyepiece*, which made this telescope magnify more than 100 times, and they found the field of vision as uniformly distinct as with Dollond's 42 inch telescope, magnifying 46 times, and were led to admire the nice figuring and centering of the very deep eyeglasses which were necessary for this amplification. They saw double stars with a degree of perfection which astonished them. These telescopes, however, have never yet come into general use; and one reason, perhaps, is, that they are much more apt to be deranged than telescopes constructed of object-glasses which are solid. If any species of glass, or other solid transparent substance could be found with the same optical properties, instruments might perhaps be constructed of a larger size, and considerably superior to our best achromatic telescopes.* It is said that Mr. Blair, the son of Dr. Blair, some years ago engaged in prosecuting his father's views, but I have not heard anything respecting the result of his investigations.

BARLOW'S REFRACTING TELESCOPE WITH A FLUID CONCAVE LENS.

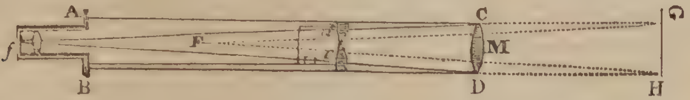
Professor Barlow, not many years ago suggested a new fluid telescope, which is deserving of attention, and about the year 1829 constructed one of pretty large dimensions. The fluid he employs for this purpose is the *sulphuret of carbon*, which he found to be a substance which possessed every requisite he could desire. Its index is nearly the same as that of the best flint glass, with a dispersive power more than double. It is perfectly colorless, beautifully transparent, and, although very expansible, possesses the same, or very nearly the same, optical properties under all circumstances to which it is likely to be exposed in astronomical observations, except, perhaps, direct observations on the solar disc, which will probably be found inadmissible. Mr. Barlow first constructed an object-glass with this fluid of three inches aperture, with which he could see the small star in Polaris with a power of 46, and with the higher powers several stars which are considered to require a good telescope, for example, 70, p Ophiuchi, 29 Bootes, the quadruple star ε Lyræ, ζ Aquarii, α Herculis, &c. He next constructed a 6 inch object-glass. With this instrument, the small star in Polaris is so distinct and brilliant, with a power of 143, that its transit might be taken with the utmost certainty. As the mode of constructing these telescopes is somewhat novel, it may be expedient to enter somewhat into detail.

In the usual construction of achromatic telescopes, the two or three lenses composing the object-glass are brought into immediate contact; and in the fluid telescope of Dr. Blair, the construction was the same, the fluid having been inclosed in the object-glass itself. But in Mr. Barlow's telescope, the fluid correcting lens is placed at a distance from the plate lens equal to half its focal length, and it might be carried still farther back, and yet possess dispersive power to render the object-glass achromatic. By this means, the fluid lens, which is the most difficult part of the construction, is reduced to one-half, or to less than one-half of the size of the plate lens; consequently, to construct a telescope of 10 or 12 inches aperture involves no greater difficulty in the manipulation than in making a telescope of the usual description of 5 or 6 inches aperture, except in the simple plate lens itself; and, hence, a telescope of this kind of 10 or 12 feet length will be equivalent, in its focal power, to one of 16 or 20 feet. By this means the tube may be shortened several feet, and yet possess a focal power more considerable than could be conveniently given to it on the usual principle of construction. This will be better understood from the above diagram (fig. 61).

---

* For a more particular account of Dr. Blair's instruments and experiments, the reader is referred to his Dissertation on this subject in vol. ii, of the "Transactions of the Royal Society of Edinburgh," which occupies 76 pages, or to Nicholson's "Journal of Natural Philosophy," &c., quarto series, vol. i, April—September, 1797.

Fig. 61.



In this figure *A B C D* represent the tube of the 6 inch telescope, *C D* the plate object-glass, *F* the first focus of rays, *d e* the fluid concave lens, distant from the former 24 inches; the focal length *M F* being 48, and, consequently, as 48 : 6 : : 24: 3 inches, the diameter of the fluid lens. The resulting compound focus is 62.5 inches. It is obvious, therefore, that the rays *d f*, *e f*, arrive at the focus under the same convergency, and with the same light as if they proceeded from a lens of six inches diameter, placed at a distance beyond the object-glass *C D* (as *G H*), determined by producing those rays until they meet the sides of the tube in *G H*, namely, at 62.5 inches beyond the fluid lens. Hence, it is obvious, the rays will converge as they would do from an object-glass, *G H*, of the usual kind with a focus of 10 feet 5 inches. We have thus, therefore, shortened the tube 38.5 inches, or have at least the advantage of a focus 38.5 inches longer than our tube; and the same principle may be carried much further, so as to reduce the usual length of refracting telescopes nearly one half, without increasing the aberration in the first glass beyond the least that can possibly belong to a telescope of the usual kind of the whole length. It should likewise be observed, that the adjustment for focus may be made either in the usual way or by a slight movement of the fluid lens, as in the Gregorian Reflectors by means of the small speculum.

Mr. Barlow afterward constructed another larger telescope on the same principle, the clear aperture of which is ⅞ inches. Its tube is 11 feet, which, together with the eyepiece, makes the whole length 12 feet, but its effective focus is, on the principle stated, 18 feet. It carries a power of 700 on the closest double stars in South's and Herschel's catalogue, and the stars are, with that power, round and defined, although the field is not then so bright as could be desired. The telescope is mounted on a revolving stand, which works with considerable accuracy as an azimuth and altitude instrument. To give steadiness to the stand, it has been made substantial and heavy, its weight by estimation being about 400 pounds, and that of the telescope 130 pounds, yet its motions are so smooth, and the power so arranged, that it may be managed by one person with the greatest ease, the star being followed by a slight touch, scarcely exceeding that of the keys of a piano-forte. The focal length of the plate lens is 78 inches, and of the fluid lens 59.8 inches; which, at the distance of 40 inches, produce a focal length of 104 inches, a total length of 12 feet, and an equivalent focus of 18 feet. The curves of the parallel meniscus checks for containing the fluid are 30 inches and 144 inches, the latter toward the eye. The curves for the plate lens are 56.4 and 144. There is an interior tube 5 inches diameter, and 3 feet 6 inches long, which carries the cell in which the fluid is inclosed, and an apparatus by which it may be moved backward and forward, so that the proper adjustment may be made for color in the first instance, and afterward the focus is obtained by the usual rack-work motion. The following is the mode by which the fluid was inclosed. After the best position has been determined practically for the checks forming the fluid lens, these, with the ring between them, ground and polished accurately to the same curves, are applied together, and taken into an artificial high temperature, exceeding the greatest at which the telescope is ever expected to be used. After remaining here with the fluid some time, the space between the glasses is completely filled, immediately closed, cooled down by evaporation, and removed into a lower temperature. By this means a sudden condensation takes place, an external pressure is brought on the checks, and a bubble formed inside, which is, of course, filled with the vapor of the fluid; the excess of the atmospheric pressure beyond that of the vapor being afterward always acting externally to prevent contact. The extreme edges are then sealed with the serum of human blood, or by strong fish glue, and some thin pliable metal surface. By this process, Mr. Barlow says, "I have every reason to believe the lens becomes as durable as any lens of solid glass. At all events, I have the satisfaction of stating, that my first 3 inch telescope has now been completed more than fifteen months, and that no change whatever has taken place in its performance, nor the least perceptible alteration either in the quantity or the quality of the fluid."

The following are some of the observations which have been made with this telescope, and the tests to which it has been subjected. The very small star which accompanies the pole star is generally one of the first tests applied to telescopes. This small point of light appeared brilliant and distinct; it was best seen with a power of 120, but was visible with a power of 700. The small star in Aldebaran was very distinct with a power of 120. The small star α Lyræ was distinctly visible with the same power. The small star called by Sir J. Herschel *Debilissima*, between 4 ε and 5 Lyræ, whose existence, he says, could not be suspected in either the 5 or 7 feet equatorial, and invisible also with the 7 and 10 feet reflectors of 6 and 9 inches aperture, but seen double with the 20 feet reflector, is seen very satisfactorily double with this telescope, η Persei, marked as double in South and Herschel's catalogue, at the distance of 28″, with another small star at the distance of 3′ 67″, is seen distinctly sixfold, four of the small stars being within a considerably less distance than the remote one of η marked in the catalogue. And, rejecting the remote star, the principal and the four other stars form a miniature representation of Jupiter and his satellites, three of them being nearly in a line on one side, and the other on the opposite. *Castor* is distinctly double with

120, and well opened, and stars perfectly round with 360 and 700. γ Leonis and α Piscium are seen with the same powers equally round and distinct. In ε Bootis, the small star is well separated from the larger, and its blue color well marked with a power of 360. η Coronæ Borealis is seen double with a power of 360 and 700. 52 Orionis, ζ Orionis and others of the same class, are also well-defined with the same powers. In regard to the planets which happened to be visible, Venus appeared beautifully white and well-defined with a power of 120, but showed some color with 360. Saturn with the 120 power is a very brilliant object, the double ring and belts being well and satisfactorily defined, and with the 360 power it is still very fine. The moon also is remarkably beautiful, the edges and the shadows being well marked, while the quantity of light is such as to bring to view every minute distinction of figure and shade.

The principal objections that may be made to this construction of a telescope are such as these: Can the fluid be permanently secured? Will it preserve its transparency and other optical properties? Will it not act upon the surface of the glass and partially destroy it? &c. To such inquiries Mr. Barlow replies, that experience is the only test we have; our spirit levels, spirit thermometers, &c., show that some fluids, at least, may be preserved for many years without experiencing any change, and without producing any in the appearance of the glass tubes containing them. But should any of these happen, except the last, nothing can be more simple than to supply the means of replacing the fluid at any time, and by any person, without disturbing the adjustment of the telescope. He expresses his hope that, should these experiments be prosecuted, an achromatic telescope shall ultimately be produced which shall exceed in aperture and power any instruments of the kind hitherto attempted. If the prejudice against the use of fluids could be removed, he feels convinced that well-directed practice would soon lead to the construction of the most perfect instruments, on this principle, at a comparatively small expense. "I am convinced," he says, "judging from what has been paid for large object-glasses, that my telescope, telescope stand, and the building for observation, with every other requisite convenience, have been constructed for a less sum than would be demanded for the object-glass only, if one could be produced of the same diameter of plate and flint glass; and this is a consideration which should have some weight, and encourage a perseverance in the principle of construction."*

ROGERS'S ACHROMATIC TELESCOPE ON A NEW PLAN.

The object of this construction is to render a small disc of flint glass available to perform the office of compensation to a much larger one of crown glass, and thus to render possible the construction of telescopes of much larger aperture than are now common, without hindrance from the difficulty at present experienced in procuring large discs of flint glass. It is well known to those who are acquainted with telescopes, that in the construction of an ordinary achromatic object-glass, in which a single crown lens is compensated by a single one of flint, the two lenses admit of being separated only by an interval too small to afford any material advantage, *in diminishing the diameter of the flint lens*, by placing it in a narrow part of the cone of rays, the actual amount of their difference in point of dispersive power being such as to render the correction of the chromatic aberration impossible when their mutual distance exceeds a certain limit. This inconvenience Mr. Rogers proposes to obviate by employing, as a correcting lens, not a single lens of flint, but a compound one consisting of a convex crown and concave flint, whose foci are such as to cause their combination to act as a plain glass on the mean refrangible rays. Then it is evident that by means of the greater dispersive power of flint than of crown glass, this will act as a concave on the violet, and as a convex on the red rays, and *that* the more powerfully, according as the lenses separately have greater powers or curvature. If then, such a compound lens be interposed between the object-glass of a telescope—supposed to be a single lens of plate or crown glass—and its focus, it will cause no alteration in the focus for mean rays, while it will lengthen the focus for violet, and shorten it for red rays. Now this is precisely what is wanted to produce an achromatic union of all the rays in the focus; and as nothing in this construction limits the powers of the individual correcting lenses, they may therefore be applied anywhere that convenience may dictate; and, thus, theoretically speaking, a disc of flint glass, however small, may be made to correct the color of one of crown, however large.

This construction likewise possesses other and very remarkable advantages: for, first, when the correcting lens is approximately constructed on a calculation founded on its intended aperture, and on the refractive and dispersive indices of its materials, the final and complete dispersion of color may be effected, not by altering the lenses by grinding them anew, but by shifting the combination nearer to, or farther from the object-glass, as occasion may require, along the tube of a telescope, by a screw motion, until the condition of achromaticity is satisfied in the best manner possible; and, secondly, the spherical aberration may in like manner be finally corrected, by slightly separating the lenses of the correcting glass, whose surfaces should for this purpose be figured to curvatures previously determined by calculation to admit of this mode of correction—a condition which Mr. Rogers finds to be always possible. The following is the rule which he lays down for the determination of the foci of the lenses of the correcting glass: "The focal length of either lens is to that of the object-glass in a ratio compounded of the ratio of the square of the aperture of the correcting lens to that of the object-glass, and of the ratio of the difference of the dispersive indices of the crown and flint glass to the dispersive index of crown." For example, to correct the color of a lens of crown or plate glass of 9 inches aperture and 14 feet focal length (the dimensions of the telescope of Fraunhofer, at Dorpat) by a disc of flint glass 3 inches in diameter, the focus of either lens of the correcting lens will require to be about 9 inches. To correct it by a 4 inch disc will require a focus of about 16 inches each.

Mr. Rogers remarks, that it is not indispensable to make the correcting glass act as a plane lens. It is sufficient if it be so adjusted as to have a shorter focus for red rays than for violet. If preserving this condition, it be made to act as a concave lens, the advantage procured by Mr. Barlow's construction of reducing the length of the telescope with the same focal power is secured; and he considers, moreover, that by a proper adaptation of the distances, foci, &c., of the lenses, we might hope to combine with all these advantages that of the destruction of the secondary spectrum, and thus obtain a perfect telescope.

---

* A more detailed account of the processes connected with the construction of this telescope will be found in a paper presented to the Royal Society in 1827, and published in the Philosophical Transactions of that Society for 1828, and likewise another paper, published in the Transactions for 1829. From these documents, chiefly, the preceding account has been abridged. See also the "Edinburgh New Philosophical Journal" for January—April, 1828, and Brewster's "Edinburgh Journal of Science" for October, 1829.

The above is an abstract of a paper read to the "Astronomical Society of London" in April, 1828, by A. Rogers, Esq.

The reader will easily perceive that the principle on which Mr. Rogers proposes to construct his telescope is very nearly similar to that of Professor Barlow, described above, with this difference, that the correcting lens of the professor's telescope is composed of a transparent *fluid*, while that of Mr. Rogers is a *solid* lens consisting of a convex crown and concave flint. The general object intended to be accomplished by both is the same, namely, to make a correcting lens of a comparatively small diameter serve the purpose of a large disc of flint glass, which has hitherto been very expensive, and very difficult to be procured; and likewise to reduce the length of the telescope, while the advantage of a long focal power is secured. A telescope on this principle was constructed seven or eight years ago by Mr. Wilson, lecturer on Philosophy and Chemistry, Glasgow, before he was aware that Mr. Rogers had proposed a similar plan. I have had an opportunity of particularly inspecting Mr. Wilson's telescope, and trying its effects on terrestrial objects with high powers, and was, on the whole, highly pleased with its performance. It appeared to be almost perfectly achromatic, and produced a distinct and *well-defined* image of minute distant objects, such as small letters on sign posts, at two, three, and four miles distant; but I had no opportunity of trying its effects on double stars or any other celestial objects. The instrument is above 6 feet long; the object-lens is a plano-convex of crown glass, 4 feet focal distance and 4 inches diameter, the plain side next the object.

At 26 inches distant from the object-lens is the compound lens of 2 inches in diameter; and the two lenses of which it is composed are both ground to a radius of 3¾ inches. That made of crown glass is *plano-convex*, the other, made of flint glass, is plano-concave, and are placed close together, the convex side being next the object, and the concave side next the eye. The greater refractive power of the flint glass renders the compound one slightly concave in its effect (although the radius of curvature is similar in both), and lengthens the focus to 6 feet from the object-glass; and this is consequently the length of the instrument. The compound corrector so placed intercepts all those rays which go to form the image in the field of view, producing there an achromatic image. The concave power of the corrector renders the image larger than if directly produced by a convex lens of the same focus. The concavity of the corrector is valuable also in this respect, that a very slight alteration in its distance from the object-glass changes the focal distance much more than if it were plain, and enables us to adjust the instrument to perfect achromatism with great precision.

CHAPTER V.

ON REFLECTING TELESCOPES.

SECTION I.

History of the invention, and a general description of the construction of these instruments.

Reflecting telescopes are those which represent the images of distant objects by reflection, chiefly from concave mirrors.

Before the achromatic telescope was invented there were two glaring imperfections in refracting telescopes, which the astronomers of the seventeenth century were anxious to correct. The first was its very great length when a high power was to be applied, which rendered it very unwieldy and difficult to use. The second imperfection was the incorrectness of the image as formed by a single lens. Mathematicians had demonstrated that a pencil of rays could not be collected in a single point by a spherical lens, and also that the image transmitted by such a lens would be in some degree incurvated. After several attempts had been made to correct this imperfection by grinding lenses to the figure of one of the conic sections, Sir I. Newton happened to commence an examination of the colors formed by a prism; and having, by the means of this simple instrument, discovered the different refrangibility of the rays of light—to which we have several times adverted in the preceding descriptions—he then perceived that the errors of telescopes, arising from that cause alone, were some hundred times greater than such as were occasioned by the spherical figure of lenses, which induced this illustrious philosopher to turn his attention to the improvement of telescopes by reflection.

It is generally supposed that Mr. James Gregory,—a son of the Rev. John Gregory, minister of Drumoak, in the county of Aberdeen—was the first who suggested the construction of a reflecting telescope. He was a young man of uncommon genius, and an eminent mathematician; and in the year 1663, at the age of only 24, he published in London his treatise entitled "Optica Promota," in which he explained the theory of that species of reflecting telescope which still bears his name, and which he stated as being his own invention. But as Gregory, according to his own account, was endowed with no mechanical dexterity, and could find no workman capable of realizing his invention, after some fruitless attempts to form proper specula, he was obliged to give up the pursuit, so that this telescope remained for a considerable time neglected It was several years after Gregory suggested the construction of reflecting telescopes before Newton directed his attention fully to the subject. In a letter addressed to the secretary of the Royal Society, dated in February, 1672, he says, "Finding reflections to be regular, so that the angle of reflection of all sorts of rays was equal to the angle of incidence, I understood, that by their mediation, optic instruments might be brought to any degree of perfection imaginable, providing a reflecting substance could be found which would polish as finely as glass, and reflect as much light as glass transmits, and the art of communicating to it a parabolic figure be also obtained. Amid these thoughts I was forced from Cambridge by the intervening plague, and it was more than two years before I proceeded further."

Fig. 62.

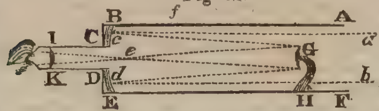


Fig. 63.

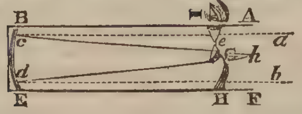

Fig. 64

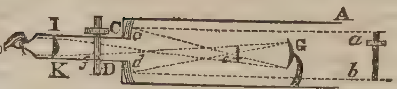

Fig. 65

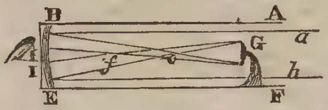

It was toward the end of 1668, or in the beginning of the following year, when Newton, being obliged to have recourse to reflectors, and not relying on any artificer for making the specula, set about the work himself, and early in the year 1672, completed two small reflecting telescopes. In these he ground the great speculum into a spherical concave, although he approved of the parabolic form, but found himself unable to accomplish it. These telescopes were of a construction somewhat different from what Gregory had suggested, and although only 6 inches long, were considered as equal to a six feet common refracting telescope. It is not a little singular, however, that we hear no more about the construction of reflectors until more than half a century afterward. It was not until the year 1723 that any reflectors were known to have been made, adapted to celestial observations. In that year Mr. Hadley, the inventor of the reflecting quadrant which goes by his name, published in No. 376 of the Philosophical Transactions, an account of a large reflector on Newton's plan, which he had just then constructed, the performance of which left no room to doubt that this invention would remain any longer in obscurity. The large speculum of this instrument was 62⅝ inches focal distance and 5 inches diameter, was furnished with magnifying powers of from 190 to 230 times, and equaled in performance the famous aërial telescope of Huygens of 123 feet in length.* Since this period the reflecting telescope has been in general use among astronomers in most countries of Europe, and has received numerous improvements, under the direction of Short, Mudge, Edwards, and Herschel, the last of whom constructed reflectors of 7, 10, 20, and even 40 feet in focal length, which far surpassed, in brightness and magnifying power, all the instruments of this description which had previously been attempted.

I shall now proceed to give a brief sketch of the nature of a reflecting telescope, and the different forms in which they have been proposed to be constructed.

Fig. 66.

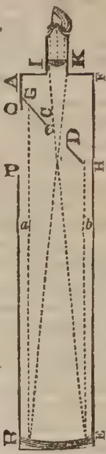

Fig. 62 represents the reflecting telescope as originally proposed by Gregory. *A B E F* represents a tube open at *A F* toward the object; at the other end is placed a concave speculum, *B E*, with a hole, *C D*, in its center, the focus of which is at *e*. A little beyond this focus, toward the object end of the telescope, *A F*, is placed another small concave mirror, *G*, having its polished face turned toward the great speculum, and is supported by an arm, *G H*, fastened to a slider connected with the tube. At the end of the great tube, *B E*, is screwed in a small tube, *C D K I*, containing a small plano-convex lens, *I K*. Such are the essential parts of this instrument and their relative positions. It will be recollected in our description of the properties of concave mirrors (see p. 24), that, when rays proceed from a distant object, and fall upon a concave speculum, they paint an image or representation of the object in its focus before the speculum. Now suppose two parallel rays, *a b*, falling on the speculum *B E*, in *c d*; they are reflected to its focus *e*, where an inverted image of the object is formed at a little more than the focal distance of the small speculum from its surface, and serves, as it were, for an object on which the small mirror may act. By the action of this mirror this first image is reflected to a point about *f*, where a second image is formed very large and erect. This image is magnified in the proportion of *f G* to *e G*, the rays from which are transmitted to the eyeglass *I K*, through which the eye perceives the object clear and distinct, after the proper adjustments have been made.

Suppose the focal distance of the great mirror was 9 inches, and the focal distance of the small mirror 1½ inch—were we to remove the eyepiece of this telescope, and look through the hole of the great mirror, we should see the image of the object depicted upon the face of the small speculum, and magnified in the proportion of 9 to 1½, or 6 times, on the same principle as a common convex object-glass 9 inches focal length, with an eyeglass whose focus is 1½ inch, magnifies 6 times. This may be regarded as the first part of the magnifying power. If, now, we suppose the small speculum placed a little more than 1½ inch from the image formed by the great speculum, a second image is formed about *f*, as much exceeding the first in its dimensions as it exceeds it in distance from the small speculum, on the principle on which the object-glass of a compound microscope forms a large image near the eyeglass. Suppose this distance to be 9 times greater, then the whole magnifying power will be compounded of 6 multiplied by 9, or 54 times. As a telescope it magnifies 6 times, and in the microscope part 9 times. Such is the *general* idea of the Gregorian telescope, the minute particulars and structure of which can only be clearly perceived by a direct inspection of the instrument.

The Newtonian Reflector.—This instrument is somewhat different both in its form and in its mode of operation from that of Gregory. It is represented in fig. 63, where *B A E F* is the tube, and *B E* the object concave mirror, which reflects the parallel rays *a b* to a *plane* speculum *G*, placed 45°, or half a right angle to the axis of the concave speculum. This small plane reflector must be of an oval form; the length of the oval should be to the breadth as 7 to 5, on account of the obliquity of its position. It is supported on an arm fixed to the side of the tube; an eyeglass is placed in a small tube, movable in the larger tube, so as to be perpendicular to the axis of the large reflector, the perpendicular line passing through the center of the small mirror. The small mirror is situated between the large mirror and its focus, that its distance from this focal point may be equal to the distance from the center of the mirror to the center of the eyeglass. When the rays *a b* from a distant object fall upon the large speculum at *c d*, they are reflected toward a focus at *h;* but, being intercepted by the plane mirror *G*, they are reflected perpendicularly to the eyeglass at *I*, in the side of the tube, and the image formed near that position at *e* is viewed through a small plano-convex lens. The magnifying power of this telescope is in the proportion of the focal distance of the speculum to that of the eyeglass. Thus, if the focal distance of the speculum be 36 inches, and that of the eyeglass one-third of an inch, the magnifying power will be 108 times. It was this form of the reflecting telescope that Newton invented, which Sir W. Herschel adopted, and with which he made most of his observations and discoveries.

---

* A particular description of this telescope, with the machinery for moving it, illustrated with an engraving, may be seen in Reid and Gray's "Abridgment of the Philosophical Transactions," vol. vi, Part 1 for 1723, p. 147—152.

The Cassegrainian Reflector.—This mode of the reflecting telescope, suggested by M. Cassegrain, a Frenchman, is represented in fig. 64. It is constructed in the same way as the Gregorian, with the exception of a small *convex* speculum, *G*, being substituted in the room of the small concave in Gregory's construction. As the focus of a convex mirror is negative, it is placed at a distance from the large speculum equal to the difference of their foci; that is, if the focal length of the large speculum be 18 inches, and that of the small convex 2 inches, they are placed at 16 inches distant from each other, on a principle similar to that of the Galilean telescope, in which the concave eyeglass is placed within the focus of the object-glass by a space equal to the focal length of the eyeglass. In this telescope, likewise, instead of two there is only *one image* formed, namely, that in the focus of the eyeglass; and, on this account, some are of opinion that the distinctness is considerably greater than in the Gregorian. Mr. Ramsden was of opinion that this construction is preferable to either of the former reflectors, because the aberrations of the two metals have a tendency to correct each other, whereas in the Gregorian, both the metals being concave, any error in the specula will be doubled. It is his opinion that the aberrations in the Cassegrainian construction to that of the Gregorian is as 3 to 5. The length of this telescope is shorter than that of a Gregorian of equal focal length by twice the focal length of the small mirror, and it shows everything in an *inverted* position, and, consequently, is not adapted for viewing terrestrial objects.

Dr. Hook's Reflector.—Before the reflecting telescope was much known, Dr. Hook contrived one, the form of which is represented fig. 65, which differs in little or nothing from the Gregorian, except that the eyeglass, *I*, is placed in the hole of the great speculum, *B E*.

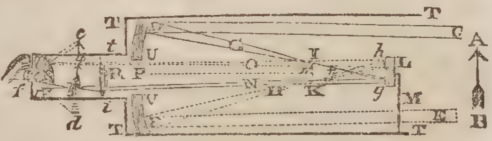
Martin's Reflector.—Mr. Benjamin Martin a distinguished writer on optical and philosophical science, about a century ago, described a new form of the reflecting telescope, approximating to the Newtonian structure, which he contrived for his own use. It is represented in fig. 66. *A B E F* is the tube, in which there is an opening or aperture, *O P*, in the upper part. Against this hole, within the tube, is placed a large plane speculum, *G H*, at half a right angle with the axis or sides of the tubes, with a hole, *C D*, perforated through its middle. The parallel rays *a b*, falling on the inclined plane *G H*, are reflected perpendicularly and parallel on the great speculum *B E* in the bottom of the tube. From thence they are reflected, converging to a focus, *e*, through the hole of the plane mirror *C D*, which, being also the focus of the eyeglass *I K*, the eye will perceive the object magnified and distinct.

In the figures referred to in the above descriptions, only one eyeglass is represented, to avoid complexity; but in most reflecting telescopes, the eyepiece consists of a combination of two plano-convex glasses, as in fig. 67, which produces a more correct and a larger field of view than a single lens. This combination is generally known by the name of the *Huygenian Eyepiece,* which shall be described in the section on the *eyepieces* of telescopes.

The following rule has been given for finding the magnifying power of the Gregorian telescope: Multiply the focal distance of the great mirror by the distance of the small mirror from the image next the eye, and multiply the focal distance of the small mirror by the focal distance of the eyeglass; then divide the product of the former multiplication by the product of the latter, and the quotient will express the magnifying power. The following are the dimensions of one of the reflecting telescopes constructed by Mr. Short, who was long distinguished as the most eminent maker of such instruments on a large scale, and whose large reflectors are still to be found in various observatories throughout Europe:

The focal distance of the great mirror, 9.6 inches; or *P m*, fig. 67, its breadth, *F D*, 2.3; the focal distance of the small mirror, *L n*, 1.5, or 1½ inch; its breadth, *g h*, 0.6 or 6-10ths of an inch; the breadth in the hole in the great mirror, *U V*, 0.5, or half an inch; the distance between the small mirror and the next eyeglass, *L R*, 14.2; the distance between the two eyeglasses, *S R*, 2.4; the focal distance of the eyeglass next the metal, 3.8; and the focal distance of the eyeglass next the eye, *S a*, 1.1, 11-10ths of an inch. The magnifying power of this telescope was about 60 times. Taking this telescope as a standard, the following table of the dimensions and magnifying powers of Gregorian reflecting telescopes, as constructed by Mr. Short, has been computed:

Fig. 67.



Mr. Short—who was born in Edinburgh in 1710, and died near London, 1768—was considered as the most accurate constructor of reflecting telescopes during the period which intervened from 1732 to 1768. In 1743 he constructed a reflector for Lord Thomas Spencer of 12 feet focal length, for which he received 600 guineas. He made several other telescopes of the same focal distance, with greater improvements and higher

Focal distance of the great mirror.		Breadth of the great mirror.		Focus of the small speculum.		Breadth of the hole in the great speculum.		Distance between the small speculum and the first eye-glass.		Focal distance of the glass next the metals.		Focal distance of the glass next the eye.		Distance between the plane sides of the two glasses.		Magnifying power.	Distance between the second glass and the small eye-hole.

magnifiers; and, in 1752, finished one for the King of Spain, for which, with its whole apparatus, he received £1200. This was considered the noblest instrument of its kind that had then been constructed, and perhaps it was never surpassed until Herschel constructed his twenty and forty feet reflectors. High as the prices of large telescopes now are, Mr. Short charged for his instruments at a much higher rate than opticians now do, although the price of labor, and every other article required in the construction of a telescope is now much dearer. But he had then scarcely any competitor, and he spared neither trouble nor expense to make his telescopes perfect, and put such a price upon them as properly repaid him. The following table contains a statement of the apertures, powers, and prices of Gregorian telescopes, as constructed by Mr. James Short:*

Number.	Focal length in inches.	Diameter of aperture in inches.	Magnifying powers.			Prices in guineas.
1	3	1.1	1 Power of	18	times,	3
2	4½	1.3	1 "	25	"	4
3	7	1.9	1 "	40	"	6
4	9½	2.5	2 Powers of	40 and 60	"	8
5	12	3.0	2 "	55 and 85	"	10
6	12	3.0	4 "	35, 55, 85, and 110	"	14
7	18	3.8	4 "	55, 95, 130, and 200	"	20
8	24	4.5	4 "	90, 150, 230, and 300	"	35
9	36	6.3	4 "	100, 200, 300, and 400	"	75
10	48	7.6	4 "	120, 260, 380, and 500	"	100
11	72	12.2	4 "	200, 400, 600, and 800	"	300
12	144	18.0	4 "	300, 600, 900, and 1200	"	800

From this table it appears that Mr. Short charged 75 guineas for a 3 feet reflector, whereas such an instrument is now marked in the London opticians' catalogues at £23 when mounted on a common brass stand, and £39 18s. when accompanied with rack-work motions and other apparatus. It is now generally understood that in the above table Short always greatly *overrated* the higher powers of his telescopes. By experiment, they were generally found to magnify *much less* than here expressed.

General Remarks on Gregorian Reflectors.—1. In regard to the hole, *U V*, of the great speculum, its diameter should be equal, or nearly so, to that of the small speculum, *L*, fig. 67; for if it be less, no more parallel rays will be reflected than if it were equal to *g h*, and it may do harm in contracting the visible area within too narrow limits; nor must it be larger than the mirror *L*, because some parallel rays will then be lost, and those of most consequence, as being nearest the center. 2. The small hole at *e*, to which the eye is applied, must be nicely adjusted to the size of the cone of rays proceeding from the nearest lens, *S*. If it be larger, it will permit the foreign light of the sky or other objects to enter the eye, so as to prevent distinct vision; for the eye should receive no light but what comes from the surface of the small mirror, *L*. If the hole be smaller than the cylinder of rays at *e*, then some of the necessary light will be excluded, and the object rendered more obscure. The diameter of this hole may be found by dividing the aperture of the telescope in inches by its magnifying power Thus, if we divide the diameter of one of Short's telescopes, the diameter of whose large speculum is 2.30, by 60, the magnifying power, the quotient will be .0383, which is nearly the 1-25th of an inch. Sometimes this hole is made so small as the 1-50th of an inch. When this hole is, by any derangement, shifted from its proper position, it sometimes requires great nicety to adjust it, and, before it is accurately adjusted, the telescope is unfit for accurate observation. 3. It is usual to fix a plate with a hole in it at *a b*, the focus of the eyeglass *S*, of such a diameter as will circumscribe the image, so as to exhibit only that part of it which appears distinct, and to exclude the superfluous rays. 4. There is an adjusting screw on the outside of the great tube, connected with the small speculum, by which that speculum may be pushed backward or forward to adjust the instrument to distinct vision. The hand is applied for this purpose at *T*.

Newtonian Telescopes.—These telescopes are now more frequently used for celestial observations than during the last century, when Gregorian reflectors were generally preferred. Sir W. Herschel was chiefly instrumental in introducing this form of the reflecting telescope to the more particular attention of astronomers, by the splendor and extent of the discoveries which it enabled him to make. In this telescope there is no hole required in the middle of the great speculum, as in the Gregorian construction, which circumstance secures the use of all the rays which flow from the central parts of the mirror.

---

* Miss Short, who has erected and who superintends an observatory on the Calton Hill, Edinburgh, is the descendant of a brother of Mr. Short. She is in possession of a large Gregorian reflector, about 12 feet long, made by Mr. Short, and mounted on an equatorial axis. It was originally placed in a small observatory erected on the Calton Hill about the year 1776, but for many years past it has been little used.

The following table contains a statement of the apertures and magnifying powers of Newtonian telescopes, and the focal distances of their eyeglasses. The first column contains the focal length of the great speculum in feet; the second, its linear aperture in inches; the third, the focal distance of the single glass in decimals, or in 1000ths of an inch, and the fourth column contains the magnifying power. This portion of the table was constructed by using the dimensions of Mr. Hadley's Newtonian telescope, formerly referred to, as a standard, the focal distance of the great mirror being 62½ inches, its medium aperture 5 inches, and power 208. The fifth, sixth, and seventh columns contain the apertures of the concave speculum, the focal lengths of the eyeglasses, and the magnifying powers, as calculated by Sir D. Brewster, from a telescope of Mr. Hauksbee, taken as a standard, whose focal length was 3 feet 3 inches, its aperture about 4 inches and magnifying power 226 times.

One great advantage of reflecting telescopes above common refractors is, that they will admit of eyeglasses of a much shorter focal distance, and, consequently, will magnify so much the more, for the rays are not colored by reflection from a concave mirror, if it be ground to a true figure, as they are by passing through a convex glass, though figured and polished with the utmost exactness. It will be perceived from the above table that the focal length of the eyeglasses is very small, the lowest there stated being only about 1-10th of an inch, and the highest little more than ¼th of an inch focal distance. Sir W. Herschel obtained the high powers which he sometimes put upon his telescopes by using small double convex lenses for eyeglasses, some of which did not exceed the *one fiftieth of an inch* in focal length. When the focal length of the concave speculum and that of the eyeglass are given, the magnifying power is found by dividing the former by the latter, after having reduced the focal length of the concave speculum to inches. Thus the 6 feet speculum, multiplied by 12, produces 72 inches, which, divided by Brewster's number for the focus of the eyeglass = 200, or 1-5th of an inch, produces a quotient of 360 as the magnifying power. It has been calculated that, if the metals of a Newtonian telescope be worked as exquisitely as those in Sir W. Herschel's 7 feet reflector, the highest power that such a telescope should bear with perfect distinctness will be found by multiplying the diameter of the great speculum in inches by 74, and the focal distance of the single eyeglass may be found by dividing the focal distance of the great mirror by the magnifying power. Thus 6.25—the aperture in inches of Herschel's 7 feet Newtonian—multiplied by 74, is 462½, the magnifying power; and 7 multiplied by 12, and divided by 462, is 50.182 of an inch, the focal distance of the single eyeglass required. But it is seldom that more than one-half of this power can be applied with effect to any of the planetary bodies. For general purposes, the power produced by multiplying the diameter of the speculum by 30 or 40 will be found most satisfactory.

The following are the general prices of reflecting telescopes as made by the London opticians:

	£	s.
A four feet, seven inch aperture Gregorian reflector, with the vertical motions upon a new invented principle, as well as apparatus to render the tube more steady in observation, according to the additional apparatus of small speculums, eyepieces, micrometers, &c. *from* 80 to	120	0
Three feet long, mounted on a plain brass stand	23	2
Ditto, with rack-work motions, improved mounting, and metals	39	18
Two feet long, without rack-work, and with 4 magnifying powers, improved .	15	15
Ditto, with rack-work motion . . .	22	1
Eighteen inch, on a plain stand .	9	9
Twelve inch, ditto . . .	6	6

The above are the prices stated in Messrs. W. and S. Jones's catalogue.

The following list of prices of the various kinds of reflecting telescopes is from Messrs. Tulley's (of Islington) catalogue:

	£.	s.
1 foot *Gregorian* reflector, on pillar and claw stand, metal 2½ inches diameter, packed in a mahogany box	6	6
1½ foot ditto, on pillar and claw stand, metal 3 inches diameter, packed in a mahogany box	11	11
2 feet ditto, metal 4 inches diameter	16	16
Ditto, ditto, with rack-work motions	25	4
3 feet ditto, metal 5 inches diameter, with rack work motions	42	0
Ditto, metal 6 inches diameter, on a tripod stand, with center of gravity motion	68	5
4 feet ditto, metal 7 inches diameter, as above	105	0
6 feet ditto, metal 9 inches diameter, on an improved iron stand	210	0
7 feet *Newtonian* reflectors, 6 inches aperture, mounted on a new and improved stand	105	0
Ditto, ditto, metal 7 inches diameter	126	0
9 feet ditto, metal 9 inches diameter	210	0
10 feet ditto, metal 10 inches diameter	315	0
12 feet ditto, metal 12 inches diameter	525	0

Comparative Brightness of Achromatic and Reflecting Telescopes.—The late astronomer royal, Dr. Maskelyne, from a comparison of a variety of telescopes, was led to the following conclusion: "that the aperture of a common reflecting telescope, in order to show objects as bright as the achromatic, must be to that of an achromatic telescope as 8 to 5;" in other words, an achromatic whose object-glass is 5 inches in diameter, will show objects with as great a degree of brightness as a reflector whose large speculum is 8 inches in diameter. This result, if correct, must be owing to the small number of rays reflected from a speculum compared with the number transmitted through an achromatic object-glass.

SECTION II.

THE HERSCHELIAN TELESCOPE.

SOON after Sir William Herschel commenced his astronomical career, he introduced a new era in the history of reflecting telescopes. After he had cast and polished an immense variety of specula for telescopes of different sizes, he at length, in the year 1782, finished a 20 feet reflector with a large aperture. Being sensible of the vast quantity of light which is lost by a second reflection from the small speculum, he determined to throw it aside altogether, and mounted this 20 feet reflector on a stand that admitted of being used without a small speculum in making *front observations;* that is, in sitting with his back to the object, and looking directly toward the surface of the speculum. Many of his discoveries and measurements of double stars were made with this instrument, until at length, in the year 1785, he put the finishing hand to that gigantic speculum, which soon became the object of universal astonishment, and which was intended for his *forty-feet* reflecting telescope. He had succeeded so well in constructing reflecting telescopes of comparatively small aperture, that they would bear higher magnifying powers than had ever previously been applied; but he found that a deficiency of light could only be remedied by an increased diameter of the large speculum, which therefore was his main object when he undertook to accomplish a work which to a man less enterprising would have appeared impracticable. The difficulties he had to overcome were numerous, particularly in the operative department of preparing, melting, annealing, grinding, and polishing a mass of metal that was too unwieldy to be moved without the aid of mechanical powers. At length, however, all difficulties having been overcome, this magnificent instrument was completed, with all its complicated apparatus, and erected for observation, on the 28th of August, 1789, and on the same day the sixth satellite of Saturn was detected, as a prelude to still further discoveries which were afterward made by this instrument in the celestial regions.

It would be too tedious to attempt a description of all the machinery and apparatus connected with this noble instrument. The reader who wishes to peruse a minute description of the stairs, ladders, platform, rollers, and of every circumstance relating to joiner's work, carpenter's work, smith's work, and other particulars connected with the formation and erection of this telescope, will find the details recorded in the 85th volume of the Philosophical Transactions of the Royal Society of London for 1795, in which there are sixty-three pages of letter-press, and eighteen plates illustrative of the subject. I shall content myself with giving a short outline of the essential parts belonging to this instrument.

The *tube* of this telescope is made of rolled or sheet iron, joined together without rivets; the thickness of the sheets is somewhat less than $\frac{1}{36}$th part of an inch, or 14 pounds weight for a square foot. Great care was taken that the cylindrical form should be secured, and the whole was coated over three or four times with paint, inside and outside, to secure it against the damp. This tube was removed from the place in which it was formed by 24 men, divided into six sets, so that two men on each side, with a pole 5 feet long in their hands, to which was affixed a piece of coarse cloth 7 feet long, going under the tube, and joined to a pole 5 feet long in the hands of two other men, assisted in carrying the tube. The *length* of this tube is 39 feet 4 inches, the diameter 4 feet 10 inches; and, on a moderate computation, it was ascertained that a wooden tube of proper dimensions would have exceeded an iron one in weight by at least 3000 pounds. Reckoning the circumference of the tube 15 feet, its length 39⅓ feet, and 14 lbs. for the weight of a square foot, it must have contained 590 square feet, and weighed 8260 pounds. Various hoops were fixed within the tube, and longitudinal bars of iron connecting some of them are attached to the two ends of the tube, by way of bracing the sheets, and preserving the shape perfect, when the pulleys are applied to give the necessary elevation at the upper end, and that the speculum may be kept secure at the lower end. The lower end of the tube is firmly supported on rollers, that are capable of being moved forward or backward by a double rack, connected with a set of wheels and pinions. By an adjustment at the lower extremity of the tube, the speculum is turned to a small inclination, so that the line of collimation may not be coincident with the longitudinal axis of the tube, but may cross the tube diagonally, and meet the eye in the air at about two inches from the edge of the tube, which is the peculiarity of the construction that supersedes the necessity of applying a second reflector. Hence no part of the head of the observer intercepts the incident rays, and the observation is taken with the face looking at the speculum, the back being turned to the object to be observed.

The large speculum is inclosed in a strong iron ring, braced across with bars of iron, and an inclosure of iron, and ten sheets make a case for it. It is lifted by three handles of iron attached to the sides of the ring, and is put into, and taken out of, its proper place in the tube by the help of a movable crane, running on a carriage, which operation requires great care. The speculum is made of a metallic composition, and is 49½ inches in diameter; but the concave polished surface is only 48 inches, or 4 feet in diameter. Its thickness is 3½ inches; and when it came from the cast its weight was 2118 pounds. The metals for its formation were procured at a warehouse in Thames street, London, where they kept ingots of two kinds ready made, one of white and the other of bell-metal; and it was composed of two ingots of bell-metal for one of white. It was not to be expected that a speculum of such large dimensions could have a perfect figure imparted to its surface, nor that the curve, whatever it be, would remain identically the same in changes of temperature; therefore we are not surprised when we are told that the magnifying powers used with this telescope seldom exceeded 200, the quantity of light collected by so large a surface being the principal aim of the maker. The raising of the balcony, on which the observer stands, and the sliding of the lower end of the tube, in which the speculum rests, are effected by separate tackles, and require only occasional motions; but the elevation of the telescope requires the main tackle to be employed, and the motion usually given in altitude at once was two degrees; the breadth of the zone in which the observations were made, as the motion of the sphere in right ascension brought the objects into view. A star, however, could be followed for about a quarter of an hour. Three persons were employed in using this telescope, one to work the tackle, another to observe, and a third to mark down the observations. The elevation was pointed out by a small quadrant fixed to the main tube, near the lower end, but the polar distance was indicated by a piece of machinery, worked by a string, which continually indicated the degree and minute on a dial in the small house adjoining, while the time was shown by a clock in the same place, Miss Herschel performing the office of registrar.

At the upper end the tube is open, and directed to the part of the heavens intended for observation, and the observer, standing on the foot-board, looks down the tube, and perceives the object by rays reflected from the speculum through the eyeglass at the opening of the tube. When the telescope is directed to any objects near the zenith, the observer is necessarily at an elevation of at least 40 feet from the ground. Near the place of the eyeglass is the end of a tin pipe, into which a mouthpiece may be placed, so that, during an observation, a person may direct his voice into this pipe, while his eye is at the glass. This pipe, which is 1⅙ inch in diameter, runs down to the bottom of the tube, where it goes into a turning joint, thence into a drawing tube, and out of this into another turning joint, from whence it proceeds, by a set of sliding tubes, toward the front of the foundation timber. Its use is to convey the voice of the observer to his assistants, for at the last place it divides itself into two branches, one going into the observatory, the other into the workman's room, ascending in both places through the floor, and terminates in the usual shape of speaking trumpets. Though the voice passes in this manner through a tube, with many inflections, and through not less than 115 feet, it requires very little exertion to be well understood.

To direct so unwieldy a body to any part of the heavens at pleasure, many mechanical contrivances were evidently necessary. The whole apparatus rests upon rollers, and care was previously taken of the foundation in the ground. This consists of concentrical brick walls, the outermost 42 feet, the innermost 21 feet in diameter, 2 feet 6 inches deep under ground, 2 feet 3 inches broad at the bottom, and 1 foot 2 inches at the top, capped with paving stones 3 inches thick, and 12¾ inches broad.

In the center is a large post of oak, framed together with braces under ground, and walled fast to brickwork to make it steady. Round this center the whole frame is moved horizontally by means of 20 rollers, 12 upon the outer and 8 upon the inner wall. The vertical motion is given to the instrument by means of ropes and pulleys, passing over the main beam supported by the ladders. These ladders are 49 feet long, and there is a movable gallery with 24 rollers to ease its motion. There is a staircase intended for persons who wish to ascend into the gallery without being obliged to go up the ladder. The ease with which the horizontal and vertical motions may be communicated to the tube may be conceived from a remark of Sir W. Herschel, that in the year 1789 he several times observed Saturn, two or three hours before and after its meridian passage, with one single person to continue, at his directions, the necessary horizontal and vertical motions.

By this telescope the sixth and seventh satellites of Saturn were discovered, only one of which is within the reach of the 20 feet reflector, or even of a 25 feet instrument. The discovery of the satellites of the planet Uranus, however, was made by the 20 feet reflector, but only after it had been converted from the Newtonian to the Herschelian construction, which affords a proof of the superiority of the latter construction over the former when the same speculum is used. Never had the heavens before been observed with so extraordinary an instrument as the forty-feet reflector. The nebulosities which are found among the fixed stars in various regions of the heavens appeared almost all to resolve themselves into an innumerable multitude of stars; others, hitherto imperceptible, seemed to have acquired a distinct light. On the entrance of Sirius into the field of the telescope, the eye was so violently affected that stars of less magnitude could not immediately after be perceived, and it was necessary to wait for 20 minutes before these stars could be observed. The ring of Saturn had always before ceased to be visible when its plane was directed toward the earth; but the feeble light which it reflects in that position was enough for Herschel's instrument, and the ring, even then, still remained visible to him.

It has been generally considered that this telescope was capable of carrying a power of 6000 times; and, perhaps, for the purpose of an experiment, and for trying its effect on certain objects, such a power may have been applied, in which case the eyeglass must have been only 2-25ths of an inch focal distance, or somewhat less than 1-12th of an inch. But such a power could not be generally applied with any good effect to the planetary bodies, and I question much whether any power above 1000 times was ever generally used; for it is the quantity of light which the telescope collects, more than the magnifying power, that enables us to penetrate, with effect, into the distant spaces of the firmament; and hence, as above stated, the power seldom exceeded 200, which, on account of the large diameter of the speculum, would enable the instrument to penetrate into the distant celestial spaces perhaps farther than if a power of as many thousands of times had been applied.

Sir John Herschel, who inherits all the science, skill, and industry of his father, some time ago ground and polished a new speculum for the 20 feet tube, formerly noticed, which is connected with a stand, pulleys, and other appendages similar to those above described, though of smaller dimensions. This telescope shows the double stars exceedingly well-defined, and was one of the principal instruments used in forming his catalogue of these objects which was presented to the Royal Society, in conjunction with that of Sir James South, about the year 1828. I suppose it is likewise the same telescope with which Sir John lately made his sidereal observations at the Cape of Good Hope.

SECTION III.

Ramage's large reflecting telescope.

The largest *front view* reflecting telescope in this country, next to Herschel's 40 feet instrument, is that which was erected at the Royal Observatory at Greenwich in the year 1820, by Mr. Ramage of Aberdeen. The diameter of the concave reflector is 15 inches, and its focal length 25 feet. It is erected on machinery which bears a certain resemblance to that of Herschel's, which we have now described, but the mechanical arrangements are greatly simplified, so that the instrument is manageable by an observer without an assistant. The tube is composed of a twelve-sided prism of deal ⅝ths of an inch thick. At the mouth is a double cylinder of different diameters on the same axis; around this a cord is wound by a winch, and passes up from the small cylinder, over a pulley, and down through another pulley on to the large cylinder. When the winch, therefore, is turned to raise the telescope, the endless cord is unwound from the smaller cylinder and wound on to the larger, the difference of the size of the two cylinders will be double the quantity raised, and a mechanical force to any extent may thus be obtained, by duly proportioning the diameters of the two cylinders: by this contrivance the necessity of an assistant is superseded. The view through this instrument first astonished those observers who had not been accustomed to examine a heavenly body with a telescope possessing so much light, and its performance was deemed quite extraordinary. But when the first impression had subsided, and different trials had been made in different states of the atmosphere, it was discovered that the central portion of the speculum was more perfectly figured than the ring bordering on the extreme edges. When the aperture was limited to ten or twelve inches, the performance as to the distinctness in its defining power was greatly improved, and the light was so brilliant that the astronomer royal was disposed to entertain an opinion that it might equal that of a good achromatic refractor of the same dimensions. When, however, very small and obscure objects are to be observed, the whole light of the entire aperture may be used with advantage on favorable evenings.

The eyepieces adapted to this telescope have powers which magnify the object linearly from 100 to 1500 times, which are competent to fulfill all the purposes of vision when cleared of aberration. When the telescope is placed in the plane of the meridian, and elevated, together with the gallery, into any required altitude, the *meridional sweeps*, formerly practiced by Sir W. Herschel, and continued by Sir John with great success, in the examination of double stars and nebula, may be managed with great ease.

Mr. Ramage had a telescope of about the same size erected in an open space in Aberdeen, which I had an opportunity of inspecting when I paid a visit to that gentleman in 1833, but cloudy weather prevented my obtaining a view of any celestial bodies through it. He showed me at that time two or three large speculums, from 12 to 18 inches in diameter, which he had finished some time before, and which appeared most beautifully polished. He told me, too, that he had ground and polished them simply with his hand, without the aid of any machinery or mechanical power; a circumstance which, he said, astonished the opticians of London when it was stated, and which they considered as almost incredible. His experience in casting and polishing metals of various sizes during a period of 15 or 16 years qualified him to prepare specula of great luster, and with an unusually high polish. It has been asserted that a fifty feet telescope by Ramage of 21 inches aperture, was intended to be substituted for the 25 feet instrument erected at Greenwich, and the speculum, it is understood, was prepared, and ready for use, provided the Navy Board was disposed to defray the expense of carrying the plan into execution; but, unfortunately, this ingenious artist was unexpectedly cut off in the midst of his career; about the year 1835.

SECTION IV.

The aerial reflector constructed by the author.

A particular description of this telescope was given in the "Edinburgh New Philosophical Journal" for April—July, 1826, conducted by Professor Jameson, the greater part of which was copied in the "London Encyclopædia," under the article *Telescope*. From this description I shall endeavor to condense a brief account of this instrument, with a few additional remarks.

About the year 1822, an old speculum 27 inches in focal length, very imperfectly polished, happened accidentally to come into my possession, and feeling no inclination to fit it up in the Gregorian form, I adopted the resolution of throwing aside the small speculum, and attempting the *front view*, notwithstanding the uniform assertion of opticians that such an attempt in instruments of a small size is impracticable. I had some ground for expecting success in this attempt from several experiments I had previously made, particularly from some modifications made in the construction of astronomical eyepieces, which have a tendency to correct the aberration of the rays of light when they proceed somewhat obliquely from a lens or speculum. In the first instance, I placed the speculum at one end of a tube of the form of the segment of a cone, the end next the eye being somewhat wider than that at which the speculum was fixed, and its length about an inch shorter than the focal distance of the mirror. A small tube for receiving the different eyepieces was fixed in the inside of the large tube at the end next the eye, and connected with an apparatus by which it could occasionally be moved either in a vertical or horizontal direction. With the instrument fitted up in this manner, I obtained some interesting views of the moon and of terrestrial objects; but, finding that one side of the tube intercepted a considerable portion of light from the object, I determined to throw aside the tube altogether, and to fit up the instrument on a different plan.

A short mahogany tube, about three inches long, was prepared, to serve as a socket for holding the speculum. To the side of this tube an arm was attached, about the length of the focal distance of the mirror, at the extremity of which a brass tube for receiving the eyepieces was fixed, connected with screws and sockets, by which it might be raised or depressed, and turned to the right hand or to the left, and with adjusting apparatus, by which it might be brought nearer to or farther from the speculum. Fig. 69 exhibits a general representation of the instrument in profile. *A B* is the short tube which holds the speculum; *C D* the arm which carries the eyetubes, which consists of two distinct pieces of mahogany; the part *D* being capable of sliding along the under side of *C*, through the brass sockets *E F*. To the under part of the socket, *F*, is attached a brass nut with a female screw, in which the male screw, *a b*, acts by applying the hand to the knob *c*, which serves for adjusting the instrument to distinct vision. *G* is the brass tube which receives the eyepieces. It is supported by a strong brass wire, *d e*, which passes through a nut connected with another strong wire, which passes through the arm *D*. By means of the nut *f*, this tube may be elevated or depressed, and firmly fixed in its proper position; and by the nut *d* it may be brought nearer to, or farther from, the arm *D*.

By the same apparatus it is also rendered capable of being moved either in a vertical or horizontal direction; but when it is once adjusted to its proper position, it must be firmly fixed, and requires no further attention. The eyepiece represented in this figure is the one used for terrestrial objects, which consists of the tubes belonging to a pocket achromatic telescope. When an astronomical eyepiece is used, the length of the instrument extends only to the point *I*. In looking through this telescope the right eye is applied to the point *H*, and the observer's head is understood to be uncovered, or, at least tightly covered with a thin cap. For those who use only the left eye, the arm would require to be placed on the opposite side of the tube, or the arm, along with the tube, be made to turn round 180 degrees.

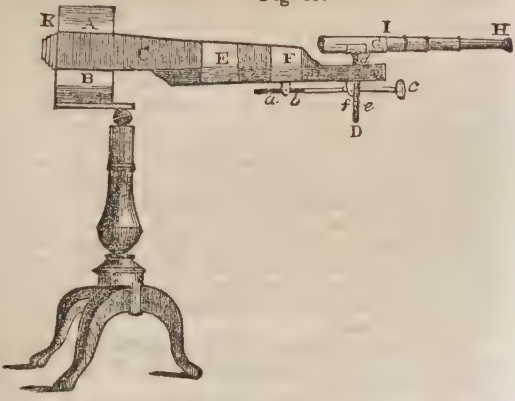
Fig. 70 represents a front, or rather an oblique view of the instrument, in which the position of the speculum may be seen. All the specula which I fitted up in this form having been originally intended for Gregorian reflectors, have holes in their centers. The eyepiece is therefore directed to a point nearly equidistant from the hole to the left hand edge of the speculum, that is to the point *a*. In one of these instruments fitted up with a four feet speculum, the line of vision is directed to the point *b* on the opposite side of the speculum, but in this case the eyetube is removed farther from the arm than in the former case. The hole in the center of the speculum is obviously a defect in this construction of a reflecting telescope, as it prevents us from obtaining the full advantage of the rays which fall near the center of the mirror; yet the performance of the instruments, even with this disadvantage, is superior to what we should previously have been led to expect.

The principal nicety in the construction of the instrument consists in the adjustment and proper direction of the eyetube. There is only one position in which vision will be perfectly distinct. It must be neither too high nor too low; it must be fixed at a certain distance from the arm, and must be directed to a certain point of the speculum. This position must be ultimately determined by experiment when viewing terrestrial objects. A person unacquainted with this construction of the telescope would perhaps find it difficult, in the first instance, to make this adjustment; but were it at any time deranged, through accident or otherwise, I can easily make the adjustment anew in the course of a minute or two.

In pointing this telescope to the object intended to be viewed, the eye is applied at *K*, fig. 69, and looking along the arm, toward the eyepiece, until it nearly coincides with the object, it will, in most cases be readily found. In this way I can easily point this instrument to Jupiter or Saturn, or to any of the other planets visible to the naked eye, even when a power of 160 or 170 times is applied. When high magnifying powers, however, are used, it may be expedient to fix, on the upper part of the short tube on which the speculum rests, a finder, such as that which is used in Newtonian telescopes. When the moon is the object intended to be viewed, she may be instantly found by moving the instrument until her reflected image be seen from the eye-end of the telescope on the face of the mirror.

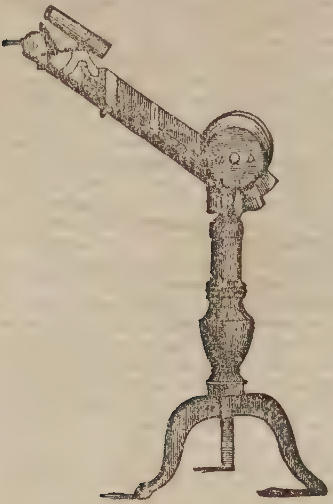
I have fitted up several instruments of the above description with specula of 16, 27, 35, and 49 inches focal distance. One of these, having a speculum of 27 inches focal length, and an astronomical eyepiece, producing a magnifying power of about 90 times, serves as a good astronomical telescope. By this instrument the belts and satellites of Jupiter, the ring of Saturn, and the mountains and cavities of the moon, may be contemplated with great ease and distinctness. With a magnifying power of 35 or 40 times, terrestrial objects appear remarkably bright and well-defined. When compared with a Gregorian, the quantity of light

Fig. 69.



upon the object appears nearly doubled, and the image is equally distinct, although the speculum has several blemishes, and its surface is but imperfectly polished. It represents objects in their natural colors, without that dingy and yellowish tinge which appears when looking through a Gregorian. Another of these instruments is about four feet long. The speculum which belongs to it is a very old one: when it came into my possession, it was so completely tarnished as scarcely to reflect a ray of light. After it was cleaned, it appeared to be scarcely half polished, and its surface is covered with yellowish stains which cannot be erased. Were it fitted up upon the Gregorian plan, it would, I presume, be of very little use, unless when a very small magnifying power was applied; yet in its present form it bears with distinctness a magnifying power of 130 times, and is equal in its performance to a 3½ feet achromatic. It exhibits distinct and interesting views of the diversities of shade, and of the mountains, vales, cavities and other inequalities of the moon's surface. With a power of about 50 times, and a terrestrial eyepiece, it forms an excellent telescope for land objects, and exhibits them in a brilliant and novel aspect. The smallest instrument I have attempted to construct on this plan is only 5½ inches focal distance, and 1¾ths of an inch in diameter. With a magnifying power of about 15 times, it shows terrestrial objects with distinctness and brilliancy. But I should deem it inexpedient to fit up any instrument of this description with specula of a shorter focal distance than 20 or 24 inches. The longer the focal distance, the more distinctness may be expected, although the aperture of the speculum should be comparatively small.

Fig. 70.



The following are some of the properties and advantages peculiar to this construction of the reflecting telescope:

1. It is *extremely simple*, and may be fitted up at a comparatively *small expense*. Instead of large and expensive brass tubes, such as are used in the Gregorian and Newtonian construction, little more is required than a short mahogany tube, two or three inches long, to serve as a socket for the speculum, with an arm connected with it about the focal length of the speculum. The expense of small specula, either plain or concave, is saved, together with the numerous screws, springs, &c., for centering the two specula, and placing the small mirror parallel to the large one. The only adjustment requisite in this construction is that of the eyetube to the speculum; and, by means of the simple apparatus above described, it can be effected in the course of a few minutes. Almost the whole expense of the instrument consists in the price of the speculum and the eyepieces. The expense of fitting up the four feet speculum alluded to above, *exclusive of speculum and eyepiece*, but including mahogany tube and arm, brass sockets, screws, eyetube, brass joint, and a cast-iron stand, painted and varnished, did not amount to £1 8s. A Gregorian of the same size would have required a brass tube at least 4½ feet in length, which would cost five or six guineas, beside the apparatus connected with the small speculum, and the additional expense connected with the fitting up of the joint and stand requisite for supporting and steadying so unwieldy an instrument. While the one instrument would require two persons to carry it from one room to another, and would occupy a considerable space in an ordinary apartment, the other can be moved with the utmost ease, with one hand, to any moderate distance, and the space it occupies is extremely small.

2. *It is more convenient for viewing celestial objects at a high altitude than other telescopes.* When we look through a Gregorian reflector or an achromatic telescope of four or five feet in length, to an object elevated 50 or 60 degrees above the horizon, the body requires to be placed in an uneasy and distorted position, and the eye is somewhat strained while the observation is continued; but when viewing similar objects by the *Aerial Reflector*, we can either stand perfectly erect, or sit on a chair, with the same ease as we sit at a desk when reading a book or writing a letter. In this way, the surface of the moon or any other of the planets may be contemplated for an hour or two without the least weariness or fatigue. A delineation of the lunar surface may be taken with this instrument with more ease and accuracy than with any other instrument, as the observer can sketch the outline of the object by one eye on a tablet placed a little below the eyepiece, while the other eye is looking at the object. For the purpose of accommodating the instrument to a sitting or standing posture, a small table was constructed, capable of being elevated or depressed at pleasure, on which the stand of the telescope is placed. When the telescope is four or five feet long, and the object at a very high elevation, the instrument may be placed on the floor of the apartment, and the observer will stand in an erect position.

3. This instrument is considerably *shorter* than a Gregorian telescope whose mirror is of the same focal length. When an astronomical eyepiece is used, the whole length of the instrument is nothing more than the focal length of the speculum; but a Gregorian, whose large speculum is four feet focus, will be nearly five feet in length, including the eyepiece.

4. The Aerial Reflector far excels the Gregorian in brightness. The deficiency of light in the Gregorians is owing to the second reflection from the small mirror; for it has been proved by experiment that nearly the one-half of the rays of light which fall upon a reflecting surface is lost by a second reflection. The image of the object may also be presumed to be more correct, as it is not liable to any distortion by being reflected from another speculum.

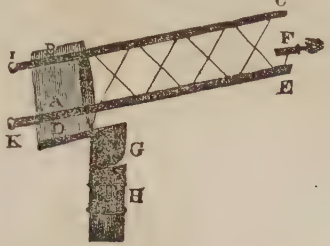
5. There is *less tremor* in these telescopes than

n. Gregorian reflectors. One cause, among others, of the tremors complained of in Gregorians is, I presume, the formation of a second image at a great distance from the first, beside that which arises from the elastic tremor of the small speculum, when carried by an arm supported only at one end; but as the image formed by the speculum, in the aerial telescope is viewed *directly*, without being exposed to any subsequent reflection, it is not so liable to the tremors which are so frequently experienced in other reflectors. Notwithstanding the length of the arm of the four feet telescope above mentioned, a celestial object appears remarkably steady when passing across the field of view, especially when it is at a moderate degree of altitude; and it is easily kept in the field by a gentle motion applied to the arm of the instrument.

In prosecuting my experiments in relation to these instruments, I wished to ascertain what effect might be produced by using a *part of a speculum* instead of the whole. For this purpose, I cut a speculum, three feet in focal length, through the center, so as to divide it into two equal parts, and fitted up each part as a distinct telescope, so that I obtained two telescopes from one speculum. In this case, I found that each half of the speculum performed nearly as well as the whole speculum had done before; at least, there appeared to be *no very sensible* diminution in the *brightness* of the object, when viewed with a moderate power, and the image was equally accurate and distinct; so that if *economy* were a particular object aimed at in the construction of these instruments, two good telescopes might be obtained from one speculum; or if a speculum happened to be broken accidentally into large fragments, one or more of the fragments may be fitted up on this principle to serve as a tolerably good telescope.

From the experiments I have made in reference to these instruments, it is demonstrable that *a tube is not necessary* in the construction of a reflecting telescope—at least, on the principle now stated—whether it be used by day or by night, for terrestrial or celestial objects; for I have frequently used these telescopes in the open air in the day-time, without any inconvenience from extraneous light. Therefore, were a reflecting telescope of 50 or 60 feet in length to be constructed, it might be fitted up at a comparatively small expense, after the expense of the metallic substances, and of casting, grinding, and polishing the speculum is defrayed. The largest instrument of this description which has hitherto been constructed is the 40 feet reflector of Sir W. Herschel. This complicated and most unwieldy instrument had a tube of rolled or sheet iron 39 feet 4 inches in length, about 15 feet in circumference, and weighed about 8000 pounds. Now I conceive that such enormous tubes, in instruments of such dimensions, are altogether unnecessary. Nothing more is requisite than a short tube for holding the speculum. Connected with one side of this tube (or with both sides were it found necessary), two strong bars of wood, projecting a few feet beyond the speculum end, and extending in front as far as the focal length of the mirror, and connected by cross-bars of wood, iron, or brass, would be quite sufficient for a support to the eyepiece, and for directing the motion of the instrument. A telescope of 40 or 50 feet in length, constructed on this plan, would not require one-fifth of the expense, nor one-fourth of the apparatus and mechanical power for moving it to any required position, which were found necessary in the construction of Sir W. Herschel's large reflecting telescope. The idea here suggested will perhaps be more readily appreciated by an inspection of fig. 71, where *A* is the short tube, *B C* and *D E* the two large bars or arms, connected with crossbars, for the purpose of securing strength and steadiness. At *I* and *K*, behind the speculum, weights might be applied, if necessary, for counterbalancing the lever power of the long arm. *F* represents the position of the eyepiece, and *G H* the joint and part of the pedestal on which the instrument is placed. With regard to telescopes of smaller dimensions, as from 5 to 15 feet in focal length—with the exception of the expense of the specula and eyepieces—they might be fitted up for a sum not greater than from 3 to 10 or 15 guineas.

Fig. 71.



Were any person to attempt the construction of those telescopes, it is possible he might not succeed in his first attempts without more minute directions than I have yet given. The following directions may perhaps tend to guide the experimenter in adjusting the eye-tube to the speculum, which is a point that requires to be particularly attended to, and on which depends the accurate performance of the instrument. After having fixed the eyepiece nearly in the position it should occupy, and directed the instrument to a particular object, look along the arm of the telescope, from *K* (fig. 69), to the extremity of the eyepiece at *H*, and observe whether it nearly coincides with the object. If the object appear lower than this line of vision, the eyepiece must be lowered, and if higher, it must be raised, by means of the nuts and screws at *g d* and *f e*, until the object and the line of vision now stated nearly coincide. The eyepiece should be directed as nearly perpendicular to the front of the speculum as possible, but so that the reflected image of one's head from the mirror shall not interfere to obstruct the rays from the object. An object may be seen with an approximate degree of distinctness, but not accurately, unless this adjustment be pretty accurately made. The astronomical eyepieces used for these telescopes are fitted with a brass cap, which slides on the end next the eye, and is capable of being brought nearer to or farther from the first eyeglass. In the center of this cap, next the eye, is a small hole, about the 1–40th or 1–50th of an inch diameter, or about as wide as to admit the point of a pin or a moderate-sized needle. The distance of this hole from the lens next the eye must be adjusted by trial, until the whole field of view appears distinct. A common astronomical eyepiece, without this addition, does not answer well. I find, by experience, that terrestrial eyepieces, such as those used in good achromatic telescopes, are, on the whole, best adapted to this construction of a reflecting telescope.

I have sometimes used these instruments for the purpose of viewing perspective prints, which they exhibit in a beautiful and interesting manner. If a colored perspective be placed at one end of a large room or gallery, and strongly illuminated either by the sun or by two candles, and one of the reflectors, furnished with a small *magnifying power*, placed at the opposite end of the room, the representation of a street or a landscape will be seen in its true perspective, and will appear even more pleasant and interesting than when viewed through the common *optical diagonal machine.* If an inverting eyepiece be used—which is most eligible in this experiment—the print, of course, must be placed in an inverted position.

That reflecting telescopes of the descriptions now stated are original in their construction, appears from the uniform language of optical writers, some of whom have pronounced such attempts to be altogether impracticable. Sir David Brewster, one of the latest and most respectable writers on this subject, in the "Edinburgh Encyclopedia," art. *Optics*, and in the last edition of his *Appendix* to "Ferguson's Lectures," has the following remarks: "If we could dispense with the use of the small specula in telescopes of moderate length, by inclining the great speculum, and using an oblique, and, consequently, a *distorted* reflection, as proposed first by Le Maire, we should consider the Newtonian telescope as perfect; and on a large scale, or when the instrument exceeds 20 feet, it has undoubtedly this character, as nothing can be more simple than to magnify, by a single eyeglass, the image formed by a single speculum. As the *front view is quite impracticable*, and, indeed, *has never been attempted* in instruments of a small size, it becomes of great practicable consequence to remove as much as possible the evils which arise from the use of a small speculum," &c.

The instruments now described have effectuated, in some degree, the desirable object alluded to by this distinguished philosopher, and the mode of construction is neither that of Sir W. Herschel's front view, nor does it coincide with that proposed by Le Maire, which appears to have been a mere hint that was never realized in the construction of reflecting telescopes of a small size. The simplicity of the construction of these instruments, and the excellence of their performance, have been much admired by several scientific gentlemen and others to whom they have been exhibited. Prior to the description of them in the Edinburgh Philosophical Journal, they were exhibited in the Calton Hill Observatory, Edinburgh, in the presence of Professor Wallace and another gentleman, who compared their performance with that of an excellent Gregorian. As this instrument is distinguished from every other telescope in being used without a tube, it has been denominated "*The Aerial Reflector.*"

SECTION V.

Earl of Rosse's reflecting telescopes.

This nobleman, unlike many of his compeers, has, for a considerable number of years past, devoted his attention to the pursuits of science, and particularly to the improvement of reflecting telescopes. He is evidently possessed of high mathematical attainments, combined with an uncommon degree of mechanical ingenuity. About 14 or 15 years ago, he engaged in various experiments with the view of counteracting the effects of the spherical aberration of the specula of reflecting telescopes, which imperfection, if it could be completely remedied, would render the reflecting telescope almost a perfect instrument, as it is not affected by the different refrangibility of the rays of light. His method, we believe, consisted in forming a large speculum of two or three separate pieces of metal, which were afterward accurately combined into one—a central part, which was surrounded by one or two rings ground on the same tool. When the images formed by the separate pieces were made exactly to coincide, the image of the object toward which the whole speculum was directed was then found to be as distinct as either image had been when separate; but, at the period referred to, a sufficient number of experiments had not been made to determine that his lordship had completely accomplished the object he intended.

Great interest, however, has of late been excited by the improvements which his lordship has made in the formation of specula. Sir W. Herschel never made public the means by which he succeeded in giving such gigantic development to the reflecting telescope, and therefore the construction of a large reflector has been considered as a perilous adventure; but, according to a report of Dr. Robinson, of Armagh, to the Irish Academy, the Earl of Rosse has overcome the difficulties which have hitherto been met with, and carried to an extent which even Herschel himself did not venture to contemplate, the illuminating power of this telescope, along with a sharpness of definition little inferior to that of the achromatic; and it is scarcely possible, he observes, to preserve the necessary sobriety of language in speaking of the moon's appearance with this instrument, which Dr. Robinson believes to be the most powerful ever constructed. The difficulty of constructing large specula, and of imparting to them the requisite degree of polish, has hitherto been considered so great, that from eight to twelve inches diameter, has been, in general, their utmost size; indeed, except with the greatest reluctance, London opticians would not accept of orders for specula of more than nine inches in diameter. It appears, however, that the Earl of Rosse has succeeded by a peculiar method of molding, in casting object-mirrors of true *speculum metal of three feet in diameter, and of a weight exceeding* 17 *cwt.* He is about to construct a telescope, the speculum of which is six feet in diameter, *fifty feet focal distance*, and of the weight of four tons; and from what he has already accomplished, it is not doubted that he possesses the power to carry his design into effect. These great masses of metal, which, in the hands of all other makers of specula, would have been as untractable as so much unannealed flint glass, the Earl of Rosse has farther succeeded in bringing to the highest degree of polish, and the utmost perfection of curvature, by means of machinery. The process is conducted under water, by which means those variations of temperature, so fatal to the finest specula hitherto attempted, are effectually guarded against. To convince Dr Robinson of the efficacy of this machinery, the Earl took the three-feet speculum out of its telescope, destroyed its polished surface, and placed it under the mechanical polisher. In six hours it was taken out with a perfect new surface as bright as the original. Under the old system of hand polishing, it might have required months, and even years to effect this restoration. Even before achieving these extraordinary triumphs on the solid substance, his lordship had constructed a six-feet reflector by covering a curved surface of brass with squares of the true speculum *metal*, which gave an immense quantity of light, though subject to some irregularities, arising from the number of joinings necessary in such a mosaic work. Of the performance of his lordship's great telescope, mounted with this reflector, those who have seen it speak in terms of high admiration; but in reference to the smaller and more perfect instrument, furnished with the solid three-feet speculum, the language of the Armagh astronomer assumes a tone of enthusiasm, and even of sublimity. By means of this exquisite instrument, Dr. Robinson and Sir J. South, in the intervals of a rather unfavorable night, saw several new stars, and corrected numerous errors of other observers. For example, the planet Uranus, supposed to possess a ring similar to that of Saturn, was found not to have any such appendage; and those nebulæ, hitherto regarded, from their apparently circular outline, as "coalescing systems," appeared, when tested by the three-feet speculum, to be very far indeed from presenting a globular appearance, numerous offshoots and appendages, invisible by other telescopes, appearing in all directions radiating from their edges. Such discoveries, which reflect great honor on the Earl of Rosse, will doubtless have great effect on the interests of astronomical science.*

SECTION VI.

Reflecting telescopes with glass specula.

After making a variety of experiments with aerial telescopes constructed of metallic specula of different focal lengths, I constructed a telescope on the same plan with a concave glass mirror. Having obtained a fragment of a very large convex mirror which happened accidentally to have been broken, I caused the convex side to be foliated or silverized, and found its focal length to be about 27 inches. This mirror, which was about five inches diameter, I placed in one of the aerial reflectors instead of the metallic speculum, and tried its effects with different terrestrial eyepieces. With a power of about 35 or 40 times, it gave a beautiful and splendid view of distant terrestrial objects, the quantity of light reflected from them being considerably greater than when a metallic speculum was used, and they appeared, on the whole, well-defined. The only imperfection—as I had foreseen—consisted in a double image being formed of objects which were remarkably bright and white, such as a lighthouse whitened on the outside, and strongly illuminated by the sun. One of the images was bright, and the other faint. This was obviously owing to the two reflections from the two surfaces of the mirror—one from the convex silverized side, and the other from the concave side next the eye, which produced the faint image—which circumstance has been generally considered as a sufficient reason for rejecting the use of glass specula in telescopes. But, although very bright objects exhibited a double image, almost all the other objects in the terrestrial landscape appeared quite distinct and without any secondary image, so that a common observer could scarcely have noticed any imperfection. When the instrument, however, was directed to celestial objects, the secondary image was somewhat vivid, so that every object appeared double. Jupiter appeared with two bodies, at a little distance from each other, and his four satellites appeared increased to eight. The moon likewise appeared as a double orb, but the principal image was distinct and well-defined. Such a telescope, therefore, was not well adapted for celestial observations, but might answer well enough for viewing terrestrial objects.

Considering that the injurious effects of the secondary image arose from the images reflected from the two surfaces being formed near the same point, and at nearly the same focal distance, I formed a plan for destroying the secondary image, or at least counteracting its effects, by forming the concavity of the mirror next the eye of a portion of a sphere *different* from that of the convex side which was silverized, and from which the principal image is formed; but, for a long time, I could find no opticians possessed of tools of a sufficient length of radii for accomplishing my design. At length a London working optician undertook to finish a glass speculum according to my directions, which were, that the convex surface of the mirror should be ground on a tool which would produce a focal distance by reflection of about four feet, and that the concave surface should have its focal distance at about three feet three inches, so that the secondary image might be formed at about nine inches within the focal distance of the silverized side, and not interfere to disturb the principal image; but, either from ignorance or inattention, the artist mistook the radius for the half radius of concavity, and the speculum turned out to be only 23 inches focal distance by reflection. This mirror was fitted up as a telescope on the aerial plan, and I found, as I expected, the secondary image completely destroyed. It produced a very beautiful and brilliant view of land objects, and even the brightest objects exhibited no double image. The mirror was nearly five inches in diameter, but the image was most accurately defined when the aperture was contracted to about three inches. It was fitted with a terrestrial eyepiece which produced a magnifying power of about 25 times. When directed to the moon, it gave a very distinct and luminous view of that orb, without the least appearance of a secondary image; but as the focal distance of the speculum was scarcely half the length I had prescribed, I did not apply to it any high astronomical powers, as I find that these can only be applied with effect, in this construction, to a speculum of a considerable focal length. Happening to have at hand a convex lens ten feet focal length and four inches in diameter, the one side of which had been ground to a certain degree of concavity, I caused the convex side to be foliated, which produced a focus by reflection at 13½ inches distant. To this mirror I applied terrestrial powers of 15 and 24 with considerable distinctness. The power of 15 produced a very brilliant and distinct view of land objects. Had the mirror been at least three times the focal length, it would have formed an excellent telescope with the same aperture.

SECTION VII.

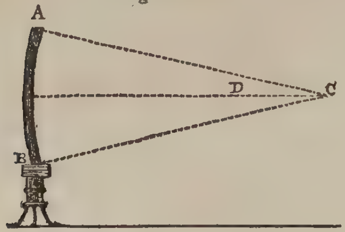
A reflecting telescope, with a single mirror and no eyepiece.

On the same principle as that by which a refracting telescope may be constructed by means of a single lens, as represented fig. 51 (page 68), we may form a telescope by reflection with a single mirror and without an eyepiece. Let *A B*, fig. 72, represent a large concave speculum, and *C* its focus: if an eye be placed at *D*, about eight or ten inches within the focal point *C*, all the objects in the direction of *C*, or behind the spectator, will be seen magnified by reflection on the face of the mirror, and strongly illuminated. The magnifying power, in this case, will be nearly in the proportion of the focal length of the mirror to the focal length of the eye for near objects. If, for example, the focal distance of the mirror be eight feet, and the distance from the eye at which we see near objects most distinctly be eight inches, the magnifying power will be in the ratio of 8 to 96, or 12 times. I have a glass mirror of this description, whose focal length is four feet eight inches, and diameter six inches, which magnifies distant objects about seven times, takes in a large field of view, and exhibits objects with great brilliancy. It presents a very distinct picture of the moon, showing the different streaks of light and shade upon her surface, and in some cases shows the larger spots which traverse the solar disc. This mode of viewing objects is extremely easy and pleasant, especially when the mirror is of a large diameter, and the observer is at first struck and gratified with the novel aspect in which the objects appear.

---

* A particular account of the Earl of Rosse's fifty-feet reflector, which is now finished, is given in the Appendix.

Fig. 72.



Were a concave mirror of this description—whether of glass or of speculum metal—to be formed to a very long focus, the magnifying power would be considerable. One of 50 feet focal length, and of a corresponding diameter, might produce a magnifying power, to certain eyes, of about 75 times; and, from the quantity of light with which the object would be seen, its effect would be much greater than the same power applied to a common telescope. Sir W. Herschel states that, on one occasion, by looking with his naked eye on the speculum of his 40 feet reflector, without the interposition of any lens or mirror, he perceived distinctly one of the satellites of Saturn, which requires the application of a considerable power to be seen by an ordinary telescope. Such an instrument is one of the most simple forms of a telescope, and would exhibit a brilliant and interesting view of the moon, or of terrestrial objects.

PRICES OF REFLECTING TELESCOPES.

1. Prices as stated by Messrs. W. and S. Jones Holborn, London.

	£.	
A 4 feet, 7 inch aperture, Gregorian reflector, with the vertical motions upon a newly invented principle, as well as apparatus to render the tube more steady for observation, according to the additional apparatus of small speculums eyepieces, micrometers, &c. *from* £80 to	120	0
3 feet long, mounted on a plain brass stand	23	9
Ditto with rack-work motions, improved mountings and metals .	39	1
2 feet long, without rack-work, and with 4 magnifying powers, improved .	15	1
Ditto improved, with rack-work motions	22	1
18 inch, on a plain stand . . .	9	
12 inch ditto	6	

2. Prices as stated by Messrs. Tulley, Islington

	£.	s
1 foot Gregorian reflector, on pillar and claw stand, metal 2½ inches, diameter, packed in a mahogany box . .	6	6
1½ foot ditto, on pillar and claw stand, metal 3 inches diameter, packed in a mahogany box	11	11
2 feet ditto, metal 4 inches diameter	16	1
Ditto with rack-work motions . .	25	4
3 feet ditto, metal 5 inches diameter, rack-work motions	42	0
4 feet ditto, metal 7 inches diameter, on a tripod stand with center of gravity motion	105	0
6 feet ditto, metal 9 inches diameter	210	0
7 feet *Newtonian*, 6 inches aperture .	105	0

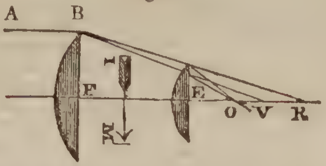
ON THE EYEPIECES OF TELESCOPES.

Although the performance of telescopes chiefly depends on the goodness of the object-glass, or the object-speculum of the instrument, yet it is of considerable importance, in order to distinct vision, and to obtain a large and uniformly distinct field of view, that the eyepiece be properly constructed. The different kinds of eyepieces may be arranged into two general divisions, *Astronomical* and *Terrestrial*.

1. *Astronomical Eyepieces.*—The most simple astronomical eyepiece is that which consists of a single convex lens; and when the focal distance of this lens, and that of the object-glass of the instrument, is accurately ascertained, the magnifying power may be nicely determined by dividing the focal length of the object-lens by that of the eyeglass; but as the pencil of white light transmitted by the object-glass will be divided by the eyeglass into its component colors, the object will appear bordered with colored fringes, and the distinctness of vision consequently injured; beside, the spherical aberration, when a single lens is used, is much greater than when two or more glasses are employed: hence astronomical eyepieces are now formed by a combination of at least two lenses.

The combination of lenses now generally used for astronomical purposes is that which is usually denominated the *Huygenian Eyepiece*, having been first proposed by the celebrated Huygens as a great improvement on the single lens eyepiece. The following figure (73) represents a section of this eyepiece: Let *A B* be a compounded pencil of white light proceeding from the object-glass; *B F* a plano-convex field-glass, with its plane side next the eyeglass *E*. The red rays of the pencil *A B*, after refraction, would cross the axis in *R*, and the violet rays in *V;* but, meeting the eyeglass *E*, the red rays will be refracted to *O*, and the violet nearly in the same direction, when they will cross each other about the point *O* in the axis, and unite. The distance of the two glasses *F E*, to produce this correction, when made of crown glass, must be equal to half the sum of their focal distances nearly: for example, suppose the focal distance of the largest, or field-lens, to be three inches, and the focal distance of the lens next the eye one inch, the two lenses should be placed exactly at the distance of two inches, the sum of their focal length being four, the half of which is two. In other words, the glass next the eye should be placed as much *within* the focus of the field-glass as is equal to its own focal distance. The focal length of a single lens that has the same magnifying power as this compound eyepiece, is equal to twice the product of the focal lengths of the two lenses divided by the sum of the same numbers; or, it is equal to half the focal length of the field-glass. Thus, in reference to the preceding example, twice the product of the focal length of the two lenses is equal to six, and their sum is four. The former number divided by the latter produces a quotient of 1½, which is the focal length of a single lens, which would produce the same magnifying power as the eyepiece; and 1½ is just half the focal length of the field-glass. The proportion of the focal lengths of the two lenses to each other, according to Huygens, should be as three to one; that is, if the field-glass be 4½ inches, the eyeglass should be 1½, and this is the proportion most generally adopted; but some opticians have recommended that the proportion should be as three to two. Boscovich recommended two similar lenses; and in this case the distance between them was equal to half the sum of their focal distances, as in the Huygenian eyepiece.

Fig. 73.



The image is formed at *I M*, at the focal distance of the lens next the eye, and at the same distance from the field-glass. When distinct vision is the principal object of an achromatic telescope, the two lenses are usually both plano-convex, and fixed with their curved faces toward the object-glass, as in the figure. Sometimes, however, they consist of what is called *crossed* lenses, that is, lenses ground on one side to a short focus, and on the other side to a pretty long focus, the sides with the deepest curves being turned toward the object-glass. A diaphragm, or aperture of a proper diameter, is placed at the focus of the eye-lens where the image formed by the object-glass falls, for the purpose of cutting off the extreme rays of the field-lens, and rendering every part of the field of view equally distinct. This is likewise the form of the eyepiece generally applied to Gregorian reflectors. In short, when accurately constructed, it is applicable to telescopes of every description. This eyepiece, having the image viewed by the eye behind the inner lens, is generally called the *negative* eyepiece, and is that which the optical instrument makers usually supply, of three or four different sizes, for so many magnifying powers, to be applied to different celestial objects, according to their nature, or the state of the atmosphere in which they are used.

Ramsden's Eyepiece.—There is another modification of lenses, known by the name of the *Positive*, or Ramsden's Eyepiece, which is much used in transit instruments, and telescopes which are furnished with micrometers, and which affords equally good vision as the other eyepiece. In this construction the lenses are plano-convex, and nearly of the same focus, but are placed at a distance from each other less than the focal distance of the glass next the eye, so that the image of the object viewed is beyond both the lenses when measuring from the eye. The flat faces of the two lenses are turned into contrary directions in this eyepiece, one facing the object-glass, and the other the eye of the observer; and as the image formed at the focus of the object-glass lies parallel to the flat face of the contiguous lens, every part of the field of view is distinct at the same adjustment, or, as opticians say, there is a *flat field*, which, without a diaphragm, prevents distortion of the object. This eyepiece is represented in

Fig. 74.

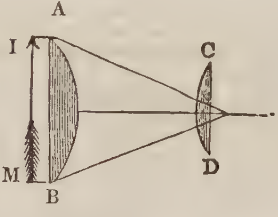


fig. 74, where *A B* and *C D* are two plano-convex lenses, with their convex sides inward. They have nearly the same focal length, and are placed at a distance from each other equal to about two-thirds of the focal length of either. The focal length to an equivalent single lens is equal to three-fourths the focal length of either lens, supposing them to have equal focal distances. This eyepiece is generally applied when wires of spider's lines are used in the common focus, as the piece containing the lenses can be taken out without disturbing the lines, and is adjustable for distinct vision; and whatever may be the measure of any object given by the wire micrometer at the solar focus, it is not altered by a change of the magnifying power when a second eyepiece of this construction is substituted.

Aberration of Lenses.—In connection with the above descriptions, the following statements respecting the spherical aberration of lenses may not be inappropriate. Mr. John Dollond, in a letter to Mr. Short, remarks, that "the aberration in a single lens is as the cube of the refracted angle; but if the refraction be caused by two lenses, the sum of the cubes of each half will be a quarter of the refracted angle, twice the cube of one being a quarter of the cube of two. So three times the cube of one is only *one-ninth* of the cube of three," &c. Hence the indistinctness of the borders of the field of view of a telescope is diminished by increasing the number of lenses in an eyepiece. Sir J. Herschel has shown that if two plano-convex lenses are put together as in fig. 75, the aberration will be only 0.2481, or *one-fourth* of that of a single lens in its best form. The focal length of the first of these lenses must be to that of the second as 1 to ⅔. If their focal lengths are equal, the aberration will be 0.603, or nearly one-half. The spherical aberration, however, may be *entirely* destroyed by combining a meniscus and double convex lens, as shown in fig. 76, the convex sides being turned to the eye when they are used as lenses, and to parallel rays when they are used as burning glasses. Sir J. Herschel has computed the following curvatures for such lenses:

Fig. 75.

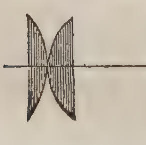

Fig. 76.

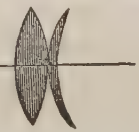


Focal length of the convex lens . .	+10.000
Radius of its first surface . . .	+ 5.833
Radius of its second surface . .	—35.000
Focal length of the meniscus . .	+17.829
Radius of its first surface . . .	+ 3.688
Radius of its second surface . .	+ 6.294
Focal length of the compound lens .	+ 6.407

On the general principles above stated, a good astronomical eyepiece may be easily constructed with two proper lenses, either according to the plan of Huygens or that of Ramsden: and, from what has been now stated, it is demonstrably certain, that, in all cases where two glasses are properly combined, such an eyepiece is superior to a single lens both in point of distinctness and of the enlargement of the field of view. I lately fitted up an eyepiece, on Ramsden's principle, with two lenses, each about three inches focal length, and 1⅜ths of an inch in diameter, placed at half an inch distant, with their convex surface facing each other, as in fig. 74, which forms an excellent eyepiece for an achromatic telescope six feet eight inches focal distance and four inches aperture, particularly for viewing clusters of stars, the Milky Way, and the large nebulæ. The field of view is large, the magnifying power is only between 50 and 60 times, and the quantity of light being so great, every celestial object appears with great brilliancy, and it is, in general, much more preferable, when applied to the stars, than any of the higher powers. When applied to *Præsepe* in Cancer, it exhibits that group at one view, as consisting of nearly 100 stars, which exhibit a beautiful and most striking appearance.

It may appear a curious circumstance that any eyepiece which is good with a short telescope is also good with a long one, but that the reverse is not true; for it is found to be more difficult to make a good eyepiece for a short than for a long focal distance of the object-glass.

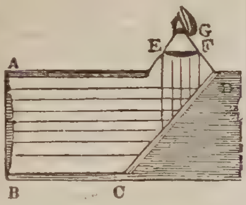
Celestial eyepieces are sometimes constructed so as to produce *variable powers.* This is effected by giving a motion to the lens next the eye, so as to remove it nearer to or farther from the field-lens; for at every different distance at which it is placed from the other lens, the magnifying power will either be increased or diminished. The greatest power is when the two lenses are nearly in contact, and the power diminishes in proportion to the distance at which the glass next the eye is removed from the other. The scale of distance, however, between the two lenses cannot be greater than the focal distance of the field, or inner glass; for if it were, the lenses would no longer form an eyepiece, but would be changed into an inverting opera-glass. For effecting the purpose now stated, the eyeglass is fixed in a tube, which slides upon an interior tube, on which is marked a scale of distances corresponding to certain magnifying powers; and in this way an eyepiece may be made to magnify about double the number of times when the lenses are in one position than when they are in another; as, for example, all the powers from 36 to 72 times may be thus applied, merely by regulating the distance between the two lenses. When the glasses are varied in this manner, the eyepiece becomes sometimes a *positive* eyepiece, like Ramsden's, and sometimes a negative one, like that of Huygens.

Diagonal Eyepieces.—The eyepieces to which we have now adverted, when adapted to refracting telescopes, both reverse and invert the object, and therefore are not calculated for showing terrestrial objects in their natural position; but as the heavenly bodies are of a spherical form, this circumstance detracts nothing from their utility. When the celestial object, however, is at a high altitude, the observer is obliged to place his head in a very inconvenient position, and to direct his eye nearly upward; in which position he cannot remain long at ease, or observe with a steady eye. To remedy this inconvenience, the diagonal eyepiece has been inverted, which admits of the eye being applied at the side, or at the upper part of the eyepiece, instead of the end; and when such an eyepiece is used, it is of no importance in what direction the telescope is elevated, as the observer can then either sit or stand erect, and look down upon the object with the utmost ease. This object is effected by placing a flat piece of polished speculum-metal at an angle of 45 degrees in respect to the two lenses of the eyepiece, which alters the direction of the converging rays, and forms an image which becomes erect with respect

to altitude, but is reversed with respect to azimuth; that is, in other words, when we look down upon the objects in the field of view, they appear erect; but that part of an object which is in reality on our right hand, appears on our left; and if it be in motion, its *apparent*, is opposite to its *real* motion; if it be moving toward the west, it will seem to move toward the east.

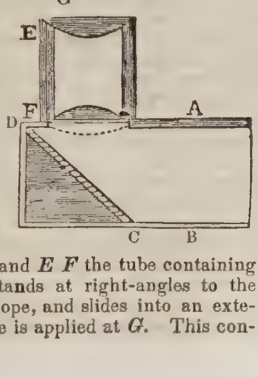
There are three situations in which the diagonal reflector in this eyepiece may be placed. It may be placed either, 1, before the eyepiece, or 2, behind it, or, 3, between the two lenses of which the eyepiece consists. The most common position of the reflector is between the lenses; and this may be done both in the negative and the positive eyepieces; but as the distance between the two lenses is necessarily considerable, to make room for the diagonal position of the reflector, the magnifying power cannot be great; otherwise a diagonal eyepiece of this construction remains always in adjustment, and is useful in all cases where a high power is not required. The preceding is a description and representation of a diagonal eyepiece of this kind in my possession.

Fig 77.



In fig. 77, *A B* represents the plano-convex lens next the object, which is about 2 inches in focal length, and ¾ of an inch in diameter; *C D*, a plain metallic speculum of an oval form, well polished, and placed at half a right-angle to the axis of the tube; and *E F*, another plano-convex lens, about 1½ inch focal distance. The center of the speculum is about 1¼th of an inch from the lens *A B*, and about half or one-third of an inch from *E F*; so that this eyepiece is a *positive* one, on the principle proposed by Ramsden. The rays proceeding from the lens *A B*, and falling upon the speculum, are reflected in a perpendicular direction to the lens *E F*, where they enter the eye at *G*, which looks down upon the object through the side of the tube. The real size of this eyepiece is much about the same as that represented in the figure. When applied to an achromatic telescope of 44½ inches focal distance, it produces a magnifying power of 36 times, and exhibits a very beautiful view of the whole of the full moon. It likewise presents a very pleasing prospect of terrestrial objects, which appear as if situated immediately below us.

Fig. 78.



Another plan of the diagonal eyepiece is represented in Fig. 78, where the speculum is fixed *within* the sliding tube which receives the eyepiece, or immediately below it. The part of the tube *A B* slides into the tube of the telescope, *C D* is the speculum placed at half a right-angle to the axis of the tube, and *E F* the tube containing the lenses, which stands at right-angles to the position of the telescope, and slides into an exterior tube, and the eye is applied at *G*. This construction of the diagonal eyepiece may be used with any eyepiece whatever, whether the Huygenian or that of Ramsden. It will admit of any magnifying power, and if several different eyepieces be fitted to the sliding tube, they may be changed at pleasure. This form of the diagonal eyepiece I therefore consider as the best and the most convenient construction, although it is not commonly adopted by opticians.

When any of these eyepieces are applied to a telescope, with the lens *E* on the upper part of it, we look down upon the object, if it be a terrestrial one, as if it were under our feet. If we turn the eyepiece round in its socket a quarter of a circle toward the left, an object directly before us in the south will appear as if it were in the *west*, and turned upside down. If, from this position, it is turned round a semicircle toward the right, and the eye applied, the same object will appear as if it were situated in the east, and inverted; and if it be turned round another quadrant, until it be directly opposite to its first position, and the eye applied from below, the object or landscape will appear as if suspended in the atmosphere above us. This eyepiece, therefore, is capable of exhibiting objects in a great variety of aspects, and the use of it is both pleasant and easy for the observer. But there is a considerable loss of light, occasioned by the reflection from the speculum, which is sensibly felt when very high powers are applied; and therefore, when very small stars are to be observed, such as some of those connected with double or triple stars, the observer should not study his own ease so much as the quantity of light he can retain with a high power, which object is best attained with an ordinary eyepiece and a telescope of large aperture.

We have said that a diagonal eyepiece may be constructed with a reflector *before* the eyepiece. In this case, the speculum is sometimes made to slide before the eye at the requisite angle of reclination, in which application each eyepiece must necessarily have a groove to receive it, and the eye must be applied without a hole to direct it, but it may be put on and taken off without disturbing the adjustment for distinct vision, and is very simple in its application. But, on the whole, the form represented in fig. 78 is the most convenient, and should generally be preferred, as any common astronomical eyepiece can be applied to it. I have used a diagonal eyepiece of this kind with good effect, when a power of 180 has been applied to the sun and other celestial objects.

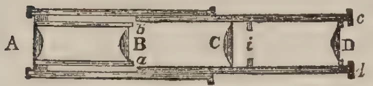
Instead of a metallic speculum, a *rectangular prism of glass* is sometimes substituted; for the rays of light are then bent by reflection from the second polished surface, which ought to be *dry*, and undergo two refractions, which achromatize them; and the same effect is thus produced as by polished metal. Ramsden sometimes gave one of the polished faces of a right-angle prism a curve, which prism served instead of a lens in an eyepiece, and also performed the office of a reflector. A semi-globe, or what has been called a bull's eye, has also been used as a diagonal eyepiece, and when the curve is well formed, and the glass good, it is achromatic, and is said to perform pretty well, but it is not superior to the forms already described.

SECTION II.

TERRESTRIAL EYEPIECES.

WHEN describing the common refracting telescope (p. 67), I have noticed that three eyeglasses, placed at double their focal distances from each other, formerly constituted the terrestrial eyepiece, as represented in fig. 47. But this construction, especially for achromatic instruments, has now become obsolete, and is never used except in small pocket spyglasses formed with a single object-lens. In its place a four glassed eyepiece has been substituted, which is now universally used in all good telescopes, and which, beside improving the vision and producing an erect position of the images of objects, presents a considerably larger field of view. During the progressive stages of improvement made in the construction of erect eyepieces by Dollond and Ramsden, three, four, and five lenses were successively introduced; and hence, in some of the old telescopes constructed by these artists, we frequently find five lenses of different descriptions composing the eyepiece. But four lenses, arranged in the manner I am now about to describe, have ultimately obtained the preference. In a telescope having a celestial eyepiece of the Huygenian form, the image that is formed in the focus of the object-glass is that which is seen magnified, and in an inverted position; but when a four glassed eyepiece is used, which produces an erect view of the object, the image is repeated, and the *second* image, which is formed by the inner pair of lenses, *A B*, on an enlarged scale, is that which the pair of lenses, *C D*, at the eye-end render visible on a scale still more enlarged. The modern terrestrial eyepiece, represented in fig. 79, is, in fact, nothing else than a compound microscope, consisting of an object-lens, an amplifying-lens, and an eyepiece composed of a pair of lenses on the principle of the Huygenian eyepiece. Its properties will be best understood by considering the first image of an object, which is formed in the focus of the object-glass, as a small luminous object to be rendered visible, in a magnified state, by a compound microscope. The object to be magnified may be considered as placed near the point *A*, and the magnified image at *i*, which is viewed by the lens *D*. Hence, if we look through such an eyepiece at a small object placed very near the lens *A*, we shall find that it acts as a compound microscope of a moderate magnifying power, increasing, in some cases, the diameter of the object about 10 times, and 100 times in surface.

Fig 79.



In order to distinguish the different lenses in this eyepiece, we may call the lens *A*, which is next to the first image, the *object-lens;* the next to it, *B*, the *amplifying-lens;* the third, or *C*, the *field-lens;* and the one next the eye, *D*, the *eye-lens.* The first image, formed a little before *A*, may be denominated the *radiant*, or the object from which the rays proceed. Now it is well known as a principle in optics, that if the radiant be brought nearer to the lens than its principal focus, the emerging rays will *diverge*, and, on the contrary, if the radiant be put farther from the lens than its principal focal distance, the emerging rays will *converge* to a point at a distance beyond the lens, which will depend on the distance of the radiant from the face of the lens. In this place an image of the radiant will be formed by the concurrence of the converging rays, but in a contrary position; and the length of the image will exceed the length of the radiant in the same proportion, as the distance of the image from the radiant exceeds that of the radiant from the lens. This secondary image of the radiant at *i*, is not well-defined when only one lens, as *A*, is used, owing to the great spherical aberrations, and therefore the amplifying lens is placed at the distance of the shorter conjugate focus, with an intervening diaphragm of a small diameter at the place of the principal focus; the uses of which lens and diaphragm are, first, to cut off the colored rays that are occasioned by the dispersive property of the object-lens, and, secondly, to bring the rays to a shorter conjugate focus for the place of the image than would have taken place with a single lens having only one refraction. As the secondary image is in this way much better defined and free from coloration, the addition of this second lens is a great improvement to vision. For this reason, I am clearly of opinion that the object-glass of a compound microscope, instead of consisting of a small single lens, should be formed of two lenses, on the principle now stated, which would unquestionably add to the distinctness of vision.

With respect to *the proportions of the focal lengths of the lenses* in this four glass eyepiece, Mr. Coddington states, that if the focal lengths, reckoning from *A* to *D*, fig. 79, be as the numbers 3, 4, 4, and 3, and the distances between them on the same scale, 4, 6, and 5, 2, the radii, reckoning from the outer surface of *A*, should be thus:

A	First surface	27	nearly plano-convex.
	Second surface	1	
B	First surface	9	a meniscus.
	Second surface	4	
C	First surface	1	nearly plano-convex.
	Second surface	21	
D	First surface	1	double convex.
	Second surface	24	

Sir D. Brewster states that a good achromatic eyepiece may be made of four lenses, if their focal lengths, reckoning from that next the object, be as the numbers 14, 21, 27, 32; their distances, 23, 44, 40; their apertures, 5.6, 3.4, 2.6; and the aperture of the diaphragm placed in the interior focus of the fourth eyeglass, 7. Another proportion may be stated: Suppose the lens next the object, *A*, to be 1⅞ths of an inch focal length, then *B* may be 2½ inches; *C*, 2 inches; and *D*, 1½; and their distances, *A B*, 2½; *B C*, 3⅝ths; and *C D*, 2⅜ths. In one of Ramsden's small telescopes, whose object-glass was 8½ inches in focal length, and its magnifying power 15.4, the focal lengths of the eyeglasses were, *A*, 0.775 of an inch; *B*, 1.025; *C*, 1.01; *D*, 0.79; the distances, *A B*, 1.18; *B C*, 1.83; and *C D*, 1.105. In the excellent achromatic telescope of Dollond's construction which belonged to the Duc de Chaulnes, the focal lengths of the eyeglasses, beginning with that next the object, were 14¼ lines, 19, 22¾, 14; their distances, 22.48 lines, 46.17, 21.45; and their thickness at the center, 1.23 lines, 1.25, 1.47. The fourth lens was plano-convex, with the plane side to the eye, and the rest were double convex lenses. This telescope was in focal length three feet five and a half inches.

The magnifying power of this eyepiece, as usually made, differs only in a small degree from what would be produced by using the first or the fourth glass alone, in which case the magnifying power would be somewhat greater, but the vision less distinct; and were the lens next the eye used alone without the field-glass, the field of view would be much contracted. Stops should be placed between the lenses *A* and *B*, near to *B*, and a larger one between *C* and *D*, to prevent any false light from passing through the lenses to the eye. The more stops that are introduced into a telescope—which should all be blackened—provided they do not hinder the pencils of light proceeding from the object, the better will the instrument perform.

For the information of amateur constructors of telescopes, I shall here state the dimensions of two or three four glassed eyepieces in my possession, which perform with great distinctness, and present a pretty large field of view. In one of these, adapted to a 44½ inch achromatic, the lens, *A*, next the object, is 1⅞ths of an inch focal length and about one inch in diameter, with the plane side next the object. The focal length of the lens *B*, 2 1-10th inches, diameter 7-10ths of an inch, with its plane side next *A;* distance of these lenses from each other, 2 4-10ths inches; distance of the field-lens *C* from the lens *B*, 5½ inches. The small hole or diaphragm between *A* and *B* is at the focus of *A*, and is about one-sixth of an inch in diameter, and about three-eighths of an inch from the lens *B*. The field-lens *C* is two inches focal length, and 1¼th of an inch in diameter, with its plane side next the eye. The lens next the eye *D*, is one inch focal distance, half an inch in diameter, and is distant from the field-glass 1¾ths of an inch, with its plane side next the eye. The magnifying power of this eyepiece is equivalent to that of a single lens whose focal length is half an inch, and with the 44½ inch object-glass produces a power of about 90 times. The lens next the eye can be changed for another of 1⅜ths of an inch focal length, which produces a power of 65, and the two glasses *C D* can be changed for another set of a longer focal distance, which produces a power of 45 times. The whole length of this eyepiece is 11½ inches.

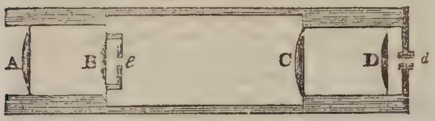
In another eyepiece, adapted to a pocket achromatic, whose object-glass is nine inches focal length, the lens *A* is one inch focal length and half an inch in diameter; the lens *B*, 1¼th of an inch, and half an inch in diameter; their distance, 1½ inches; the lens *C*, 1 1-10th of an inch focal length and five-eighths of an inch in diameter; the eyelens *D*, five-eighths of an inch focal length and three-eighths of an inch in diameter; distance between *C* and *D*, 1⅛th of an inch; the distance between *B* and *C*, 1¾ths of an inch. The whole length of this eyepiece is 4½ inches, and its power is nearly equal to that of a single lens of half or six-tenths of an inch focal length, the magnifying power of the telescope being about 16 times. Another eyepiece of much larger dimensions has the lens *A* of 2½ inches focal length and three-fourths of an inch in diameter; the lens *B*, 2¾ths inches focus and five-eighths of an inch in diameter, and their distance 2¾ths inches; the lens *C*, 2⅝ths inches focus and 1⅛th of an inch in diameter: the lens *D*, 1¾ths of an inch focus and three-fourths of an inch in diameter; distance from each other, 2¾ths inches. The distance between the lenses *B* and *C* is four inches. The magnifying power is equal to that of a single lens 1⅛th of an inch focal distance. When applied to an achromatic object-glass six feet seven inches focal length, it produces a power of about 70 times. This eyepiece has a movable tube nine inches in length, in which the two lenses next the eye are contained, by pulling out which, and consequently increasing the distance between the lenses *B* and *C*, the magnifying power may be increased to 100, 120, or 140, according to the distance to which this movable tube is drawn out. It has also a second and third set of lenses, corresponding to *C* and *D*, of a shorter focal distance, which produce higher magnifying powers on a principle to be afterward explained.

DESCRIPTION OF AN EYEPIECE, ETC., OF AN OLD DUTCH ACHROMATIC TELESCOPE.

About twenty or thirty years ago, I purchased, in an optician's shop in Edinburgh, a small achromatic telescope, made in Amsterdam, which was supposed by the optician to have been constructed prior to the invention of achromatic telescopes by Mr. Dollond. It is mounted wholly of brass, and in all its parts is a piece of beautiful and exquisite workmanship, and the utmost care seems to have been taken to have all the glasses and diaphragms accurately adjusted. The object-glass is a double achromatic, 6½ inches focal distance and one inch in diameter, but the clear aperture is only seven-eighths of an inch in diameter. It is perfectly achromatic, and would bear a power of 50 times if it had a sufficient quantity of light. The following inscription is engraved on the tube adjacent to the object-glass: "*Jan van Deyl en Zoon, Invenit et Fecit, Amsterdam, Ao.* 1769." Although Dollond exhibited the principle of an achromatic eight or ten years before the date here specified, yet it is not improbable that the artist whose name is here stated may not have heard of Dollond's invention, and that he was really, as he assumes, one of the inventors of the achromatic telescope; for the invention of this telescope by Dollond was not very generally known, except among philosophers and the London opticians, until a number of years after the date above stated. Euler, in his "Letters to a German Princess," in which telescopes are particularly described, makes no mention of, nor the least allusion to, the invention of Dollond, though this was a subject which particularly engaged his attention. Now these letters were written in 1762, but were not published until 1770. When alluding to the defects in telescopes arising from the different refrangibility of the rays of light, in Letter 43, and that they might possibly be rectified by means of different transparent substances, he says, "But neither theory nor practice have hitherto been carried to the degree of perfection necessary to the execution of a structure which should remedy these defects." Mr. B. Martin, in his "Gentleman and Lady's Philosophy," published in 1781, alludes to the achromatic telescope, but speaks of it as if it were but very little, if at all, superior to the common refracting telescope: and therefore I think it highly probable that Jan van Deyl was really an inventor of an achromatic telescope before he had any notice of what Dollond and others had done in this way some short time before.

But my principal object in adverting to this telescope is to describe the structure of the eyepiece, which is a very fine one, and which is somewhat different from the achromatic eyepiece above described. It consists of four glasses, two combined next the eye, and two next the object. Each of these combinations forms an astronomical eyepiece nearly similar to the Huygenian. The lens *A*, next the object, fig. 80, is five-eighths of an inch focal distance, and 4-10ths of an inch in diameter; the lens *B*, three-eighths of an inch focus, and one-fifth of an inch in diameter, and the distance between them somewhat less than five-eighths of an inch; the diameter of the aperture *e* about 1-15th of an inch. This combination forms an excellent astronomical eyepiece, with a large flat field, and its magnifying power is equivalent to that of a single lens five-eighths or six-eighths of an inch focal length. The lens *C* is half an inch focal length, and 4-10ths of an inch in diameter; the lens *D*, a quarter of an inch focus, and about one-fifth of an inch in diameter; their distance about half an inch or a small fraction more. The hole at *d* is about 1-20th or 1-25th of an inch in diameter, and the distance between the lenses *B* and *C* about 1½ inches. The whole length of the eyepiece is 3¼ inches—exactly the same size as represented in the engraving. Its magnifying power is equal to that of a single lens one-fourth of an inch focal length; and consequently the telescope, though only 9½ inches long, magnifies twenty-six times with great distinctness, though there is a little deficiency of light when viewing land objects which are not well illuminated.

Fig. 80.



The glasses of this telescope are all plano-convex, with their convex sides toward the object, except the lens *D*, which is double convex, but flattest on the side next the eye, and they are all very accurately finished. The two lenses *C* and *D* form an astronomical eyepiece nearly similar to that formed by the lenses *A* and *B*. The focus of the telescope is adjusted by a screw, the threads of which are formed upon the outside of a tube into which the eyepiece slides. The eyepiece and apparatus connected with it is screwed into the inside of the main tube when not in use, when the instrument forms a compact brass cylinder six inches long, which is inclosed in a fish skin case, lined with silk velvet, which opens with hinges.

The lenses in the eyepieces formerly described, though stated to be plano-convexes, are, for the most part, *crossed glasses*, that is, ground on tools of a long focus on the one side, and to a short focus on the other. The construction of the eyepiece of the Dutch telescope above described is one which might be adopted with a good effect in most of our achromatic telescopes; and I am persuaded, from the application I have made of it to various telescopes, that it is even superior in distinctness and accuracy, and in the *flatness of field* which it produces to the eyepiece in common use. The two astronomical eyepieces of which it consists, when applied to large achromatic telescopes, perform with great accuracy, and are excellently adapted for celestial observations.

SECTION III.

Description of the pancratic eyetube.

From what we have stated when describing the common terrestrial eyepiece now applied to achromatic instruments (p. 98, fig. 79), it appears obvious that any variety of magnifying powers, within certain limits, may be obtained by removing the set of lenses *C D*, fig. 79, nearer to or farther from the tube which contains the lenses *A* and *B*, on the same principle as the magnifying power of a compound microscope is increased by removing the eyeglasses to a greater distance from the object lens. If, then, the pair of eyelenses *C D* be attached to an inner tube that will draw out and increase their distance from the inner pair of lenses, as the tube *a b c d*, the magnifying power may be indefinitely increased or diminished by pushing in or drawing out the sliding tube, and a scale might be placed on this tube, which, if divided into equal intervals, will be a scale of magnifying powers, by which the power of the telescope will be seen at every division, when the lowest power is once determined.

Sir David Brewster, in his "Treatise on New Philosophical Instruments," Book I, chap. vii, page 59, published in 1813, has adverted to this circumstance in his description of an "Eyepiece Wire Micrometer," and complains of Mr. Ezekiel Walker having in the "Philosophical Magazine" for August, 1811, described such an instrument as an invention of his own. Dr. Kitchener, some years afterward, described what he called a Pancratic or omnipotent eyepiece, and got one made by Dollond, with a few modifications different from that suggested by Brewster and Walker, which were little else than cutting the single tube into several parts, and giving it the *appearance* of a new invention. In fact, none of these gentlemen had a right to claim it as his peculiar invention, as the principle was known and recognized long before. I had increased the magnifying powers of telescopes on the same principle several years before any of these gentlemen communicated their views on the subject, although I never formally constructed a scale of powers. Mr. B. Martin, who died in 1782, proposed many years before, such a movable interior tube as that alluded to for varying the magnifying power

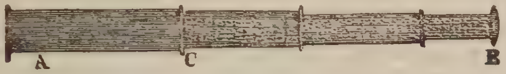
In order to give the reader a more specific idea of this contrivance, I shall present him with figure and description of one of Dr. Kitchener's pancratic eyepieces, copied from one lately in my possession. The following are the exact dimensions of this instrument, with the focal distances, &c., of the glasses, &c., of which it is composed.

	In.	Tenths.
Length of the whole eyepiece, consisting of four tubes, when fully drawn out, or the distance from *A* to *B*, fig. 81	14	4
Length of the three tubes on which the scale is engraved, from the commencement of the divisions at *B* to their termination at *C*	9	15
Each division into tens is equal to 3-10ths of an inch.		
When the three inner tubes are shut up to *C*, the length of the eyepiece is exactly	5	5
When these tubes are thus shut up, the magnifying power for a 3½ feet achromatic is 100 times, which is the smallest power. When the inner tube is drawn out one-third of an inch, or to the first division, the power is 110, &c.		
Focal distance of the lens next the object	1	0
Breadth of ditto	0	65
The plane side of this glass is next the object.		
Focal distance of the second glass from the object	1	5
This glass is double and equally convex.		
Breadth	0	5
Distance between these two glasses	1	7
Focal distance of the third or field		

	In.	Tenths.
lens, which is plano on the side next the eye	1	1
Breadth of ditto	0	55
Focal distance of the lens next the eye	0	6
Breadth of ditto	0	43
This glass is plane on the side next the eye.		
Distance between the third and fourth glasses	1	1

From the figure and description, the reader will be at no loss to perceive how the magnifying power is ascertained by this eyepiece. If the lowest power for a 44 inch telescope be found to be 100 when the three sliding tubes are shut into the larger one, then by drawing out the tube next the eye four divisions, a power of 140 is produced; by drawing out the tube next the eye its whole length, and the second tube to the division marked 220, a power of 220 times is produced; and drawing out all the tubes to their utmost extent, as represented in the figure, a power of 400 is obtained. These powers are by far too high for such a telescope, as the powers between 300 and 400 can seldom or never be used. Were the scale to begin at 50 and terminate at 200, it would be much better adapted to a 3½ feet telescope. Each alteration of the magnifying power requires a new adjustment of the eyepiece for distinct vision. As the magnifying power is increased, the distance between the eyeglass and the object-glass must be diminished. Dr. Kitchener says that "the pancratic eyetube gives a better defined image of a fixed star, and shows double stars decidedly more distinct and perfectly separated, than any other eyetube, and that such tubes will probably enable us to determine the distances of these objects from each other in a more perfect manner than has been possible heretofore." These tubes are made by Dollond, London, and are sold for two guineas each; but I do not think they excel in distinctness those which are occasionally made by Mr. Tulley and other opticians.

Fig. 81.



CHAPTER VI.

MISCELLANEOUS REMARKS IN RELATION TO TELESCOPES.

The following remarks, chiefly in regard to the manner of using telescopes, may perhaps be useful to young observers, who are not much accustomed to the mode of managing these instruments.

1. *Adjustments requisite to be attended to in the use of Telescopes.*—When near objects are viewed with a considerable magnifying power, the eyetube requires to be removed farther from the object-glass than when very distant objects are contemplated. When the telescope is adjusted for an object 6, 8, or 10 miles distant, a very considerable alteration in the adjustment is requisite in order to see distinctly an object at the distance of two or three hundred yards, especially if the instrument is furnished with a high magnifying power. In this last case, the eyetube requires to be drawn out to a considerable distance beyond the focus for parallel rays. I have found that, in a telescope which magnifies 70 times, when adjusted for an object at the distance of two miles, the adjustment requires to be altered fully one inch in order to perceive distinctly an object at the distance of two or three hundred yards; that is, the tube must be drawn, in this case, an inch farther from the object-glass, and pushed in the same extent, when we wish to view an object at the distance of two or three miles. These adjustments are made, in pocket perspectives, by gently sliding the eyetube in or out, by giving it a gentle circular or spiral motion, until the object appears distinct. In using telescopes which are held in the hand, the best plan is to draw all the tubes out to their full length, and then, looking at the object, with the left band supporting the main tube near the object-glass, and the right supporting the eyetube, gently and gradually push in the eyepiece until distinct vision be obtained. In Gregorian reflecting telescopes this adjustment is made by means of a screw connected with the small speculum; and in large achromatics, by means of a rack and pinion connected with the eyetube. When the magnifying power of a telescope is comparatively small, the eyetube requires to be altered only a very little.

There is another adjustment requisite to be attended to in order to adapt the telescope to the eyes of different persons. Those whose eyes are too convex, or who are short-sighted, require the eyetube to be pushed in, and those whose eyes are somewhat flattened, as old people, require the tube to be drawn out. Indeed, there are scarcely two persons whose eyes do not require different adjustments in a slight degree. In some cases I have found that the difference of adjustment for two individuals, in order to produce distinct vision in each, amounted to nearly half an inch. Hence the difficulty of exhibiting the sun, moon, and planets through telescopes, and even terrestrial objects, to a company of persons who are unacquainted with the mode of using or adjusting such instruments, not one-half of whom generally see the object distinctly; for upon the proper adjustment of a telescope to the eye, the accuracy of vision in all cases depends, and no one except the individual actually looking through the instrument can be certain that it is accurately adjusted to his eye; and even the individual himself, from not being accustomed to the view of certain objects, may be uncertain whether or not the adjustment be correct. I have found by experience that when the magnifying powers are high, as 150 or 200, the difference of adjustment required for different eyes is very slight; but when low powers are used, as 20, 30, or 40, the difference of the requisite adjustments is sometimes very considerable, amounting to a quarter or half an inch.

2. *State of the atmosphere most proper for observing Terrestrial and Celestial Objects.*—The atmosphere which is thrown around the globe, while it is essentially requisite to the physical constitution of our world, and the comfort of its inhabitants, is found in many instances a serious obstruction to the accurate performance of telescopes. Sometimes it is obscured by mists and exhalations; sometimes it is thrown into violent undulations by the heat of the sun and the process of evaporation; and even, in certain cases, where there appears a pure unclouded azure, there is an agitation among its particles, and the substances incorporated with them, which prevents the telescope from producing distinct vision either of terrestrial or celestial objects. For viewing distant terrestrial objects, especially with high powers, the best time is early in the morning, a little after sunrise, and from that period until about nine o'clock, A. M., in summer, and in the evening about two or three hours before sunset. From about ten o'clock, A. M., until four or five in the afternoon, in summer, if the sky be clear and the sun shining, there is generally a considerable undulation in the atmosphere, occasioned by the solar rays and the rapid evaporation, which prevents high powers from being used with distinctness on any telescope, however excellent. The objects, at such times, when powers of 50, 70, or 100 are applied, appear to undulate like the waves of the sea, and, notwithstanding every effort to adjust the telescope, they appear confused and indistinct. Even with very moderate magnifying powers this imperfection is perceptible. In such circumstances, I have sometimes used a power of 200 times on distant land objects with good effect a little before sunset, when, in the forenoon of the same day, I could not have applied a power of 50 with any degree of distinctness. On days when the air is clear and the atmosphere covered with clouds, terrestrial objects may be viewed with considerably high powers. When there has been a long continued drought, the atmosphere is then in a very unfit state for enjoying distinct vision with high magnifying powers, on account of the quantity of vapors with which the atmosphere is then surcharged, and the undulations they produce. But, after copious showers of rain, especially if accompanied with high winds, the air is purified, and distant objects appear with greater brilliancy and distinctness than at any other seasons. In using telescopes, the objects at which we look should, if possible, be nearly in a direction opposite to that of the sun. When they are viewed nearly in the direction of the sun, their shadows are turned toward us, and they consequently appear dim and obscure. By not attending to this circumstance, some persons, in trying telescopes, have pronounced a good instrument to be imperfect, which, had it been tried on objects properly illuminated, would have been found to be excellent. In our variable northerly climate the atmosphere is not so clear and serene for telescopic observation as in Italy, the south of France, and in many of the countries which lie within the tropics. The undulations of the air, owing to the causes alluded to above, constitute one of the principal reasons why a telescope magnifying above a hundred times can seldom be used with any good effect in viewing terrestrial objects, though I have sometimes used a power of nearly 200 with considerable distinctness in the stillness of a summer or autumnal evening, when the rays of the declining sun strongly illuminated distant objects.

The atmosphere is likewise frequently a great obstruction to the distinct perception of *celestial* objects. It is scarcely possible for one who has not been accustomed to astronomical observations to form a conception of the very great difference there is in the appearance of some of the heavenly bodies in different states of the atmosphere. There are certain conditions of the atmosphere essentially requisite for making accurate observations with powerful telescopes, and it is but seldom, especially in our climate, that all the favorable circumstances concur. The nights must be very clear and serene—the moon absent—no twilight—no haziness—no violent wind—no sudden change of temperature, as from thaw to frost—and no surcharge of the atmosphere with aqueous vapor. I have frequently found that, on the first and second nights after a thaw, when a strong frost had set in, and when the heavens appeared very brilliant, and the stars vivid and sparkling, the planets, when viewed with high powers, appeared remarkably undefined and indistinct; their margins appeared waving and jagged; and the belts of Jupiter, which at other times were remarkably distinct, were so obscured and ill-defined that they could with difficulty be traced. This was probably owing to the quantity of aqueous vapor, and perhaps icy particles, then floating in the air, and to the undulations thereby produced. When a hard frost has continued a considerable time, this impediment to distinct observation is in a great measure removed. But I have never enjoyed more accurate and distinct views of the heavenly bodies than in fresh, serene evenings, when there was no frost and no wind, and only a few fleecy clouds occasionally hovering around. On such evenings, and on such alone, the highest powers may be applied. I have used magnifying powers on such occasions with good effect which could not have been applied, so as to insure distinct vision, more frequently than two or three days in the course of a year.

Sir William Herschel has observed, in reference to this point, "In beautiful nights, when the outside of our telescopes is dropping with moisture, discharged from the atmosphere, there are now and then favorable *hours* in which it is hardly possible to put a limit to the magnifying powers; but such valuable opportunities are extremely scarce, and with large instruments it will always be lost labor to observe at other times. In order, therefore, to calculate how long a time it must take to sweep the heavens, as far as they are within the reach of my forty feet telescope, charged with a magnifying power of 1000, I have had recourse to my journals to find how many favorable hours we may annually hope for in this climate; and, under all favorable circumstances, it appears that a year which will afford ninety, or, at most, one hundred *hours*, is to be called very productive." "In the equator, with my twenty feet telescope, I have swept over zones of two degrees with a power of 157, but an allowance of ten minutes in polar distance must be made for lapping the sweeps over one another where they join. As the breadth of the zones may be increased toward the poles, the northern hemisphere may be swept in about 40 zones; to these we must add 19 southern zones; then 59 zones, which, on account of the sweeps lapping over one another about five minutes of time in right ascension, we must reckon of 25 hours each, will give 1475 hours; and allowing 100 hours per year, we find that with the twenty feet telescope the heavens may be swept in about fourteen years and three-quarters. Now the time of sweeping with different magnifying powers will be as the squares of the powers; and putting p and t for the power and time in the twenty feet telescope, and P=1000 for the power in the forty feet instrument, we shall have $p^2 : t : : P^2 : \frac{tP2}{p2} = 59840$. Then, making the same allowance for 100 hours per year, it appears that it will require not less than 598 years to look with the forty feet reflector, charged with the above-mentioned power, only one single moment into each point of space; and even then, so much of the southern hemisphere will remain unexplored as will take up 213 years more to examine."*

From the above remarks of so eminent an observer, the reader will perceive how difficult it is to explore the heavens with minuteness and accuracy, and with how many disappointments, arising from the state of the atmosphere, the astronomer must lay his account, when employed in planetary or sidereal investigation. Beside the circumstances now stated, it ought to be noticed that a star or a planet is only in a situation for a high magnifying power about half the time it is above the horizon. The density of the atmosphere, and the quantity of vapors with which it is charged near the horizon, prevent distinct vision of celestial objects with high powers until they have risen to at least 15 or 20 degrees in altitude, and the highest magnifiers can scarcely be applied with good effect unless the object is near the meridian, and at a considerable elevation above the horizon. If the moon be viewed a little after her rising, and afterward when she comes to her highest elevation in autumn, the difference in her appearance and distinctness will be strikingly perceptible. It is impossible to guess whether a night be well adapted for celestial observations until we actually make the experiment, and instruments are frequently condemned, when tried at improper seasons, when the atmosphere only is in fault. A certain observer remarks, "I have never seen the face of Saturn more distinctly than in a night when the air has been so hazy that with my naked eye I could hardly discern a star of less than the third magnitude. The degree of the transparency of the air is likewise varying almost in the course of every minute, so that even in the course of the same half hour planets and stars will appear perfectly defined, and the reverse. The vapors moving and undulating the atmosphere, even when the sky appears clear to the naked eye, will in a few instants destroy the distinctness of vision, and in a few seconds more the object will resume its clear and well-defined aspect."†

3. *On the magnifying Powers requisite for observing the Phenomena of the different Planets, Comets, double Stars, &c.*—There are some objects connected with astronomy which cannot be perceived without having recourse to instruments and to powers of great magnitude; but it is a vulgar error to imagine that very large and very expensive telescopes are absolutely necessary for viewing the greater part of the more interesting scenery of the heavens. Most of the phenomena of the planets, comets, double stars, and other objects, are visible with instruments of moderate dimensions, so that every one who has a relish for celestial investigations may, at a comparatively small expense, procure a telescope for occasional observations which will show the principal objects and phenomena described in books on astronomy. Many persons have been misled by some occasional remarks which Sir W. Herschel made, in reference to certain very high powers which he sometimes put, by way of experiment, on some of his telescopes, as if these were the powers requisite for viewing the objects to which he refers. For example, it is stated that he once put a power of 6450 times on his seven feet Newtonian telescope of 6 3-10ths inches aperture; but this was only for the purpose of an experiment, and could be of no use whatever when applied to the moon, the planets, and most objects in the heavens. Herschel, through the whole course of his writings, mentions his only having used it *twice*, namely, on the stars α Lyræ and γ Leonis, which stars can be seen more distinctly and sharply defined with a power of 420. To produce a power of 6450 on such a telescope would require a lens of only 1-77th of an inch in focal distance; and it is questioned by some whether Herschel had lenses of so small a size in his possession, or whether it is possible to form them with accuracy.

Powers requisite for observing the Phenomena of the Planets.—The planet *Mercury* requires a considerable magnifying power in order to perceive its phases with distinctness. I have seldom viewed this planet with a less power than 100 and 150, with which powers its half-moon, its gibbous, and its crescent phase may be distinctly perceived. With a power of 40, 50, or even 60 times, these phases can with difficulty be seen, especially as it is generally at a low altitude when such observations are made. The phases of *Venus* are much more easily distinguished, especially the *crescent* phase, which is seen to the greatest advantage about a month before and after the inferior conjunction. With a power not exceeding 25 or 30 times, this phase, at such periods, may be easily perceived. It requires, however, much higher powers to perceive distinctly the variations of the gibbous phase; and if this planet be not viewed at a considerably high altitude when in a half-moon or gibbous phase, the obscurity and undulations of the atmosphere near the horizon prevent such phases from being accurately distinguished, even when high powers are applied. Although certain phenomena of the planets may be seen with such low powers as I have now stated, yet in every instance the highest magnifying powers consistent with distinctness should be preferred, as the eye is not then strained, and the object appears with a greater degree of magnitude and splendor. The planet *Mars* requires a considerable degree of magnifying power, even when at its nearest distance from the earth, in order to discern its spots and its gibbous phase. I have never obtained a satisfactory view of the spots which mark the surface, and their relative position, with a less power than 130, 160, or 200 times; and even with such powers, persons not much accustomed to look through telescopes find a difficulty in distinguishing them.

The strongest and most prominent *belts of Jupiter* may be seen with a power of about 45, which power may be put upon a twenty-inch achromatic or a one foot reflector; but a satisfactory view of all the belts, and the relative positions they occupy, cannot be obtained with much lower powers than 80, 100, or 140. The most common positions of these belts are, one dark and well-defined belt to the south of Jupiter's equator; another of nearly the same description to the north of it, and one about his north and his south polar circles. These polar belts are much more faint, and, consequently, not so easily distinguished as the equatorial belts. The *moons* of this planet, in a very clear night, may sometimes be seen with a pocket one foot achromatic glass magnifying about 15 or 16 times. Some people have pretended that they could see some of these satellites with their naked eye; but this is very doubtful, and it is probable that such persons mistook certain fixed stars which happened to be near Jupiter for his satellites. But, in order to have a clear and interesting view of these, powers of at least 80 or 100 times should be used. In order to perceive their immersions into the shadow of Jupiter, and the exact moment of their emersions from it, a telescope not less than a 44 inch achromatic, with a power of 150, should be employed. When these satellites are viewed through large telescopes with high magnifying powers, they appear with well-defined discs, like small planets. The planet Jupiter has generally been considered as a good test by which to try telescopes for celestial purposes. When it is near the meridian and at a high altitude, if its general surface, its belts, and its margin appear distinct and well-defined, it forms a strong presumptive evidence that the instrument is a good one.

---

* Philosophical Transactions for 1800, vol. xc, p. 80, &c.

† In using telescopes within doors, care should generally be taken that there be no fires in the apartment where they are placed for observation, and that the air within be nearly of the same temperature as the air of the surrounding atmosphere; for if the room be filled with heated air, when the windows are opened there will be a current of cold rushing in, and of heated rushing out, which will produce such an undulation and tremulous motion as will prevent any celestial object from being distinctly seen.

The planet *Saturn* forms one of the most interesting objects for telescopic observation. The *ring* of Saturn may be *seen* with a power of 45; but it can only be contemplated with advantage when powers of 100, 150, and 200 are applied to a three or a five feet achromatic. The *belts of Saturn* are not to be seen distinctly with an achromatic of less than 2¾ths inches aperture, or a Gregorian reflector of less than four inches aperture, nor with a less magnifying power than 100 times. Sir W. Herschel has drawn this planet with five belts across its disc; but it is seldom that above one or two of them can be seen by moderate-sized telescopes and common observers. The *division* of the double ring, when the planet is in a favorable position for observation, and in a high altitude, may sometimes be perceived with a 44 inch achromatic, with an aperture of 2¾ths inches, and with powers of 150 or 180; but higher powers and larger instruments are generally requisite to perceive this phenomenon distinctly; and even when a portion of it is seen at the extremities of the *ansæ*, the division cannot, in every case, be traced along the whole of the half-circumference of the ring which is presented to our eye. Mr. Hadley's engraving of Saturn, in the "Philosophical Transactions" for 1723, though taken with a Newtonian reflector with a power of 228, represents the division of the ring as seen only on the ansæ or extremities of the elliptical figure in which the ring appears. The best period for observing this division is when the ring appears at its utmost width. In this position it was seen in 1840, and it will appear nearly in the same position in 1855. When the ring appears like a very narrow ellipse a short time previous to its disappearance, the division, or dark space between the rings, cannot be seen by ordinary instruments.

Sir W. Herschel very properly observes, "There is not, perhaps, another object in the heavens that presents us with such a variety of extraordinary phenomena as the planet Saturn: a magnificent globe, encompassed by a stupendous double ring; attended by seven satellites; ornamented with equatorial belts; compressed at the poles; turning upon its axis; mutually eclipsing its ring and satellites, and eclipsed by them; the most distant of the rings also turning upon its axis, and the same taking place with the farthest of the satellites; all the parts of the system of Saturn occasionally reflecting light on each other; the rings and moons illuminating the nights of the Saturnian, the globe and satellites enlightening the dark parts of the ring; and the planet and rings throwing back the sun's beams upon the moons, when they are deprived of them at the time of their conjunctions." This illustrious astronomer states that with a new seven feet mirror of extraordinary distinctness he examined this planet, and found that the ring reflects more light than the body, and with a power of 570 the color of the body becomes yellowish, while that of the ring remains more white. On March 11, 1780, he tried the powers of 222, 332, and 440 successively, and found the light of Saturn less intense than that of the ring; the color of the body turning, with the high powers, to a kind of yellow white, while that of the ring still remained white.

Most of the *satellites* of Saturn are difficult to be perceived with ordinary telescopes, excepting the fourth, which may be seen with powers of from 60 to 100 times. It was discovered by Huygens in 1655 by means of a common refracting telescope 12 feet long, which might magnify about 70 times. The next in brightness to this is the fifth satellite, which Cassini discovered in 1671 by means of a 17 feet refractor, which might carry a power of above 80 times. The third was discovered by the same astronomer in 1672 by a longer telescope; and the first and second in 1684, by means of two excellent object-glasses of 100 and 136 feet, which might have magnified from 200 to 230 times. They were afterward seen by two other glasses of 70 and 90 feet, made by Campani, and sent from Rome to the Royal Observatory at Paris by the king's order, after the discovery of the third and fifth satellites. It is asserted, however, that all those five satellites were afterward seen with a telescope of 34 feet, with an aperture of 3-10ths inches, which would magnify about 120 times. These satellites, on the whole, except the fourth and fifth, are not easily detected. Dr. Derham, who frequently viewed Saturn through Huygens' glass of 126 feet focal length, declares, in the preface to his "Astro-Theology," that he could never perceive above three of the satellites. Sir W. Herschel observes, that the visibility of these minute and extremely faint objects depends more on the *penetrating* than upon the *magnifying* power of our telescopes; and that with a ten feet Newtonian, charged with a magnifying power of only 60, he saw all the five old satellites; but the sixth and seventh, which were discovered and were easily seen with his forty feet telescope, and were also visible in his twenty feet instrument, were not discernible in the seven or the ten feet telescopes, though all that *magnifying power* can do may be done as well with the seven feet as with any larger instrument. Speaking of the seventh satellite, he says, "Even in my forty feet reflector it appears no bigger than a very small lucid point. I see it, however, very well in the twenty feet reflector, to which the exquisite figure of the speculum not a little contributes." A late observer asserts that in 1825, with a twelve feet achromatic, of seven inches aperture, made by Tulley, with a power of 150, the seven satellites were easily visible, but not so easily with a power of 200; and that the planet appeared as bright as brilliantly burnished silver, and the division in the ring and a belt were very plainly distinguished with a power of 200.

The planet *Uranus*, being generally invisible to the naked eye, is seldom an object of attention to common observers. A considerable magnifying power is requisite to make it appear in a planetary form with a well-defined disc. The best periods for detecting it are when it is near its opposition to the sun, or when it happens to approximate to any of the other planets, or to a well known fixed star. When none of these circumstances occur, its position requires to be pointed out by an equatorial telescope. On the morning of the 25th of January, 1841, this planet happened to be in conjunction with Venus, at which time it was only four minutes north of that planet. Several days before this conjunction I made observations on Uranus. On the evening of the 24th, about eight hours before the conjunction, the two planets appeared in the same field of the telescope, the one exceedingly splendid, and the other more obscure, but distinct and well-defined. Uranus could not be perceived either with the naked eye or with an opera-glass, but could be distinguished as a very small star by means of a pocket achromatic telescope magnifying about 14 times. It is questionable whether, under the most favorable circumstances, this planet can ever be distinguished by the naked eye. With magnifying powers of 30 and 70, it appeared as a moderately large star with a steady light, but without any sensible disc. With powers of 120, 180, and 250, it presented a round and pretty well-defined disc, but not so luminous and distinct as it would have done in a higher altitude.

The *Double Stars* require a great *variety* of powers in order to distinguish the small stars that accompany the larger. Some of them are distinguished with moderate powers, while others require pretty large instruments, furnished with high magnifying eyepieces. I shall therefore select only a few as a specimen. The star *Castor*, or α Geminorum, may be easily seen to be double with powers of from 70 to 100. I have sometimes seen these stars, which are nearly equal in size and color, with a terrestrial power of 44 on a 44 inch achromatic. The appearance of this star with such powers is somewhat similar to that of η Coronæ in a seven feet achromatic of five inches aperture, with a power of 500. γ Andromedæ may be seen with a moderate power. In a thirty inch achromatic of two inches aperture and a power of 80, it appears like ε Bootis when seen in a five feet achromatic with a power of 460. This star is said to be visible even in a one foot achromatic with a power of 35. ε Lyræ, which is a quintuple star, but appears to the naked eye as a single star, may be seen to be double with a power of from six to twelve times. γ *Leonis* is visible in a 44 inch achromatic with a power of 180 or 200. *Rigel*, in a 3½ feet achromatic, may be seen with powers varying from 130 to 200. The small star, however, which accompanies Rigel, is sometimes difficult to be perceived, even with such powers. ε *Bootis* is seldom distinctly defined with an achromatic of less aperture than 3¼ inches, or a reflector of less than five inches, with a power of at least 250.

These and similar stars are not to be expected to be seen equally well at all times, even when the magnifying and illuminating powers are properly proportioned, as much depends upon the state of the weather, and the pureness of the atmosphere. In order to perceive the closest of the double stars, Sir W. Herschel recommends that the power of the telescope should be adjusted upon a star known to be single, of nearly the same altitude, magnitude, and color with the double star which is to be observed, or upon one star above and another below it. Thus the late Mr. Albert, the astronomer, could not see the two stars of γ Leonis when the focus was adjusted upon that star itself, but he soon observed the small star after he had adjusted the focus upon Regulus. An exact adjustment of the focus of the instrument is indispensably requisite in order to perceive such minute objects.

In viewing the *Nebulæ*, and the very small and immensely distant fixed stars, which require much light to render them visible, a large aperture of the object-glass or speculum, which admits of a great quantity of light, is of more importance than high magnifying powers. It is light chiefly, accompanied with a moderate magnifying power, that enables us to *penetrate* into the distant regions of space. Sir W. Herschel, when sweeping the profundities of the Milky Way, and the Hand and Club of Orion, used a telescope of the Newtonian form, 20 feet focal length and 18 7-10ths inches in diameter, with a power of only 157. On applying this telescope and power to a part of the *Via Lactea*, he found that it completely resolved the whole whitish appearance into stars, which his former telescopes had not light enough to effect, and which smaller instruments with much higher magnifying powers would not have effected. He tells us that, with this power, "the glorious multitude of stars," in the vicinity of Orion, "of all possible sizes, that presented themselves to view, was truly astonishing, and that he had fields which contained 70, 90, and 110 stars, so that a belt of fifteen degrees long and two degrees broad, which passed through the field of the telescope in an hour, could not contain less than fifty thousand stars that were large enough to be distinctly numbered." In viewing the Milky Way, the Nebulæ, and small clusters of stars, such as *Præsepe* in Cancer, I generally use a power of 55 times on an achromatic telescope six feet six inches in focal length and four inches in diameter. The eyepiece which produces this power—which I formed for the purpose—consists of two convex lenses, the one next the eye three inches focal length and 1 2-10ths of an inch diameter, and that next the object 3½ inches focus and 1 4-10ths of an inch diameter, the deepest convex surfaces being next each other, and their distance a quarter of an inch. With this eyepiece a very large and brilliant field of view is obtained; and I find it preferable to any higher powers in viewing the nebulosities and clusters of stars. In certain spaces of the heavens it sometimes presents in one field nearly a hundred stars. It likewise serves to exhibit a very clear and interesting view of the full moon.

In observing *Comets*, a very small power should generally be used, even on large instruments. These bodies possess so small a quantity of light, and they are so frequently enveloped in a vail of dense atmosphere, that *magnifying* power sometimes renders them more obscure, and therefore the *illuminating* power of a large telescope with a small power is in all cases to be preferred. A comet eyepiece should be constructed with a very large and uniformly distinct field, and should magnify only from 15 to 30 or 40 times, and the lenses of such an eyetube should be nearly two inches in diameter. The late Rev. F. Wollaston recommended, for observing comets, "a telescope with an achromatic object-glass of 16 inches focal length and two inches aperture, with a Ramsden's eyeglass magnifying about 25 times, mounted on a very firm equatorial stand, the field of view taking in two degrees of a great circle."

In viewing the *moon*, various powers may be applied, according to circumstances. The best periods of the moon for inspecting the inequalities on its surface are either when it assumes a crescent or a half-moon phase, or two or three days after the period of half-moon. Several days after full moon, and particularly about the third quarter, when the orb is waning, and when the shadows of its mountains and vales are thrown in a different direction from what they are when on the increase, the most prominent and interesting views may be obtained. The most convenient season for obtaining such views is during the autumnal months, when the moon, about the third quarter, sometimes rises as early as eight o'clock, P. M., and may be viewed at a considerably high altitude by ten or eleven. When in the positions now alluded to, and at a high altitude, very high magnifying powers may sometimes be applied with good effect, especially if the atmosphere be clear and serene. I have sometimes applied a power, in such cases, of 350 times on a 46 inch achromatic with considerable distinctness; but it is only two or three times in a year, and when the atmosphere is remarkably favorable, that such a power can be used. The autumnal evenings are generally best fitted for such observations. The *full moon* is an object which is never seen to advantage with high powers, as no shadows or inequalities on its surface can then be perceived. It forms, however, a very beautiful object when magnifying powers not higher than 40, 50, or 60 times are used. A power of 45 times, if properly constructed, will show the *whole of the moon* with a margin around it, when the darker and brighter parts of its surface will present a variegated aspect, and appear somewhat like a map to the eye of the observer.

4. *Mode of exhibiting the Solar Spots.*—The solar spots may be contemplated with advantage by magnifying powers varying from 60 to 180 times; about 90 times is a good medium power, though they may sometimes be distinguished with very low powers, such as those usually adapted to a one foot telescope, or even by means of a common opera glass. The common astronomical eyepieces given along with achromatic telescopes, and the sunglasses connected with them, are generally ill adapted for taking a pleasant and comprehensive view of the solar spots. In the higher magnifying powers, the first eyeglass is generally at too great a distance from the eye, and the sunglass which is screwed over it removes it to a still greater distance from the point to which the eye is applied, so that not above one-third of the field of view can be taken in. This circumstance renders it difficult to point the instrument to any particular small spot on the solar disc which we wish minutely to inspect; and beside, it prevents us from taking a comprehensive view of the *relative positions* of all the spots that may at any time be traversing the disc. To obviate this inconvenience, the sunglass would require to be placed so near to the glass next the eye as almost to touch it. But this is sometimes difficult to be attained, and in high powers even the thickness of the sunglass itself is sufficient to prevent the eye from taking in the whole field of view. For preventing the inconveniences to which I now allude, I generally make use of a *terrestrial* eyepiece of a considerable power, with a large field; the sunglass is fixed at the end of a short tube, which slides on the eyepiece, and permits the colored glass to approach within a line or two of the lens next the eye, so that the whole field of the telescope is completely secured. The eyepiece alluded to carries a magnifying power of 95 times for a 46 inch telescope, and takes in about three-fourths of the surface of the sun, so that the relative positions of all the spots may generally be perceived at one view. Such a power is, in most cases, quite sufficient for ordinary observations, and I have seldom found any good effect to arise from attempting very high powers when minutely examining the solar spots.

But the most pleasant mode of viewing the solar spots, especially when we wish to exhibit them to others, is to throw the image of the sun upon a white screen, placed in a room which is considerably darkened. It is difficult, however, when the sun is at a high altitude, to put this method into practice, on account of the great obliquity with which his rays then fall, which prevents a screen from being placed at any considerable distance from the eye-end of the telescope. The following plan, therefore, is that which I uniformly adopt, as being both the easiest and the most satisfactory. A telescope is placed in a convenient position, so as to be directed to the sun. This telescope is furnished with a *diagonal eyepiece*, such as that represented in fig. 77 (p. 97). The window-shutters of the apartment are all closed excepting a space sufficient to admit the solar rays; and when the telescope is properly adjusted, a beautiful image of the sun, with all the spots which then happen to diversify his surface, is thrown upon the *ceiling* of the room. This image may be from 12 to 20, or 30 inches or more in diameter, according to the distance of the ceiling from the diagonal eyepiece. The greater this distance is, the larger the image. If the sun is at a very high altitude, the image will be elliptical; if he be at no great distance from the horizon, the image will appear circular, or nearly so; but in either case the spots will be distinctly depicted, provided the focus of the telescope be accurately adjusted. In this exhibition, the apparent motion of the sun produced by the rotation of the earth, and the passage of thin fleeces of clouds across the solar disc, exhibit a very pleasing appearance.

By this mode of viewing the solar spots we may easily ascertain their diameter and magnitude, at least to a near approximation. We have only to take a scale of inches, and measure the diameter of any well-defined and remarkable spot, and then the diameter of the solar image; and, comparing the one with the other, we can ascertain the number of miles, either lineal or square, comprehended in the dimensions of the spot. For example, suppose a spot to measure half an inch in diameter, and the whole image of the sun 25 inches, the proportion between the diameter of the spot and that of the sun will be as 1 to 50; in other words, the *one-fiftieth* part of the sun's diameter. Now this diameter being 880,000 miles, this number, divided by 50, produces a quotient of 17,600=the number of miles which its diameter measures. Such a spot will therefore contain an area of 243,285,504, or more than two hundred and forty-three millions of square miles, which is 46 millions of miles more than the whole superficies of the terraqueous globe. Again, suppose the diameter of a spot measures 3-10ths of an inch, and the solar image 23 inches, the proportion of the diameter of the spot to that of the sun is as 3 to 230—the number of tenths in 23 inches. The number of miles in the spot's diameter will therefore be found by the following proportion: 230 : 880,000 :: 3 : 11,478; that is, the diameter of such a spot measures eleven thousand four hundred and seventy-eight miles. Spots of such sizes are not unfrequently seen to transit the solar disc.

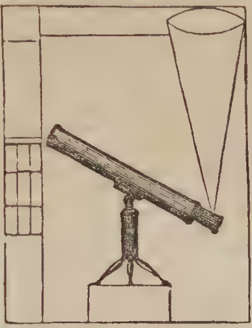
By this mode of viewing the image of the sun, his spots may be exhibited to twenty or thirty individuals at once without the least straining or injury to the eyes; and as no separate screen is requisite, and as the ceilings of rooms are generally white, the experiment may be performed in half a minute without any previous preparation except screwing on and adjusting the eyepiece. The manner of exhibiting the solar spots in this way is represented in fig. 82.

5. *On the Space-penetrating Power of Telescopes.*—The power of telescopes to penetrate into the profundity of space is the result of the quantity of light they collect and send to the eye in a state fit for vision. This property of telescopes is sometimes designated by the expression *Illuminating Power.*

Sir W. Herschel appears to have been the first who made a distinction between the *magnifying* power and the *space-penetrating* power of a telescope; and there are many examples which prove that such a distinction ought to be made, especially in the case of large instruments. For example, the small star, or speck of light which accompanies the pole-star, may be seen through a telescope of large aperture with a smaller magnifying power than with a telescope of a small aperture furnished with a much higher power. If the magnifying power is sufficient to show the small star completely separated from the rays which surround the large one, this is sufficient, in one point of view; but, in order that this effect may be produced, so as to render the small star perfectly distinguishable, a certain quantity of light must be admitted into the pupil of the eye, which quantity depends upon the area of the object-glass or speculum of the instrument, or, in other words, on the illuminating power. If we compare a telescope of 2¾ths inches aperture with one of five inches aperture, when the magnifying power of each does not exceed 50 times for terrestrial objects, the effect of illuminating power is not so evident; but if we use a power of 100 for day objects, and 180 for the heavenly bodies, the effects of illuminating power is so clearly perceptible, that objects not only appear brighter and more clearly visible in the larger telescope, but with the same magnifying power they also *appear* larger, particularly when the satellites of Jupiter and small stars are the objects we are viewing.

Sir W. Herschel remarks, that "objects are viewed in their greatest perfection when, in penetrating space, the magnifying power is so low as only to be sufficient to show the object well, and when, in magnifying objects, by way of examining them minutely, the space-penetrating power is no higher than what will suffice for the purpose; for in the use of either power, the injudicious overcharge of the other will prove hurtful to vision." When illuminating power is in too high a degree, the eye is offended by the extreme brightness of the object; when it is in too low a degree, the eye is distressed by its endeavors to see what is beyond its reach; and therefore it is desirable, when we wish to give the eye all the assistance possible, to have the illuminating and the magnifying powers in due proportion. What this proportion is, depends, in a certain degree, upon the brightness of the object. In proportion to its brightness or luminosity, the magnifying power may, to a certain extent, be increased. Sir W. Herschel remarks in reference to α Lyræ, "This star, I surmise, has light enough to bear being magnified at least a hundred thousand times, with no more than six inches of aperture." However beautifully perfect any telescopes may appear, and however sharp their *defining* power, their performance is limited by their illuminating powers, which are as the squares of the diameters of the apertures of the respective instruments. Thus a telescope whose object-glass is four inches diameter will have four times the quantity of light, or illuminating power, possessed by a telescope whose aperture is only two inches, or in the proportion of 16 to 4; the square of 4 being 16, and the square of 2 being 4.

Fig. 82.



The nature of the *space-penetrating power* to which we are adverting, and the distinction between it and magnifying power, may be illustrated from a few examples taken from Sir W. Herschel's observations.

The first observation which I shall notice refers to the *nebula* between η and ζ Ophiuchi, discovered by Messier in 1764. The observation was made with a ten feet reflector, having a magnifying power of 250, and a space-penetrating power of 28.67. His note is dated May 3, 1783. "I see several stars in it, and make no doubt a higher power and more light will resolve it all into stars. This seems to me a good nebula for the purpose of establishing the connection between nebulæ and clusters of stars in general." "June 18, 1784. The same nebula viewed with a Newtonian twenty feet reflector; penetrating power 61, and a magnifying power of 157; a very large and a very bright cluster of excessively compressed stars. The stars are but just visible, and are of unequal magnitudes. The large stars are red; the cluster is a miniature of that near Flamstead's forty-second Comæ Berenices. Right ascension, 17h. 6m. 32s. Polar distance, 108° 18′." In this case, a penetrating power of about 28, with a magnifying power of 250, barely showed a few stars; while in the second instrument the illuminating power of 60, with the magnifying power of only 157, showed them completely.

Subsequently to the date of the latter observation, the twenty feet Newtonian telescope was converted into an Herschelian instrument by taking away the small speculum, and giving the large one the proper inclination for obtaining the front view; by which alteration the illuminating power was increased from 61 to 75, and the advantage derived from the alteration was evident in the discovery of the satellites of Uranus by the altered telescope, which before was incompetent in the point of penetration, or illuminating power. "March 14, 1798, I viewed the Georgian planet (or Uranus) with a new twenty-five feet reflector. Its penetrating power is 95.85, and having just before also viewed it with my twenty feet instrument, I found that with an equal magnifying power of 300, the twenty-five feet telescope had considerably the advantage of the former." The aperture of the twenty feet instrument was 18.8 inches, and that of the twenty-five feet telescope 24 inches, so that the superior effect of the latter instrument must have been owing to its greater illuminating power. The following observations show the superior power of the forty feet telescope, as compared with the twenty feet. "Feb. 24, 1786, I viewed the nebula near Flamstead's fifth Serpentis with my twenty feet reflector, magnifying power 157. The most beautiful, extremely compressed cluster of small stars, the greatest part of them gathered together into one brilliant nucleus, evidently consisting of stars, surrounded with many detached gathering stars of the same size and color. R. A., 15h. 7m. 12s. P. D. 87° 8″." "May 27, 1791, I viewed the same object with my forty feet telescope, penetrating power 191.69, magnifying power 370. A beautiful cluster of stars. I counted about 200 of them. The middle of it is so compressed that it is impossible to distinguish the stars." "Nov. 5, 1791, I viewed Saturn with the twenty and forty feet telescopes. *Twenty feet.*—The fifth satellite of Saturn is very small. The first, second, third, fourth and fifth, and the new sixth satellites are in their calculated places. *Forty feet.*—I see the new sixth satellite much better than with the twenty feet. The fifth is also much larger here than in the twenty feet, in which it was nearly the same size as a small fixed star, but here it is considerably larger than that star."

These examples, and many others of a similar kind, explain sufficiently the nature and extent of that species of power that one telescope possesses over another, in consequence of its enlarged aperture; but the exact quantity of this power is in some degree uncertain. To ascertain practically the illuminating power of telescopes, we must try them with equal powers on such objects as the following: the small stars near the pole-star, and near Rigel and ι Bootis; the division in the ring of Saturn; and distant objects in the twilight or toward the evening. These objects are distinctly seen with a five feet achromatic of 3 8-10ths inches aperture, and an illuminating power of 144, while they are scarcely visible in a 3½ feet with an aperture of 2¾ths inches, and an illuminating power of 72, supposing the same magnifying power to be applied. The illuminating power of a telescope is best estimated, in regard to land objects, when it is tried on minute objects, and such as are badly lighted up; and the advantage of a telescope with a large aperture will be most obvious when it is compared with another of inferior size in the close of the evening, when looking at a printed bill composed of letters of various sizes. As darkness comes on, the use of illuminating power becomes more evident. In a five feet telescope some small letters will be legible which are hardly discernible in the 3½ feet, and in the 2½ feet are quite undefinable, though the magnifying powers be equal. Sir W. Herschel informs us that, in the year 1776, when he had erected a telescope of twenty feet focal length of the Newtonian construction, one of its effects by trial was, that when, toward evening, on account of darkness, the natural eye could not penetrate far into space, the telescope possessed that power sufficiently to show, by the dial of a distant church steeple, what o'clock it was, notwithstanding the naked eye could no longer see the steeple itself.

In order to convey an idea of the *numbers* by which the degree of space-penetrating power is expressed, and the general grounds on which they rest, the following statements may be made. The depth to which the naked eye can penetrate into the spaces of the heavens is considered as extending to the twelfth order of distances; in other words, it can perceive a star at a distance twelve times farther than those luminaries, such as Sirius, Arcturus, or Capella, which, from their vivid light, we presume to be nearest to us. It has been stated above that Herschel calculated his ten feet telescope to have a space-penetrating power of 28.67, that is, it could enable us to descry a star 28 times farther distant than the naked eye can reach. His twenty feet Newtonian was considered as having a similar power of 61; his 25 feet, nearly 96; and his forty feet instrument, a power of 191.69. If each of these numbers be multiplied by 12, the product will indicate how much farther these telescopes will penetrate into space than the nearest range of the fixed stars, such as those of the first magnitude. For instance, the penetrating power of the forty feet reflector being 191.69, this number, multiplied by 12, gives a product of 2300, which shows that, were there a series of two thousand three hundred stars extended in a line beyond Sirius, Capella, and similar stars, each star separated from the one beyond it by a space equal to the distance of Sirius from the earth, they might be all seen through the forty-feet telescope In short, the penetrating power of telescopes is a circumstance which requires to be particularly attended to in our observations of celestial phenomena, and in many cases is of more importance than *magnifying* power. It is the effect produced by illuminating power that renders telescopes, furnished with comparatively small magnifying powers, much more efficient in observing comets, and certain nebulæ and clusters of stars, than when high powers are attempted. Every telescope may be so adjusted as to produce different space-penetrating powers. If we wish to diminish such a power, we have only to contract the object-glass or speculum by placing circular rims, or apertures of different degrees of breadth, across the mouth of the great tube of the instrument. But we cannot increase this illuminating power beyond a certain extent, which is limited by the diameter of the object-glass. When we wish illuminating power beyond this limit, we must be furnished with an object-glass or speculum of a larger size; and hence the rapid advance in price of instruments which have large apertures, and consequently high illuminating powers. Mr. Tulley's 3½ feet achromatics of 2¾ths inches aperture sell at £26 5s.; when the aperture is 3¼th inches, the price is £42; when 3¾inches, £68 5s. The following table contains a statement of the "comparative lengths, apertures, illuminating powers, and prices of achromatic refractors and Gregorian reflectors," according to Dr. Kitchener:

The illuminating powers stated in the following table are only comparative. Fixing on the number 25 as the illuminating power of a two feet telescope, 1 6-10ths of an inch aperture, that of a 2½ feet, two inches aperture, will be 40; of a five feet, 3 8-10ths inches aperture, 144, &c. If the illuminating power of a Gregorian 1½ foot, and three inches aperture, be 90, a five feet, with nine inches aperture, will be 810, &c.

6. *On choosing Telescopes, and ascertaining their Properties.*—It is an object of considerable importance to every astronomical observer that he should be enabled to form a judgment of the qualities of his telescope, and of any instruments of this description which he may intend to purchase. The following directions may perhaps be useful to the reader in directing him in the choice of an achromatic refracting telescope:

Supposing that an achromatic telescope of 3½ feet focal length and 3¼th inches aperture were offered for sale, and that it were required to ascertain whether the object-glass, on which its excellence chiefly depends, is a good one, and duly adjusted, some opinion may be formed by laying the tube of the telescope in a horizontal position, on a firm support, about the hight of the eye, and by placing a printed card or a watch-glass vertically, but in an inverted position, against some wall or pillar at 40 or 50 yards distant, so as to be exposed to a clear sky. When the telescope is directed to this object, and accurately adjusted to the eye, should the letters on the card, or the strokes and dots on the watch glass, appear clearly and sharply defined, without any mistiness or coloration, and if very small spots appear well-defined, great hopes may be entertained that the glass will turn out a good one. But a telescope may appear a good one, when viewing common terrestrial objects, to eyes unaccustomed to discriminate deviations from perfect vision, while it may turn out to be an indifferent one when directed to certain celestial objects. Instead, therefore, of a printed card, fix a black board, or one-half of a sheet of black paper, in a vertical position at the same distance, and a circular disc of white writing paper, about one-fourth of an inch in diameter, on the center of the black ground; then, having directed the telescope to this object, and adjusted for the place of distinct vision, mark with a black-lead pencil the sliding eyetube at the end of the main tube, so that this position can always be known; and if this sliding tube be gradually drawn out or pushed in while the eye beholds the disc, it will gradually enlarge and lose its color until its edges cease to be well-defined. Now if the enlarged misty circle is observed to be concentric with the disc itself, the object-glass is properly centered, as it has reference to the tube; but if the misty circle goes to one side of the disc, the cell of the object-glass is not at right angles to the tube, and must have its screws removed and its holes elongated by a rat-tailed file small enough to enter the holes. When this has been done, the cell may be replaced, and the disc examined a second time, and a slight stroke on one edge of the cell by a wooden mallet will show by the alteration made in the position of the misty portion of the disc how the adjustment is to be effected, which is known to be right when a motion in the sliding tube will make the diluted disc enlarge in a circle concentric with the disc itself When the disc will enlarge so as to make a ring of diluted white light round its circumference, as the sliding tube holding the eyepiece is pushed in or drawn out, the cell may be finally fixed by the screws passing through its elongated holes.

When the object-glass is thus adjusted, it may then be ascertained whether the curves of the respective lenses composing the object-glass are well formed, and suitable for each other. If a small motion of the sliding tube of about 1-10th of an inch in a 3½ feet telescope from the point of distinct vision will dilute the light of the disc and render the appearance confused, the figure of the object-glass is good, particularly if the same effect will take place at equal distances from the point of distinct vision when the tube is alternately drawn out and pushed in. A telescope that will admit of much motion in the sliding tube, without sensibly affecting the distinctness of vision will not define an object well at any point of adjustment, and must be considered as having an imperfect object-glass, inasmuch as the spherical aberration of the transmitted rays is not duly corrected. The due adjustment of the convex lens or lenses to the concave one will be judged of by the absence of coloration round the enlarged disc, and is a property distinct from the spherical aberration; the achromatism depending on the relative focal distances of the convex and concave lenses is regulated by the relative dispersive powers of the pieces of glass made use of, but the distinctness of vision depends on a good figure of the computed curves that limit the focal distances. When an object-glass is free from imperfection in both these respects, it may be called a good glass for terrestrial purposes.

It still, however, remains to be determined how far such an object-glass may be good for viewing a star or a planet, and can only be known by actual observations on the heavenly bodies. When a good telescope is directed to the moon or to Jupiter, the achromatism may be judged of by alternately pushing in and drawing out the eyepiece from the place of distinct vision. In the former case, a ring of purple will be formed round the edge; and in the latter, a ring of light green, which is the central color of the prismatic spectrum; for these appearances show that the extreme colors, red and violet, are corrected. Again, if one part of a lens employed have a different refractive power from another part of it, that is, if the flint-glass particularly is not homogeneous, a star of the first and even of the second magnitude will point out the natural defect by the exhibition of an irradiation, or what is called *a wing*, at one side, which no perfection of figure or of adjustment will banish, and the greater the aperture, the more liable is the evil to happen: hence caps with different apertures are usually supplied with large telescopes, that the extreme parts of the glass may be cut off in observations requiring a round and well-defined image of the body observed.

Another method of determining the figure and quality of an object-glass is by first covering its center by a circular piece of paper, as much as one-half of its diameter, and adjusting it for distinct vision of a given object, such as the disc above-mentioned, when the central rays are intercepted, and then trying if the focal length remains unaltered when the paper is taken away and an aperture of the same size applied, so that the extreme rays may in their turn be cut off. If the vision remains equally distinct in both cases, without any new adjustment for focal distance, the figure is good, and the spherical aberration cured, and it may be seen by viewing a star of the first magnitude successively in both cases, whether the irradiation is produced more by the extreme or by the central parts of the glass; or, in case the one-half be faulty and the other good, a semicircular aperture, by being turned gradually round in trial, will detect what semicircle contains the defective portion of the glass; and if such portion should be covered, the only inconvenience that would ensue would be the loss of so much light as is thus excluded. When an object-glass produces radiations in a large star, it is unfit for the nicer observations of astronomy, such as viewing double stars of the first class. The smaller a large star appears in any telescope, the better is the figure of the object-glass; but if the image of the star be free from wings, the size of its disc is not an objection in practical observations.*

Some opticians are in the habit of inserting a diaphragm into the body of the large tube, to cut off the extreme rays coming from the object-glass when the figure is not good, instead of lessening the aperture by a cap. When this is the case, a deficiency of light will be the consequence beyond what the apparent aperture warrants. It is therefore proper to examine that the diaphragm be not placed too near the object-glass, so as to intercept any of the useful rays. Sometimes a portion of the object-glass is cut off by the stop in the eyetube. To ascertain this, adjust the telescope to distinct vision, then take out the eyeglasses, and put your finger on some other object on the edge of the outside of the object-glass, and look down the tube; if you can see the top of your finger, or any object in its place, just peeping over the edge of the object-glass, no part is cut off. I once had a 3½ feet telescope whose object-glass measured three inches in diameter, which was neither so bright, nor did it perform in other respects nearly so well as another of the same length whose object-glass was only 2¾ths inches in diameter; but I found that a diaphragm was placed about a foot within the end of the large tube, which reduced the aperture of the object-glass to less than 2⅙ inches, and when it was removed the telescope was less distinct than before. The powers given along with this instrument were much lower than usual, none of them exceeding 100 times. This is a trick not uncommon with some opticians.

Dr. Pearson mentions that an old Dollond's telescope of 63 inches focal length and 3¾ths inches aperture, supposed to be an excellent one, was brought to Mr. Tulley when he was present, and the result of the examination was that its achromatism was not perfect. The imperfection was thus determined by experiment. A small glass globe was placed at forty yards' distance from the object-end of the telescope when the sun was shining, and the speck of light seen reflected from this globe formed a good substitute for a large star, as an object to be viewed. When the focal length of the object-glass was adjusted to this luminous object, no judgment could be formed of its prismatic aberrations until the eyepiece had been pushed in beyond the place of correct vision; but when the telescope was shortened a little, the luminous disc occasioned by such shortening was strongly tinged with *red* rays at its circumference. On the contrary, when the eyepiece was drawn out so as to lengthen the telescope too much, the disc thus produced was tinged with a small circle of *red* at its *center*, thereby denoting that the convex lens had too short a focal length; and Mr. Tulley observed, that if one or both of the curves of the convex lens were flattened until the total focal length should be about four inches increased, it would render the telescope quite achromatic, provided in doing this the aberration should not be increased.

The following general remarks may be added: 1. To make anything like an accurate comparison of telescopes, they must be tried not only at the same place, but as nearly as possible at the same time, and, if the instruments are of the same length and construction, if possible, with the same eyepiece. 2. A difference of eight or ten times in the magnifying power will sometimes, on certain objects, give quite a different character to a telescope. It has been found by various experiments that object-glasses of two or three inches longer focus will produce different vision with the same eyepiece. 3. Care must be taken to ascertain that the eyeglasses are perfectly clean and free from defects. The defects of glass are either from veins, specks, scratches, color, or an incorrect figure. To discover veins in an eye or an object-glass, place a candle at the distance of four or five yards; then look through the glass, and move it from your eye until it appear full of light; you will then see every vein, or other imperfection in it, which may distort the objects and render vision imperfect. Specks or scratches, especially in object-glasses, are not so injurious as veins, for they do not distort the object, but only intercept a portion of the light. 4. We cannot judge accurately of the excellence of any telescope by observing objects with which we are not familiarly acquainted. Opticians generally try an instrument at their own marks, such as the dial-plate of a watch, a finely engraved card, a weathercock, or the moon and the planet Jupiter, when near the meridian. Of several telescopes of the same length, aperture, and magnifying power, that one is generally considered the best with which we can read a given print at the greatest distance, especially if the print consists of *figures*, such as a table of logarithms, where the eye is not apt to be deceived by the imagination in *guessing* at the sense of a passage when two or three words are distinguished.

There is a circumstance which I have frequently noticed in reference to achromatic telescopes, particularly those of a small size, and which I have never seen noticed by any optical writer. It is this: if the telescope, when we are viewing objects, be gradually turned round its axis, there is a certain position in which the objects will appear distinct and accurately defined; and if it be turned round exactly a semicircle from this point, the same degree of distinctness is perceived, but in all other positions there is an evident want of clearness and defining power. This

---

* The above directions and remarks are abridged with some alterations from Dr. Pearson's "Introduction to Practical Astronomy," vol. ii.

I find to be the case in more than ten one-foot and two-feet telescopes now in my possession, and therefore I have put marks upon the object-end of each of them to indicate the positions in which they should be used for distinct observation. This is a circumstance which requires, in many cases, to be attended to in the choice and the use of telescopical instruments, and in fixing and adjusting them on their pedestals. In some telescopes this defect is very striking, but it is in some measure perceptible in the great majority of instruments which I have had occasion to inspect. Even in large and expensive achromatic telescopes this defect is sometimes observable. I have an achromatic whose object-glass is 4 1-10th inches in diameter, which was much improved in its defining power by being unscrewed from its original position, or turned round its axis about one-eighth part of its circumference. This defect is best detected by looking at a large printed bill, or a signpost at a distance, when on turning round the telescope or object-glass, the letters will appear much better defined in one position than in another. The position in which the object appears least distinct is when the upper part of the telescope is a quadrant of a circle different from the two positions above stated, or at an equal distance from each of them.

7. *On the mode of determining the magnifying power of Telescopes.*—In regard to refracting telescopes, we have already shown that, when a single eyeglass is used, the magnifying power may be found by dividing the focal distance of the object-glass by that of the eyeglass; but when a Huygenian eyepiece, or a four-glass terrestrial eyepiece, such as is now common in achromatic telescopes, is used, the magnifying power cannot be ascertained in this manner; and in some of the delicate observations of practical astronomy, it is of the utmost importance to know the exact magnifying power of the instrument with which the observations are made, particularly when micrometrical measurements are employed to obtain the desired results. The following is a general method of finding the magnifying powers of telescopes when the instrument called a *dynameter* is not employed, and it answers for refracting and reflecting telescopes of every description.

Having put up a small circle of paper an inch or two in diameter at the distance of about 100 yards, draw upon a card two black parallel lines, whose distance from each other is equal to the diameter of the paper circle; then view through the telescope the paper circle with one eye, and the parallel lines with the other, and let the parallel lines be moved nearer to or farther from the eye, until they seem exactly to cover the small circle viewed through the telescope; the quotient obtained by dividing the distance of the paper circle by the distance of the parallel lines from the eye will be the magnifying power of the telescope. It requires a little practice before this experiment can be performed with accuracy. The one eye must be accustomed to look at an object near at hand, while the other is looking at a more distant object through the telescope. Both eyes must be open at the same time, and the image of the object seen through the telescope must be brought into apparent contact with the real object near at hand. But a little practice will soon enable any observer to perform the experiment with ease and correctness, if the telescope be mounted on a firm stand, and its elevation or depression produced by rack-work.

The following is another method founded on the same principle: Measure the space occupied by a number of the courses, or rows of bricks in a modern building, which, upon an average, is found to have eight courses in two feet, so that each course or row is three inches. Then cut a piece of paper three inches in hight, and of the length of a brick, which is about nine inches, so that it may represent a brick, and fixing the paper against the brick wall, place the telescope to be examined at the distance of about 80 or 100 yards from it. Now, looking through the telescope at the paper with one eye, and at the same time, with the other eye, looking past the telescope, observe what extent of wall the magnified image of the paper appears to cover; then count the courses of bricks in that extent and it will give the magnifying power of the telescope. It is to be observed, however, that the magnifying power determined in this way will be a fraction greater than for very distant objects, as the focal distance of the telescope is necessarily lengthened in order to obtain distinct vision of near objects.

In comparing the magnifying powers of two telescopes, or of the same telescope when different magnifying powers are employed, I generally use the following simple method. The telescopes are placed at eight or ten feet distance from a window, with their eye-ends parallel to each other, or at the same distance from the window. Looking at a distant object, I fix upon a portion of it whose magnified image will appear to fill exactly two or three panes of the window; then, putting on a different power, or looking through another telescope, I observe the same object, and mark exactly the extent of its image on the window-panes, and compare the extent of the one image with the other. Suppose, for example, that the one telescope has been previously found to magnify ninety times, and that the image of the object fixed upon exactly fills three panes of the window, and that with the other power or the other telescope the image fills exactly two panes, then the magnifying power is equal to two-thirds of the former, or sixty times; and were it to fill only one pane, the power would be about thirty times A more correct method is to place at one side of the window a narrow board two or three feet long, divided into fifteen or twenty equal parts, and observe how many of these parts appear to be covered by the respective image of the different telescopes. Suppose, in the one case, ten divisions to be covered by the image in a telescope magnifying ninety times, and that the image of the same object in another telescope measures six divisions, then its power is found by the following proportion: 10: 90: : 6: 54; that is, this telescope magnifies 54 times.

Another mode which I have used for determining, to a near approximation, the powers of telescopes, is as follows: Endeavor to find the focus of a single lens which is exactly equivalent to the magnifying power of the eyepiece, whether the Huygenian or the common terrestrial eyepiece. This may be done by taking a small lens, and using it as an object-glass to the eyepiece. Looking through the eyepiece to a window, and holding the lens at a proper distance, observe whether the image of one of the panes exactly coincides with the pane as seen by the naked eye; if it does, then the magnifying power of the eyepiece is equal to that of the lens. If the lens be half an inch in focal length, the eyepiece will produce the same magnifying power as a single lens when used as an eyeglass to the telescope, and the magnifying power will then be found by dividing the focal distance of the object-glass by that of the eyeglass; but if the image of the pane of glass does not exactly coincide with the pane as seen by the other eye, then proportional parts may be taken by observing the divisions of such a board as described above, or we may try lenses of different focal distances. Suppose, for example, that a lens two inches focal length had been used, and that the image of a pane covered exactly the space of two panes, the power of the eyepiece is then equal to that of a single lens of one inch focal distance.

The following is another mode depending on the same general principle. If a slip of writing-paper one inch long, or a disc of the same material one inch in diameter, be placed on a black ground at from 30 to 50 yards' distance from the object-end of the telescope, and a staff painted white, and divided into inches and parts by strong black lines, be placed vertically near the said paper or disc, the eye that is directed through the telescope, when adjusted for vision, will see the magnified disc, and the other eye, looking along the outside of the telescope, will observe the number of inches and parts that the disc projected on it will just cover, and as many inches as are thus covered will indicate the magnifying power of the telescope, at the distance for which it is adjusted for distinct vison. The solar power, or powers for very distant objects, may be obtained by the following proportion: As the terrestrial focal length at the given distance is to the solar focal length, so is the terrestrial to the solar power. For example, a disc of white paper one inch in diameter was placed on a black board, and suspended on a wall contiguous to a vertical black staff that was graduated into inches by strong white lines, at a distance of 33 yards 2½ feet, and when the adjustment for vision was made with a 42 inch telescope, the left eye of the observer viewed the disc projected on the staff, while the right eye observed that the enlarged image of the disc covered just 58½ inches on the staff, which number was the measure of the magnifying power at the distance answering to 33 yards 2½ feet, which in this case exceeded the solar focus by an inch and a half. Then, according to the above analogy, we have, as 43.5 : 42 : :58.5 : 56.5 nearly. Hence the magnifying power due to the solar focal length of the telescope in question is 56.5, and the distance 33 yards 2½ feet, is that which corresponds to an elongation of the solar focal distance an inch and a half.* If we multiply the terrestrial and the solar focal distances together, and divide the product by their difference, we shall again obtain the distance of the terrestrial object from the telescope. Thus, $\frac{43\cdot5+42}{1\cdot5}$=1218 inches=101.5 feet, or 33 yards 2½ feet.

The magnifying power of a telescope is also determined by measuring the image which the object-glass or the large speculum of a telescope forms at its solar focus. This is accomplished by means of an instrument called a *Dynameter*. This apparatus consists of a strip of mother-of-pearl, marked with equal divisions, from the 1–100th to the 1–1000th of an inch apart, according to the accuracy required. This measure is attached to a magnifying lens in its focus, in order to make the small divisions more apparent. When the power of a telescope is required, the person must measure the clear aperture of the object-glass; then, holding the pearl *dynameter* next the eyeglass, let him observe how many divisions the small circle of light occupies when the instrument is directed to a bright object; then, by dividing the diameter of the object-glass by the diameter of this circle of light, the power will be obtained.* The most accurate instrument of this kind is the *Double Image Dynameter*, invented by Ramsden, and another on the same principle now made by Dollond, a particular description of which may be found in Dr. Pearson's "Introduction to Practical Astronomy." The advantage attending these dynameters is, that they do not require any knowledge of the thickness and focal lengths of any of the lenses employed in a telescope, nor yet of their number and relative positions; neither does it make any difference whether the construction be refracting or reflecting, direct or inverting. One operation includes the result arising from the most complicated construction.

I shall only mention further the following method of discovering the magnifying power, which is founded on the same general principle as alluded to above. Let the telescope be placed in such a position opposite the sun that the rays of light may fall perpendicularly on the object-glass; the pencil of rays may be received on a piece of paper, and its diameter measured. Then, as the diameter of the pencil of rays is to that of the object-glass, so is the magnifying power of the telescope.

8. *On cleaning the Lenses of Telescopes.*—It is necessary, in order to distinct vision, that the glasses, particularly the eyeglasses of telescopes, be kept perfectly clean, free of damp, dust, or whatever may impede the transmission of the rays of light; but great caution ought to be exercised in the wiping of them, as they are apt to be scratched or otherwise injured by a rough and incautious mode of cleaning them. They should never be attempted to be wiped unless they really require it; and in this case, they should be wiped carefully and gently with a piece of new and soft lamb's-skin leather; if this be not at hand, a piece of fine silk paper, or fine clean linen may be used as a substitute. The lens which requires to be most particularly attended to is the second glass from the eye, or the field-glass; for if any dust or other impediment be found upon this glass, it is always distinctly seen, being magnified by the glass next the eye. The next glass which requires attention is the fourth from the eye, or that which is next the object. Unless the glass next the eye be very dusty, a few small spots or grains of dust are seldom perceptible. The object-glass of an achromatic should seldom be touched unless damp adheres to it. Care should be taken never to use pocket-handkerchiefs or dirty rags for wiping lenses. From the frequent use of such articles, the glasses of seamen's telescopes get dimmed and scratched in the course of a few years. If the glasses be exceedingly dirty, and if greasy substances are attached to them, they may be soaked in spirits and water, and afterward carefully wiped. In replacing the glasses in their socket, care should be taken not to touch the surfaces with the fingers, as they would be dimmed with the perspiration; they should be taken hold of by the edges only, and carefully screwed into the same cells from which they were taken.

ON MEGALASCOPES, OR TELESCOPES FOR VIEWING VERY NEAR OBJECTS.

It appears to have been almost overlooked by opticians and others, that telescopes may be constructed so as to exhibit a beautiful and minute view of very near objects, and to produce even a microscopic effect without the least alteration in the *arrangement* of the lenses of which they are composed. This object is effected simply by making the eyetube of a telescope of such a length as to be capable of being drawn out twelve or thirteen inches beyond the point of distinct vision for distant objects. The telescope is then rendered capable of exhibiting with distinctness all kinds of objects from the most distant to those which are placed within three or four feet of the instrument, or not nearer than double the focal distance of the object-glass. Our telescopes, however, are seldom or never fitted with tubes that slide farther than an inch or two beyond the point of distinct vision for distant objects, although a tube of a longer size than usual, or an additional tube, would cost but a trifling expense.

---

* Pearson's "Practical Astronomy," vol. ii.

* The mother-of-pearl dynameter may be purchased for about twelve shillings. See fig. 57, *a*, *b*, *c*, p. 75.

The following, among many others, are some of the objects on which I have tried many amusing experiments with telescopes fitted up with the long tubes to which I allude. The telescope to which I shall more particularly advert is an achromatic, mounted on a pedestal, having an object-glass about nineteen inches focal length, and 1⅝ths of an inch in diameter, with magnifying powers for distant objects of thirteen and twenty times. When this instrument is directed to a miniature portrait 3½ inches in length, placed in a good light, at the distance of about eight or ten feet, it appears as large as an oil painting four or five feet long, and represents the individual as large as life. The features of the face appear to stand out in bold relief; and perhaps there is no representation of the human figure that more resembles the living prototype than in this exhibition, provided the miniature is finely executed. In this case the tube requires to be pulled out four or five inches from the point of distinct vision for distant objects, and consequently the magnifying power is proportionably increased. Another class of objects to which such a telescope may be applied is *Perspective Prints*, either of public buildings, streets, or landscapes. When viewed in this way they present a panoramic appearance, and seem nearly as natural as life, just in the same manner as they appear in the Optical Diagonal Machine, or when reflected in a large concave mirror, with this advantage, that while in these instruments the left-hand side of the print appears where the right should be, the objects seen through the telescope appear exactly in their natural position. In this case, however, the telescope should have a small magnifying power, not exceeding five or six times, so as to take in the whole of the landscape. If an astronomical eyepiece be used, the print will require to be inverted.

Other kinds of objects which may be viewed with this instrument are trees, flowers, and other objects in gardens immediately adjacent to the apartment in which we make our observations. In this way we may obtain a distinct view of a variety of rural objects, which we cannot easily approach, such as the buds and blossoms on the tops of trees, and the insects with which they may be infested. There are certain objects on which the telescope may be made to produce a powerful microscopical effect, such as the more delicate and beautiful kinds of flowers, the leaves of trees, and similar objects. In viewing such objects, the telescope may be brought within little more than double the focal distance of the object-glass from the objects to be viewed, and then the magnifying power is very considerably increased. A nosegay composed of a variety of delicate flowers, or even a single flower, such as the sea pink, makes a splendid appearance in this way. A peacock's feather, or even the fibers on a common quill, appear very beautiful when placed in a proper light. The leaves of trees, particularly the leaf of the plane-tree, when placed against a window-pane, so that the light may shine through them, appear, in all their internal ramifications, more distinct, beautiful, and interesting than when viewed in any other way; and in such views a large portion of the object is at once exhibited to the eye. In this case, the eyepiece of such a telescope as that alluded to requires to be drawn out twelve or fourteen inches beyond the point of distinct vision for objects at a distance, and the distance between these near objects and the object-end of the telescope is only about 3½ feet.

A telescope having a diagonal eyepiece presents a very pleasant view of near objects in this manner. With an instrument of this kind I have frequently viewed the larger kind of small objects alluded to above, such as the leaves of shrubs and trees, flowers consisting of a variety of parts, the fibers of a peacock's feather, and similar objects. In this case, the object-glass of the instrument, which is 10½ inches focal length, was brought within 22 inches of the object, and the eye looked down upon it in the same manner as when we view objects in a compound microscope. A common pocket achromatic telescope may be used for the purposes now stated, provided the tube in the eyepiece containing the two lenses next the object be taken out, in which case the two glasses next the eye form an astronomical eyepiece, and the tubes may be drawn out five or six inches beyond the focal point for distant objects, and will produce distinct vision for objects not farther distant than about 20 or 24 inches; but in this case, the objects to be viewed must be inverted, in order that they may be seen in their natural positions when viewed through the instrument. Telescopes of a large size and high magnifying powers may likewise be used with advantage for viewing very near objects in gardens adjacent to the room in which the instruments are placed, provided the sliding tube next the eye has a range of two or three inches beyond the point of vision for distant objects. In this case, a magnifying power of 100 times on a 3½ or a five feet achromatic produces a very pleasant effect. In making the observations to which I have now alluded, it is requisite in order to distinct vision, and to obtain a pleasing view of the objects, that the instrument should be placed on a pedestal, and capable of motion in every direction. The adjustment for distinct vision may be made either by the sliding tube, or by removing the telescope nearer to or farther from the object.

REFLECTIONS ON LIGHT AND VISION, AND ON THE NATURE AND UTILITY OF TELESCOPES.

Light is one of the most wonderful and beneficial, and, at the same time, one of the most mysterious agents in the material creation. Though the sun from which it flows to this part of our system is nearly a hundred millions of miles from our globe, yet we perceive it as evidently, and feel its influence as powerfully, as if it emanated from no higher a region than the clouds. It supplies life and comfort to our physical system, and without its influence and operations on the various objects around us, we could scarcely subsist and participate of enjoyment for a single hour. It is diffused around us on every hand from its fountain, the sun; and even the stars, though at a distance hundreds of thousands of times greater than that of the solar orb, transmit to our distant region a portion of this element. It gives beauty and fertility to the earth, it supports the vegetable and animal tribes, and is connected with the various motions which are going forward throughout the system of the universe. It unfolds to us the whole scenery of external nature; the lofty mountains and the expansive plains, the majestic rivers and the mighty ocean; the trees, the flowers, the crystal streams, and the vast canopy of the sky, adorned with ten thousands of shining orbs. In short, there is scarcely an object within the range of our contemplation but what is exhibited to our understanding through the medium of light, or at least bears a certain relation to this enlivening and universal agent. When we consider the extreme minuteness of the rays of light, their inconceivable velocity, the invariable laws by which they act upon all bodies, the multifarious phenomena produced by their inflections, refractions, and reflections, while their original properties remain the same; the endless variety of colors they produce on every part of our terrestrial creation, and the facility with which millions of rays pass through the smallest apertures, and pervade substances of great density, while every ray passes forward in the crowd without disturbing another, and produces its own specific impression, we cannot but regard this element as the most wonderful, astonishing, and delightful part of the material creation. When we consider the admirable beauties and the exquisite pleasures of which light is the essential source, and how much its nature is still involved in mystery, notwithstanding the profound investigations of modern philosophers, we may well exclaim with the poet,

> "How then shall I attempt to sing of HIM
> Who, light himself, in uncreated light
> Invested deep, dwells awfully retired
> From mortal eye or angel's purer ken;
> Whose single smile has, from the first of time,
> Filled, overflowing, all yon lamps of heaven,
> That beam forever through the boundless sky."
> THOMSON.

The eye is the instrument by which we perceive the beautiful and multifarious effects of this universal agent. Its delicate and complicated structure; its diversified muscles; its coats and membranes; its different humors, possessed of different refractive powers; and the various contrivances for performing and regulating its external and internal motions, so as to accomplish the ends intended, clearly demonstrate this organ to be a masterpiece of Divine mechanism—the workmanship of Him whose intelligence surpasses conception, and whose wisdom is unsearchable. "Our sight," says Addison, "is the most perfect and delightful of all our senses. It fills the mind with the largest variety of ideas, converses with its objects at the greatest distance, and continues the longest in action, without being tired or satiated with its proper enjoyments. The sense of feeling can indeed give us a notion of extension, shape, and all other ideas that enter the eye except colors; but, at the same time, it is very much strained, and confined in its operation to the number, bulk, and distance of its particular objects. Our sight seems designed to supply all these defects, and may be considered as a more delicate and diffusive kind of touch, that spreads itself over an infinite multitude of bodies, comprehends the largest figures, and brings into our reach some of the more remote parts of the universe."

Could we suppose an order of beings indued with every human faculty but that of sight, it would appear incredible to such beings, accustomed only to the slow information of touch, that by the addition of an organ consisting of a ball and socket, of an inch in diameter, they might be enabled, in an instant of time, without changing their place, to perceive the disposition of a whole army, the order of a battle, the figure of a magnificent palace, or all the variety of a landscape. If a man were by feeling to find out the figure of the Peak of Teneriffe, or even of St. Peter's Church at Rome, it would be the work of a lifetime. It would appear still more incredible to such beings as we have supposed, if they were informed of the discoveries which may be made by this little organ in things far beyond the reach of any other sense, that by means of it we can find our way in the pathless ocean; that we can traverse the globe of the earth, determine its figure and dimensions, and delineate every region of it; yea, that we can measure the planetary orbs, and make discoveries in the sphere of the fixed stars. And if they were further informed that, by means of this same organ, we can perceive the tempers and dispositions, the passions and affections of our fellow-creatures, even when they want most to conceal them; that when the tongue is taught most artfully to lie and dissemble, the hypocrisy should appear in the countenance to a discerning eye; and that by this organ we can often perceive what is straight and what crooked in the mind as well as in the body, would it not appear still more astonishing to beings such as we have now supposed?*

Notwithstanding these wonderful properties of the organ of vision, the eye, when unassisted by art, is comparatively limited in the range of its powers. It cannot ascertain the existence of certain objects at the distance of three or four miles, nor perceive what is going forward in nature or art beyond such a limit. By its natural powers we perceive the moon to be a globe about half a degree in diameter, and diversified with two or three dusky spots, and that the sun is a luminous body of apparently the same size; that the planets are luminous points, and that about a thousand stars exist in the visible canopy of the sky. But the ten thousandth part of those luminaries which are within the reach of human vision can never be seen by the unassisted eye. Here the TELESCOPE interposes, and adds a new power to the organ of vision, by which it is enabled to extend its views to regions of space immeasurably distant, and to objects, the number and magnitude of which could never otherwise have been surmised by the human imagination. By its aid we obtain a sensible demonstration that space is boundless; that the universe is replenished with innumerable suns and worlds; that the remotest regions of immensity, immeasurably beyond the limits of unassisted vision, display the energies of Creating Power; and that the empire of the Creator extends far beyond what eye hath seen or the human imagination can conceive.

The telescope is an instrument of a much more wonderful nature than what most people are apt to imagine. However popular such instruments now are, and however common a circumstance it is to contemplate objects at a great distance which the naked eye cannot discern, yet, prior to their invention and improvement, it would have appeared a thing most mysterious, if not impossible, that objects at the distance of ten miles could be made to appear as if within a few yards of us, and that some of the heavenly bodies could be seen as distinctly as if we had been transported by some superior power hundreds of millions of miles beyond the bounds of our terrestrial habitation. Who could ever have imagined, reasoning *a priori*, that the refraction of light in glass—the same power by which a straight rod appears crooked in water, by which vision is variously distorted, and by which we are liable to innumerable deceptions—that that same power or law of nature, by the operation of which the objects in a landscape appear distorted when seen through certain panes of glass in our windows, that that power should ever be so modified and directed as to extend the boundaries of vision, and enable us clearly to distinguish scenes and objects at a distance a thousand times beyond the natural limits of our visual organs? Yet such are the discoveries which science has achieved, such the powers it has brought to light, that by glasses ground into different forms, and properly adapted to each other, we are enabled, as it were, to contract the boundaries of space, to penetrate into the most distant regions, and to bring within the reach of our knowledge the most sublime objects in the universe.

---

* Reid's Inquiry into the Human Mind, chap. iv

When Pliny declared in reference to Hipparchus, the ancient astronomer, "*Ausus rem Deo improbam annumerare posteris stellas*," that "he dared to enumerate the stars for posterity, an undertaking forbidden by God," what would that natural historian have said had it been foretold that in less than 1600 years afterward a man would arise who should enable posterity to perceive and to enumerate ten times more new stars than Hipparchus ever beheld—who should point out higher mountains on the moon than on the earth—who should discover dark spots as large as our globe in the sun, the fountain of light—who should descry four moons revolving in different periods of time around the planet Jupiter, and could show to surrounding senators the varying phases of Venus? and that another would soon after arise who should point out a double ring of six hundred thousand miles in circumference revolving around the planet Saturn, and ten hundreds of thousands of stars which neither Hipparchus nor any of the ancient astronomers could ever descry? Yet these are only a small portion of the discoveries made by Galileo and Herschel by means of the telescope. Had any one prophetically informed Archimedes, the celebrated geometrician of Syracuse, that vision would, in after ages, be thus wonderfully assisted by art; and, further, that one manner of improving vision would be to place a dark, *opaque* body directly between the object and the eye; and that another method would be, not to look at the object, but to keep the eye quite in a different, and even in an opposite direction, or to stand with the back directly opposed to it, and to behold all the parts of it, invisible to the naked eye, most distinctly in this way, he would doubtless have considered the prophet as an enthusiastic fool or a raving madman. Yet these things have been realized in modern times in the fullest extent. In the Gregorian reflecting telescope, an opaque body, namely, the small speculum near the end of the tube, interposes directly between the eye and the object. In the Newtonian reflector, and in the diagonal eyepieces formerly described, the eye is directed in a line at right angles to the object, or a deviation of 90 degrees from the direct line of vision. In Herschel's large telescopes, and in the *Aerial Reflector*, formerly described (in pp. 88-92), the back is turned to the object, and the eye in an opposite direction.

These circumstances should teach us humility and a becoming diffidence in our own powers; and they should admonish us not to be too dogmatical or peremptory in affirming what is possible or impossible in regard either to nature or art or to the operations of the Divine Being. Ar has accomplished, in modern times, achievement, in regard to locomotion, marine and aerial navigation, the improvement of vision, the separation and combinations of invisible gases, and numerous other objects, of which the men of former ages could not have formed the least conception; and even yet we can set no boundaries to the future discoveries of science and the improvements of art, but have every reason to indulge the hope that, in the ages to come, scenes of Divine mechanism in the system of nature will be unfolded, and the effects of chemical and mechanical powers displayed, of which the human mind, in its present state of progress, cannot form the most imperfect idea. Such circumstances likewise should teach us not to reject any intimations which have been made to us in relation to the character, attributes, and dispensations of the Divine Being, and the moral revelations of his will given in the Sacred Records, because we are unable to comprehend every truth and to remove every difficulty which relates to the moral government of the Great Ruler of the universe; for if we meet with many circumstances in secular science, and even in the common operations of nature, which are difficult to comprehend—if even the construction of such telescopes as we now use would have appeared an incomprehensible mystery to ancient philosophers, we must expect to find difficulties almost insurmountable to such limited minds as ours in the eternal plans and moral arrangements of the "King Immortal and Invisible," as delineated only in their outlines in the Sacred Oracles, particularly those which relate to the origin of physical and moral evil, the ultimate destiny of man, and the invisible realities of a future world.

The UTILITY of the telescope may be considered in relation to the following circumstances:

In the first place, it may be considered as an instrument or machine which virtually transports us to the distant regions of space. When we look at the moon through a telescope which magnifies 200 times, and survey its extensive plains, its lofty peaks, its circular ranges of mountains, throwing their deep shadows over the vales, its deep and rugged caverns, and all the other varieties which appear on the lunar surface, we behold such objects in the same manner as if we were standing at a point 238,800 miles from the earth in the direction of the moon, or only twelve hundred miles from that orb, reckoning its distance to be 240,000 miles. When we view the planet Saturn with a similar instrument, and obtain a view of its belts and satellites, and its magnificent rings, we are transported, as it were, through regions of space to a point in the heavens more than *nine hundred millions of miles* from the surface of our globe, and contemplate those august objects as if we were placed within five millions of miles of the surface of that planet.* Although a supernatural power sufficient to carry us in such a celestial journey a thousand miles every day were exerted, it would require more than two thousand four hundred and sixty years before we could arrive at such a distant position; yet the telescope, in a few moments, transports our visual powers to that far distant point of space. When we view with such an instrument the minute and very distant clusters of stars in the Milky Way, we are carried, in effect, through the regions of space to the distance of *five hundred thousand millions of miles* from the earth; for we behold those luminaries through the telescope nearly as if they were actually viewed from such a distant point in the spaces of the firmament. These stars cannot be conceived as less than *a hundred billions* of miles from our globe, and the instrument we have supposed brings them within the two hundredth part of this distance. Suppose we were carried forward by a rapid motion toward this point at the rate of a thousand miles *every hour*, it would require more than *fifty-seven thousand years* before we could reach that very distant station in space to which the telescope, *in effect*, transports us: so that this instrument is far more efficient in opening to our view the scenes of the universe, than if we were invested with powers of locomotion to carry us through the regions of space with the rapidity of a cannon ball at its utmost velocity; and all the while we may sit at ease in our terrestrial apartments.

---

* The distance of Saturn from the sun is 906,000,000 of miles; it is sometimes nearer to, and at other times farther from the earth, according as it is near the point of its opposition to, or conjunction with, the sun. If this number be divided by 200 hundred, the supposed magnifying power of the telescope, the quotient is 4,530,000, which expresses the distance in miles at which it enables us to contemplate this

In the next place, the telescope has been *the means of enlarging our views of the sublime scenes of creation* more than any other instrument which art has contrived. Before the invention of this instrument, the universe was generally conceived as circumscribed within very narrow limits. The earth was considered as one of the largest bodies in creation; the planets were viewed as bodies of a far less size than what they are now found to be; no bodies similar to our moon were suspected as revolving around any of them; and the stars were supposed to be little more than a number of brilliant lamps hung up to emit a few glimmering rays, and to adorn the canopy of our earthly habitation. Such a wonderful phenomenon as the ring of Saturn was never once suspected, and the sun was considered as only a large ball of fire. It was suspected, indeed, that the moon was diversified with mountains and vales, and that it might possibly be a habitable world; but nothing certainly could be determined on this point, on account of the limited nature of unassisted vision. But the telescope has been the means of expanding our views of the august scenes of creation to an almost unlimited extent: it has withdrawn the vail which formerly interposed to intercept our view of the distant glories of the sky: it has brought to light five new planetary bodies, unknown to former astronomers, one of which is more than eighty times larger than the earth, and seventeen *secondary* planets which revolve around the primary: it has expanded the dimensions of the solar system to double the extent which was formerly supposed: it has enabled us to descry hundreds of comets which would otherwise have escaped our unassisted vision, and to determine some of their trajectories and periods of revolution: it has explored the profundities of the Milky Way, and enabled us to perceive hundreds of thousands of those splendid orbs, where scarcely one is visible to the naked eye: it has laid open to our view thousands of *Nebulæ*, of various descriptions, dispersed through different regions of the firmament, many of them containing thousands of separate stars: it has directed our investigations to thousands of double, treble, and multiple stars—suns revolving around suns, and systems around systems; and has enabled us to determine some of the periods of their revolutions: it has demonstrated the immense distances of the starry orbs from our globe; and their consequent magnitudes, since it shows us that, having brought them nearer to our view by several hundreds or thousands of times, they still appear only as so many shining *points:* it has enabled us to perceive that mighty changes are going forward throughout the regions of immensity—new stars appearing, and others removed from our view, and motions of incomprehensible velocity carrying forward those magnificent orbs through the spaces of the firmament: in short, it has opened a vista to regions of space so immeasurably distant, that a cannon ball impelled with its greatest velocity would not reach tracts of creation so remote in two thousand millions of years; and even light itself, the swiftest body in nature, would require more than a thousand years before it could traverse this mighty interval. It has thus laid a foundation for our acquiring an approximate idea of the infinity of space, and for obtaining a glimpse of the far distant scenes of creation, and the immense extent of the universe.

Again, the telescope, in consequence of the discoveries it has enabled us to make, has tended *to amplify our conceptions of the attributes and the empire of the Deity.* The amplitude of our conceptions of the Divine Being bears a certain proportion to the expansion of our views in regard to his works of creation, and the operations he is incessantly carrying forward throughout the universe. If our views of the works of God, and of the manifestations he has given of himself to his intelligent creatures, be circumscribed to a narrow sphere, as to a parish, a province, a kingdom, or a single world, our conceptions of that Great Being will be proportionably limited; for it is chiefly from the manifestation of God in the material creation that our ideas of his power, his wisdom, and his other natural attributes are derived. But in proportion to the ample range or prospect we are enabled to take of the operations of the Most High, will be our conceptions of his character, attributes, and agency. Now the telescope, more than any other invention of man, has tended to open to our view the most magnificent and extensive prospects of the works of God; it has led us to ascertain that, within the limits of the solar system, there are bodies which, taken together, comprise a mass of matter nearly two thousand five hundred times greater than that of the earth; that these bodies are all constituted and arranged in such a manner as to fit them for being habitable worlds; and that the sun, the center of this system, is five hundred times larger than the whole. But, far beyond the limits of this system, it has presented to our view a universe beyond the grasp of finite intelligences, and to which human imagination can assign no boundaries: it has enabled us to descry suns clustering behind suns, rising to view in boundless perspective, in proportion to the extent of its magnifying and illuminating powers, the numbers of which are to be estimated, not merely by thousands, and tens of thousands, and hundreds of thousands, but by scores of *millions;* leaving us no room to doubt that hundreds

---

planet. If this number be subtracted from 906,000,000, the remainder is 901,470,000, which expresses the number of miles from the earth at which we are supposed to view Saturn with such an instrument.

of millions more beyond the utmost limits of human vision, even when assisted by art, lie hid from mortal view in the unexplored and unexplorable regions of immensity.

Here, then, we are presented with a scene which gives us a display of *Omnipotent Power* which no other objects can unfold, and which, without the aid of the telescope, we should never have beheld; a scene which expands our conceptions of the Divine Being to an extent which the men of former generations could never have anticipated; a scene which enables us to form an approximate idea of Him who is the "King Eternal, Immortal, and Invisible," who "created all worlds, and for whose pleasure they are and were created." Here we behold the operations of a Being whose power is illimitable and uncontrollable, and which far transcends the comprehension of the highest created intelligences; a power, displayed not only in the vast extension of material existence, and the countless number of mighty globes which the universe contains, but in the astonishingly *rapid motions* with which myriads of them are carried along through the immeasurable spaces of creation, some of those magnificent orbs moving with a velocity of one hundred and seventy thousand miles an hour. Here, likewise, we have a display of the infinite *wisdom* and intelligence of the Divine Mind, in the harmony and order with which all the mighty movements of the universe are conducted; in proportionating the magnitudes, motions, and distances of the planetary worlds; in the nice adjustment of the projectile velocity to the attractive power; in the constant proportion between the times of the periodical revolution of the planets and the cubes of their mean distances; in the *distances* of the several planets from the central body of the system, compared with their respective *densities;* and in the constancy and regularity of their motions, and the exactness with which they accomplish their destined rounds—all which circumstances evidently show that He who contrived the universe is "the only wise God," who is "wonderful in counsel and excellent in working." Here, in fine, is a display of *boundless benevolence;* for we cannot suppose, for a moment, that so many myriads of magnificent globes, fitted to be the centers of a countless number of mighty worlds, should be nothing else than barren wastes, without the least relation to intelligent existence; and if they are peopled with intellectual beings of various orders, how vast must be their numbers, and how overflowing that Divine Beneficence which has provided for them all everything requisite to their existence and happiness.

In these discoveries of the telescope we obtain a glimpse of the grandeur and the unlimited extent of God's universal empire. To this empire no boundaries can be perceived. The larger and the more powerful our telescopes are, the farther are we enabled to penetrate into those distant and unknown regions; and however far we penetrate into the abyss of space, new objects of wonder and magnificence still continue rising to our view, affording the strongest presumption that, were we to penetrate ten thousand times farther into those remote spaces of immensity, new suns, and systems, and worlds would be disclosed to our view. Over all this vast assemblage of material existence, and over all the sensitive and intellectual beings it contains, God eternally and unchangeably presides; and the minutest movements, either of the physical or the intelligent system, throughout every department of those vast dominions, are at every moment "naked and open" to his omniscient eye What *boundless intelligence* is implied in the *superintendence* and *arrangement* of the affairs of such an unlimited empire! and what a lofty and expansive idea does it convey of Him who sits on the throne of Universal Nature, and whose greatness is unsearchable! But without the aid of the telescopic tube we could not have formed such ample conceptions of the greatness, either of the Eternal Creator himself, or of the universe which he hath brought into existence.

Beside the above, the following uses of the telescope, in relation to science and common life, may be shortly noticed:

In the business of astronomy, scarcely anything can be done with accuracy without the assistance of the telescope. 1. It enables the astronomer to determine with precision *the transits of the planets and stars* across the meridian; and on the accuracy with which these transits are obtained, a variety of important conclusions and calculations depend. The computation of astronomical and nautical tables for aiding the navigator in his voyages round the globe, and facilitating his calculations of latitude and longitude, is derived from observations made by the telescope, without the use of which instrument they cannot be made with precision. 2. The *apparent diameters of the planets* can only be measured by means of this instrument, furnished with a micrometer. By the naked eye no accurate measurements of the diameters of these bodies can be taken; and without knowing their apparent diameters in minutes or seconds, their real bulk cannot be determined, even although their exact distances be known. The differences, too, between the polar and equatorial diameters cannot be ascertained without observations made by powerful telescopes. For example, the equatorial diameter of Jupiter is found to be in proportion to the polar as 14 to 13, that is, the equatorial is more than 6000 miles longer than the polar diameter, which could never have been determined by observations made by the naked eye. 3. The *parallaxes* of the heavenly bodies can only be accurately ascertained by the telescope; and it is only from the knowledge of their parallaxes that their distances from the earth or from the sun can be determined. In the case of the fixed stars, nothing of the nature of a parallax could ever be expected to be found without the aid of a telescope. It was by searching for the parallax of a certain fixed star that the important fact of the *Aberration of Light* was discovered. The observations for this purpose were made by means of a telescope 24 feet long, fixed in a certain position. 4. The motions and revolutionary periods of *Sidereal Systems* can only be determined by observations made by telescopes of great magnifying and illuminating powers. Without a telescope the small stars which accompany double or treble stars cannot be perceived, and much less their motions or variation of their relative positions. Before the invention of the telescope, such phenomena, now deemed so wonderful and interesting, could never have been surmised. 5. The accurate determination of the longitude of places on the earth's surface is ascertained by the telescope, by observing with this instrument the immersions and emersions of the satellites of Jupiter. From such observations, with the aid of a chronometer, and having the time at any known place, the situation of any unknown place is easily determined. But the eclipses of Jupiter's moons can be perceived only by telescopic instruments of considerable power. 6. By means of a telescope with cross hairs in the focus of the eye-glass, and attached to a quadrant, the altitude of the sun or of a star, particularly the pole-star, may be most accurately taken, and from such observations the *latitude* of the place may be readily and accurately deduced.

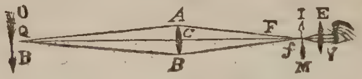
Again, in the *Surveying of Land*, the telescope is particularly useful; and for this purpose it is mounted on a stand with a horizontal and vertical motion, pointing out by divisions the degrees and minutes of inclination of the instrument. For the more accurate reading of these divisions, the two limbs are furnished with a nonius, or *Vernier's Scale*. The object here is to take the angular distances between distant objects on a plane truly horizontal, or else the angular elevation or depression of objects above or below the plane of the horizon. In order to obtain either of those kinds of angles to a requisite degree of exactness, it is necessary that the surveyor should have as clear and distinct a view as possible of the objects, or station-staves, which he fixes up for his purpose, that he may with the greater certainty determine the point of the object which exactly corresponds with the line he is taking. Now, as such objects are generally at too great a distance for the surveyor to be able to distinguish with the naked eye, he takes the assistance of the telescope, by which he obtains, 1, a distinct view of the object to which his attention is directed, and, 2, he is enabled to determine the precise point of the object aimed at by means of the cross hairs in the focus of the eyeglass. A telescope mounted for this purpose is called a *Theodolite*, which is derived from two Greek words, *θεαομαι*, *to see*, and *οδος*, *the way* or *distance*.

In the next place, the telescope is an instrument of special importance in the conducting of *Telegraphs*, and in the conveyance of *signals* of all descriptions. Without its assistance telegraphic dispatches could not be conveyed with accuracy to any considerable distance, nor in quadruple the time in which they are now communicated, and the different stations would need to be exceedingly numerous; but, by the assistance of the telescope, information may be communicated, by a series of telegraphs, with great rapidity. Twenty-seven telegraphs convey information from Paris to Calais, a distance of 160 miles, in three minutes; twenty-two, from Paris to Lisle, in two minutes; forty-six, from Strasburg to Paris, in four and a half minutes; and eighty, from Paris to Brest, in ten minutes. In many other cases which occur both on land and sea, the telescope is essentially requisite for descrying signals. The *Bell-Rock Lighthouse*, for example, is situated twelve miles from Arbroath, and from every other portion of land, so that the naked eye could not discern any signal which the keepers of that light could have it in their power to make; but by means of a large telescope in the station-house in Arbroath, the hoisting of a ball every morning at 9, A. M., which indicates that "All is well," may be distinctly recognized.

Many other uses of this instrument, in the ordinary transactions of life, will readily occur to the reader, and therefore I shall only mention the following purpose to which it may be applied, namely,

To measure the Distance of an Object from one Station.—This depends upon the increase of the focal distance of the telescope in the case of near objects. Look through a telescope at the object whose distance is required, and adjust the focus until it appear quite distinct; then slide in the drawer until the object begins to be obscure, and mark that place of the tube precisely; next draw out the tube until the object begins to be again obscured, and then make another mark as before; then take the middle point between these two marks, and that will be the point where the image of the object is formed most distinctly, which is to be nicely measured from the object-lens, and compared with the solar focus of the lens or telescope, so as to ascertain their difference. And the rule for finding the distance is: as the difference between the focal distance of the object and the solar focal distance is to the solar focal distance, so is the focal distance of the object to its true distance from the object-lens. An example will render this matter more perspicuous:

Fig. 84.



Let $A\,B$ (fig. 84) be the object-lens, $E\,Y$ the eyeglass, $F\,C$ the radius, or focus of the lens $A\,B$, and $C\!f$ the focal distance of the object $O\,B$, whose distance is to be measured. Now suppose $C\,F=48$ inches, or four feet, and that we find by the above method that $C\!f$ is 50 inches, then $F\!f$ is two inches; and the analogy is, as $F\!f=2$ is to $C\,F=48$, so is $C\!f=50$ to $C\,Q=1200$ inches, or 100 feet. Again, suppose $C\!f=49$ inches, then will $F\!f=1$ inch; and the proportion is, $1:48::49:2352=Q\,C$, or 196 feet. A telescope of this focal length, however, will measure only small distances. But suppose $A\,B$ a lens whose solar focus is 12 feet, or 144 inches, and that we find by the above method that $C\!f$, or the focal distance of the object, is 146 inches, then will $F\!f$ be two inches, and the proportion will be as $2:144::146:21024$ inches, or 1752 feet=the distance $Q\,C$. If with such a large telescope we view an object $O\,B$, and find $F\!f$ but 1-10th of an inch, this will give the distance of the object as 17,292 feet, or nearly 3⅓d miles.

Since the difference between the radius of the object-lens and the focal distance of the object is so considerable as two inches in a tube of four feet, and more than twelve inches in one of twelve feet, a method might be contrived for determining the distance of near objects by the former, and more distant objects by the latter, by inspection only. This may be done by adjusting or drawing a spiral line round the drawer or tube through the *two-inch space* in the small telescope, and by calculation graduate it for every 100 feet and the intermediate inches, and then, at the same time we view an object, we may see its distance on the tube. In making such experiments, a common object-glass of a long focal length, and a single eyeglass, are all that is requisite, since the inverted appearance of the object can cause no great inconvenience.

CHAPTER VII.

ON THE METHOD OF GRINDING AND POLISHING OPTICAL LENSES AND SPECULA.

I originally intended to enter into particular details on this subject for the purpose of gratifying those mechanics and others who wish to amuse themselves by constructing telescopes and other optical instruments for their own use; but, having dwelt so long on the subject of telescopes in the preceding pages, I am constrained to confine myself to a very general sketch.

1. *To grind and polish Lenses for Eyeglasses, Microscopes, &c.*—First provide an upright spindle, at the bottom of which a pulley is fixed, which must be turned by a wheel by means of a cord and handle. At the top of the spindle make a screw the same as a lathe-spindle, on which you may screw chocks of different sizes, to which the brass tool in which the lens is to be ground may be fixed. Having fixed upon the breadth and focal length of the lens, and whether it is to be a plano or a double convex, take a piece of tin-plate or sheet copper, and with a pair of compasses draw an arch upon its surface, near one of its extremities, with a radius equal to the focal distance of the lens, if intended to be double convex, or with half that distance if it is to be plano-convex. Remove with a file that part of the copper which is without the circular arch, and then a *convex* gauge is formed. With the same radius strike another arch, and having removed that part of the copper which is *within* it, a *concave* gauge will be obtained. The brass tool in which the glass is to be ground is then to be fixed upon a turning-lathe, and turned into a portion of a concave sphere, so as to correspond to the convex gauge. In order to obtain an accurate figure to the concave tool, a convex tool of exactly the same radius is generally formed, and they are ground one upon another with flour of emery, and when they exactly coincide they are fit for use. The convex tool will serve for grinding *concave* glasses of the same radius; and it should be occasionally ground in the concave tool to prevent it from altering its figure.

The next thing to be attended to is to prepare the piece of glass which is to be ground, by chipping it in a circular shape by means of a large pair of scissors, and removing the roughness from its edges by a common grindstone. The faces of the glass near the edges should likewise be ground on the grindstone until they nearly fit the concave gauge, by which the labor of grinding in the tool will be considerably saved. The next thing required is to prepare the emery for grinding, which is done in the following manner: Provide four or five clean earthen vessels: fill one of them with water, and put into it a pound or half a pound of fine emery, and stir it about with a stick; after which, let it stand three or four seconds, and then pour it into another vessel, which may stand about ten seconds: then pour it off again into the several vessels until the water is quite clear, and by this means emery of different degrees of fineness is obtained, which must be kept separate from each other, and worked in their proper order, beginning at the first, and working off all the marks of the grindstone; then take of the second, next of the third, &c., holding the glass upon the pan or tool with a light hand when it comes to be nearly fit for polishing. The glass, in this operation, should be cemented to a wooden handle by means of pitch or other strong cement. After the finest emery has been used, the roughness which remains may be taken away, and a slight polish given, by grinding the glass with pounded pumice-stone. Before proceeding to the polishing, the glass should be ground as smooth as possible, and all the scratches erased, otherwise the polishing will become a tedious process. The polishing is performed as follows: Tie a piece of linen rag or fine cloth about the tool, and with fine putty (calcined tin) or colcothar of vitriol (a very fine powder, sometimes called the red oxide of iron), moistened with water, continue the grinding motion, and in a short time there will be an excellent polish.

In order to grind lenses very accurately for the finest optical purposes, particularly object-glasses for telescopes, the concave tool is firmly fixed to a table or bench, and the glass wrought upon it by the hand with circular strokes, so that its center may never go beyond the edges of the tool. For every six or seven circular strokes, the glass should receive two or three cross ones along the diameter of the tool, and in different directions; and, while the operation is going on, the convex tool should, at the end of five minutes, be wrought upon the concave one for a few seconds, in order to preserve the same curvature to the tools and to the glass. The finest polish is generally given in the following way: Cover the concave tool with a layer of pitch, hardened by the addition of a little resin, to the thickness of 1-15th of an inch; then, having taken a piece of thin writing paper, press it upon the surface of the pitch with the convex tool, and pull the paper quickly from the pitch before it has adhered to it; and if the surface of the pitch is marked everywhere with the lines of the paper, it will be truly spherical. If any paper remains on the surface of the pitch, it may be rubbed off by soap and water; and if the marks of the paper should not appear on any part of it, the operation must be repeated until the polisher or bed of pitch is accurately spherical. The glass is then to be wrought on the polisher by circular and cross strokes with the putty or colcothar until it has received a complete polish. When one side is finished, the glass must be separated from its handle by inserting the point of a knife between it and the pitch, and giving it a gentle stroke. The pitch which remains upon the glass may be removed by rubbing it with a little oil, or spirits of wine. The operation of polishing on cloth is slower, and the polish less perfect than on pitch; but it is a mode best fitted for those who have little experience, and who would be apt, in the first instance, to injure the figure of the lens by polishing it on a bed of pitch.

2. *On the method of casting and grinding the Specula of Reflecting Telescopes.*—The first thing to be considered in the formation of reflecting telescopes is the *composition* of the metal of which the specula are made. The qualities required are, a sound, uniform metal, free from all microscopic pores, not liable to tarnish by absorption of moisture from the atmosphere—not so hard as to be incapable of taking a good figure and polish, nor so soft as to be easily scratched, and possessing a high reflecting power. Various compositions have been used for this purpose, of which the following are specimens: Take of good Swedish copper 32 ounces, and when melted, add 14½ ounces of grain tin to it; then, having taken off the scoria, cast it into an ingot. This metal must be a second time melted to cast a speculum; but it will fuse in this compound state with a small heat, and therefore will not calcine the tin to putty. It should be poured off as soon as it is melted, giving it no more heat than is absolutely necessary. The best method for giving the melted metal a good surface is this: the moment before it is poured off, throw into the crucible a spoonful of charcoal-dust; immediately after which, the metal must be stirred with a wooden spatula and poured into the molds. The following is another composition somewhat similar: Take two parts of copper as pure as it is possible to procure: this must be melted in a crucible by itself; then put, in another crucible, one part of pure grain tin: when they are both melted, mix and stir them with a wooden spatula, keeping a good flux on the melted surface to prevent oxydation, and then pour the metal quickly into the molds, which may be made of founders' loam.

The composition suggested, more than half a century ago, by the Rev. Mr. Edwards, has often been referred to with peculiar approbation. This gentleman took a great deal of pains to discover the best composition, and to give his metals a fine polish and the true parabolical figure. His telescopes were tried by Dr. Maskelyne, the astronomer royal, who found them greatly to excel in brightness, and to equal in other respects those made by the best artists. They showed a white object perfectly white, and all objects of their proper color. He found, after trying various combinations, the following to be the best, namely, 32 ounces of copper, with 15 or 16 ounces of grain tin (according to the purity of the copper), with the addition of one ounce of brass, one of silver, and one ounce of arsenic. This, he affirms, will form a metal capable, when polished in a proper manner, of reflecting more light than any other metal yet made public.

The Rev. J. Little, in his observations on this subject in the "Irish Transactions," proposes the following composition, which he found to answer the purpose better than any he had tried, namely, 32 parts of best bar copper, previously fluxed with the black flux of 2 parts tartar and 1 of niter, 4 parts of brass, 16 parts of tin, and 1¼ of arsenic. If the metal be granulated, by pouring it, when first melted, into water, and then fused a second time, it will be less porous than at first. In this process, the chief object is to hit on the exact point of the saturation of the copper, &c., by the tin; for if the latter be added in too great quantity, the metal will be dull colored and soft; if too little, it will not attain the most perfect whiteness, and will certainly tarnish.*

When the metal is cast, and prepared by the common grindstone for receiving its proper figure, the gauges and grinding-tools are to be formed in the same manner as formerly described for lenses, with this difference, that the radius of the gauges must always be *double* the focal length of the speculum, as the focus of parallel rays by reflection is at one half the radius of concavity. In addition to the concave and convex tools, which should be only a little broader than the metal itself, a convex elliptical tool of lead and tin should be formed with the same radius, so that its transverse should be to its conjugate diameter as 10 to 9, the latter being exactly equal to the diameter of the metal. The grinding of the speculum is then to be commenced on this tool with coarse emery powder and water, when the roughness is taken off by moving the speculum across the tool in different directions, walking round the post on which the tool is fixed, holding the speculum by the wooden handle to which it is cemented; it is then to be wrought with great care on the convex brass tool, with circular and cross strokes, and with emery of different degrees—the concave tool being sometimes ground upon the convex one, to keep them all of the same radius—and when every scratch is removed from its surface, it will be fit for receiving the final polish.

When the metal is ready for polishing, the elliptical tool is to be covered with black pitch about 1-20th of an inch thick, and the polisher formed in the same way as in the case of lenses either with the concave brass tool or with the metal itself. The colcothar of vitriol should then be triturated between two surfaces of glass, and a considerable quantity of it applied at first to the surface of the polisher. The speculum is then to be wrought in the usual way upon the polishing tool until it has received a brilliant luster, taking care to use no more of the colcothar, if it can be avoided, and only a small quantity of it, if it should be found necessary. When the metal moves stiffly on the polisher, and the colcothar assumes a dark, muddy hue, the polish advances with great rapidity. The tool will then grow warm, and would probably stick to the speculum if its motion were discontinued for a moment. At this stage of the process, therefore, we must proceed with great caution, breathing continually on the polisher until the friction is so great as to retard the motion of the speculum. When this happens, the metal is to be slipped off the tool at one side, cleaned with soft leather, and placed in a tube for the purpose of trying its performance; and if the polishing has been conducted with care, it will be found to have a true *parabolic* figure.*

It was formerly the practice, before the speculum was brought to the polisher, to smooth it on a *bed of hones*, or a convex tool made of the best blue stone, such as clockmakers use in polishing their work, which was made one-fourth part larger than the metal which was to be ground upon it, and turned as true as possible to a gauge; but this tool is not generally considered as absolutely necessary, except when silver and brass enter into the composition of the metal, in order to remove the roughness which remains after grinding with the emery.

To try the Figure of the Metal.—In order to this, the speculum must be placed in the tube of the telescope for which it is intended, and at about 20 or 30 yards distant there should be put up a watch-paper, or similar object, on which there are some very fine strokes of an engraver.

---

* *Irish Transactions*, vol. x; and Nicholson's Philosophical Journal, vol. xvi.

* Brewster's Appendix to "Ferguson's Lectures."

An annular kind of diagram should be made with card-paper, so as to cover a circular portion of the middle part of the speculum, between the hole and the circumference, equal in breadth to about one-eighth of its diameter. This paper ring should be fixed in the mouth of the telescope, and remain so during the whole experiment. There must likewise be two other circular pieces of card-paper cut out, of such sizes that one may cover the center of the metal by completely filling the hole in the annular piece now described, and the other such a round piece as shall exactly fill the tube, and so broad as that the inner edge just touches the outward circumference of the middle annular piece. All these pieces together will completely shut up the mouth of the telescope. Let the round piece which covers the center of the metal be removed, and adjust the instrument so that the image may be as sharp and distinct as possible; then replace the central piece, and remove the outside annular one, by which means the circumference only of the speculum will be exposed, and the image now formed will be from the rays reflected from the exterior side of the metal. If the two images formed by these two portions of the metal be perfectly sharp and equally distinct, the speculum is perfect and of the true parabolic curve; if, on the contrary, the image from the outside of the metal should not be distinct, and it should be necessary to bring the little speculum *nearer* by the screw, the metal is not yet brought to the parabolic figure; but if, in order to procure distinctness, we be obliged to move the small speculum farther off, then the figure of the great speculum has been carried beyond the parabolic, and has assumed the hyperbolic form.

To adjust the Eyehole of Gregorian Reflectors.—If there is only one eyeglass, then the distance of the small hole, should be as nearly as possible equal to its focal length; but in the compound Huygenian eyepiece, the distance of the eyehole may be thus found: Multiply the difference between the focal distance of the glass next to the speculum, and the distance of the two eyeglasses, by the focal distance of the glass nearest the eye; divide the product by the sum of the focal distances of the two lenses, lessened by their distance, and the quotient will be the compound focal distance required. Thus, if the focal distance of the lens next the speculum be three inches, that of the lens next the eye one inch, and their distance two inches, then the compound focal distance from the eyeglass will be $\frac{3-2+1}{3-1+2}=\frac{1}{2}$ inch. The *diameter* of the eyehole is always equal to the quotient obtained by dividing the diameter of the great speculum by the magnifying power of the telescope. It is generally from 1-25th to 1-50th of an inch in diameter. It is necessary, in many cases, to obtain *from direct experiment* an accurate determination of the place and size of the eyehole, as on this circumstance depends, in a certain degree, the accurate performance of the instrument.

To center the two specula of Gregorian Reflectors.—Extend two fine threads or wires across the aperture of the tube at right angles, so as to intersect each other exactly in the axis of the telescope Before the arm is finally fastened to the slider, place it in the tube, and through the eyepiece (without glasses) the intersection of the cross-wires must be seen exactly in the center of the hole of the arm. When this exactness is obtained, let the arm be firmly riveted and soldered to the slider.

To center Lenses.—The centering of lenses is of great importance, more especially for the object-glasses of achromatic instruments. The following is reckoned a good method: Let the lens to be centered be cemented on a brass chock, having the middle turned away so as not to touch the lens except near the edge, which will be hid when mounted. This rim is very accurately turned flat where it is to touch the glass. When the chock and cement is warm, it is made to revolve rapidly; while in motion, a lighted candle is brought before it, and its reflected image attentively watched. If this image has any motion, the lens is not flat or central; a piece of soft wood must therefore be applied to it in the manner of a turning tool, until such time as the light becomes stationary. When the whole has cooled, the edges of the lens must be turned by a diamond, or ground with emery.

For more particular details in reference to grinding and polishing specula and lenses, the reader is referred to Smith's "Complete System of Optics," Imison's "School of Arts," *Huygenii Opera*, Brewster's Appendix to "Ferguson's Lectures," "Irish Transactions," vol. x, or "Nicholson's Journal," vol. xvi, Nos. 65, 66, for January and February, 1807.

PART III.

ON VARIOUS ASTRONOMICAL INSTRUMENTS.

CHAPTER I.

ON MICROMETERS.

A MICROMETER is an instrument attached to a telescope, in order to measure small spaces in the heavens, such as the spaces between two stars, and the diameters of the sun, moon, and planets; and by the help of which, the *apparent magnitude* of all objects viewed through telescopes may be measured with great exactness.

There are various descriptions of these instruments, constructed with different substances and in various forms, of which the following constitute the principal variety: the *Wire* Micrometer—the *Spider's-line* Micrometer—the Polymetric Reticle—Divided *Object-glass* Micrometer—Divided *Eyeglass* Micrometer—Ramsden's *Catoptric* Micrometer—Rochon's *Crystal* Micrometer—Maskelyne's *Prismatic* Micrometer—Brewster's *Micrometrical Telescope*—Sir W. Herschel's *Lamp* Micrometer—Cavallo's *Mother-of-Pearl* Micrometer, and several others; but instead of attempting even a general description of these instruments, I shall confine myself merely to a very brief description of *Cavallo's Micrometer*, as its construction will be easily understood by the general reader, as it is one of the most simple of these instruments, and is so cheap as to be procured for a few shillings, while some of the instruments now mentioned are so expensive as to cost nearly as much as a tolerably good telescope.*

This micrometer consists of a thin and narrow slip of mother-of-pearl finely divided, which is placed in the focus of the eyeglass of a telescope, just where the image of the object is formed; and it may be applied either to a reflecting or a refracting telescope, provided the eyeglass be a convex lens. It is about the twentieth part of an inch broad, and of the thickness of common writing paper, divided into equal parts by parallel lines, every fifth and tenth of which is a little longer than the rest. The simplest way of fixing it is to stick it upon the diaphragm, which generally stands within the tube, and in the focus of the eyeglass. When thus fixed, if you look through the eyeglass, the divisions of the micrometrical scale will appear very distinct, unless the diaphragm is not exactly in the focus of the eyeglass, in which case it must be moved to the proper place; or the micrometer may be placed exactly in the focus of the eyelens by the interposition of a circular piece of paper, card, or by means of wax. If a person should not like to see always the micrometer in the field of the telescope, then the micrometrical scale, instead of being fixed to the diaphragm, may be fitted to a circular perforated plate of brass, of wood, or even of paper, which may be occasionally placed upon the said diaphragm. One of these micrometers, in my possession, which contains 600 divisions in an inch, is fitted up in a separate eyetube, with a glass peculiar to itself, which slides into the eyepiece of the telescope when its own proper glass is taken out.

To ascertain the Value of the Divisions of this Micrometer.—Direct the telescope to the sun, and observe how many divisions of the micrometer measure its diameter exactly; then take out of the Nautical Almanac the diameter of the sun for the day on which the observation is made; divide it by the above-mentioned number of divisions, and the quotient is the value of one division of the micrometer Thus, suppose that 26½ divisions of the micrometer measure the diameter of the sun, and that the Nautical Almanac gives for the measure of the same diameter 31′ 22″, or 1822″: divide 1822 by 26.5, and the quotient is 71″, or 1′ 11″, which is the value of one division of the micrometer, the double of which is the value of two divisions, and so on. The value of the divisions may likewise be ascertained by the passage of an equatorial star over a certain number of divisions in a certain time. The stars best situated for this purpose are such as the following: δ in the Whale, R. A. 37° 3⅓′, Dec. 37′ 50″ S.; δ in Orion, R. A. 80° 11′ 42″, Dec. 28′ 40″ S.; υ in the Lion, R. A. 171° 25′ 21″, Dec. 23′ 22″ N.; η in Virgo, R. A. 182° 10′, Dec. 33′ 27″ N. But the following is the most easy and accurate method of determining the value of the divisions.

Mark upon a wall or other place the length of *six inches*, which may be done by making two dots or lines six inches asunder, or by fixing a six inch ruler upon a stand. Then place the telescope before it, so that the ruler, or six inch length may be at right angles with the direction of the telescope, and just 57 feet 3½ inches distant from the object-glass of the telescope; this done, look through the telescope at the ruler, or other extension of six inches, and observe how many divisions of the micrometer are equal to it, and that same number of divisions is equal to half a degree, or 30′; and this is all that is necessary for the required determination; the reason of which is, because an extension of six inches subtends an angle of 30′ at the distance of 57 feet 3½ inches, as may be easily calculated from the rules of Plane Trigonometry.

---

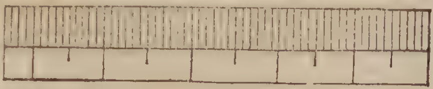
*A particular description of the micrometers here enumerated, and several others, will be found in Dr. Pearson's "Introduction to Practical Astronomy," vol. ii.

Fig. 85 exhibits this micrometer scale, but shows it four times larger than the real size of one which was adapted to a three feet achromatic telescope magnifying 84 times. The divisions upon it are the 200ths of an inch, which reach from one edge of the scale to about the middle of it, excepting every fifth and tenth division, which are longer. Two divisions of this scale are very nearly equal to one minute; and as a quarter of one of these divisions may be distinguished by estimation, therefore an angle of one-eighth of a minute, or of 7½″, may be measured with it. When a telescope magnifies more, the divisions of the micrometer must be more minute. When the focus of the eyeglass of the telescope is shorter than half an inch, the micrometer may be divided with the 500ths of an inch; by means of which, and the telescope magnifying about 200 times, one may easily and accurately measure an angle smaller than half a second. On the other hand, when the telescope does not magnify above 30 times, the divisions need not be so minute. In one of Dollond's pocket telescopes, which, when drawn out for use, is only 14 inches long, a micrometer with the hundredths of an inch is quite sufficient, and one of its divisions is equal to little less than three minutes, so that an angle of a minute may be measured by it. Supposing 11½ of those divisions equal to 30′, or 23 to a degree, any other angle measured by any other number of divisions is determined by proportion. Thus, suppose the diameter of the sun, seen through the same telescope, be found equal to 12 divisions, say, as 11½ divisions are to 30 minutes, so are 12 divisions to $\left(\frac{12+30}{11.5}\right)$ 31.3, which is the required diameter of the sun.

Practical Uses of this Micrometer.—This micrometer may be applied to the following purposes; 1. For measuring the apparent diameters of the sun, moon, and planets. 2. For measuring the apparent distances of the satellites from their primaries. 3. For measuring the cusps of the moon in eclipses. 4. For measuring the apparent distances between two contiguous stars—between a star and a planet—between a star and the moon—or between a comet and the contiguous stars, so as to determine its path. 5. For finding the difference of declination of contiguous stars, when they have nearly the same right ascension. 6. For measuring the small elevations or depressions of objects above and below the horizon. 7. For measuring the proportional parts of buildings, and other objects in perspective drawing. 8. For ascertaining whether a ship at sea, or any moving object, is coming nearer or going farther off; for if the angle subtended by the object appears to increase, it shows that the object is coming nearer, and if the angle appears to decrease, it indicates that the object is receding from us. 9. For ascertaining the real distances of objects of known extension, and hence to measure hights, depths, and horizontal distances. 10. For measuring the real extensions of objects when their distances are known. 11. For measuring the distance and size of an object when neither of them is known.

When the micrometer is adapted to those telescopes which have four glasses in the eyetube, *and when the eyetube only is used*, it may be applied to the following purposes: 1. For measuring the real or lineal dimensions of small objects, instead of the angles; for if the tube be unscrewed from the rest of the telescope, and applied to small objects, it will serve for a microscope, having a considerable magnifying power, as we have already shown (p. 97): and the micrometer, in that case, will measure the lineal dimensions of the object, as the diameter of a hair, the length of a flea, or the limbs of an insect. In order to find the value of the divisions for this purpose, we need only apply a ruler, divided into tenths of an inch, to the end of the tube, and looking through the tube, observe how many divisions of the micrometer measure one-tenth of an inch on the ruler, which will give the required value. Thus, if 30 divisions are equal to 1-10th of an inch, 300 of them must be equal to the 300th part of an inch. 2. For measuring the magnifying power of other telescopes. This is done by measuring the diameter of the pencil of light at the eye-end of the telescope in question; for, if we divide the diameter of the object-lens by the diameter of this pencil of light, the quotient will express how many times that telescope magnifies in diameter. Thus, suppose that 300 divisions of the micrometer are equal to the apparent extension of one inch—that the pencil of light is measured by four of these divisions—and that the diameter of the object-lens measures one inch and two tenths: Multiply 1.2 by 300, and the product 360, divided by 4, gives 90 for the magnifying power of the telescope.

Fig. 85.



Problems which may be solved by this Micrometer.—I. The angle—not exceeding one degree—which is subtended by an extension of one foot, being given, to find its distance from the place of observation: Rule 1. If the angle be expressed in minutes, say as the given angle is to 60, so is 687.55 to a fourth proportional, which gives the answer in inches. 2. If the angle be expressed in seconds, say, as the given angle is to 3600, so is 687.55 to a fourth proportional, which expresses the answer in inches. 3. If the angle be expressed in minutes and seconds, turn it all into seconds, proceed as above. Example: At what distance is a globe of one foot in diameter when it subtends an angle of two seconds? 2 : 3600 : : 687.55 : $\frac{3600+687.55}{2}$ = 1237596 inches, or 103132½ feet = the answer required. II. The angle which is subtended by any known extension being given, to find its distance from the place of observation: Rule: Proceed as if the extension were of one foot, by Problem I, and call the answer B; then, if the extension in question be expressed in inches, say as 12 inches are to that extension, so is B to a fourth proportional, which is the answer in inches. But if the extension in question be expressed in feet, then we need only multiply it by B, and the product is the answer in inches. Example: At what distance is a man six feet high when he appears to subtend an angle of 30″? By Problem I, if the man were one foot high the distance would be 82506 inches; but as he is six feet high, therefore multiply 82506 by 6, and the product is the required distance, namely, 495036 inches, or 41253 feet.

For greater convenience, especially in traveling, when one has not the opportunity of making such calculations, the two following tables have been calculated, the first of which shows the distance answering to any angle from one minute to one degree, which is subtended by a man whose hight is considered an extension of six feet, because at a mean, such is the hight of a man when dressed with hat and shoes on. These tables may be transcribed on a card, and may be kept always ready with a pocket telescope furnished with a micrometer. Their use is to ascertain distances without any calculations; and they are calculated only to minutes, because with a pocket telescope and micrometer it is not possible to measure an angle more accurately than to a minute. Thus, if we want to measure the extension of a street, let a foot ruler be placed at the end of the street; measure the angular appearance of it, which suppose to be 36′, and in the table we have the required distance against 36′, which is 95½ feet. Thus, also, a man who appears to be 49′ high is at the distance of 421 feet. Again: Suppose the trunk of a tree, which is known to be three feet in diameter, be observed to subtend an angle of 9½′. Take the number answering to 9′ out of the table, namely 382, and subtract from it a proportional part for the half minute, namely 19.1, which, subtracted from 382, leaves 362.9. This multiplied by 3, the diameter of the tree, produces 1087. 7 feet=the distance from the object-end of the telescope.

In this way the distance of a considerably remote object, as a town or building at ten or twelve miles' distance, may be very nearly determined, provided we have the lineal dimensions of a house or other object that stands at right angles to the line of vision. The breadth of a river, of an arm of the sea, or the distance of a lighthouse, whose elevation above the sea or any other point is known, may likewise, in this manner be easily determined.

Angles subtended by an extension of *one foot* at different distances.				Angles subtended by an extension of *six feet* at different distances.			
Angles in minutes.	Distances in feet.	Angles in minutes.	Distances in feet.	Angles in minutes.	Distances in feet.	Angles in minutes.	Distances in feet.

CHAPTER II.

ON THE EQUATORIAL TELESCOPE, OR PORTABLE OBSERVATORY.

The equatorial instrument is intended to answer a number of useful purposes in Practical Astronomy, independently of any particular observatory. Beside answering the general purpose of a quadrant, a transit instrument, a theodolite, and an azimuth instrument, it is almost the only instrument adapted for viewing the stars and planets *in the day-time*, and for following them in their apparent diurnal motions. It may be made use of in any steady room or place, and performs most of the useful problems in astronomical science.

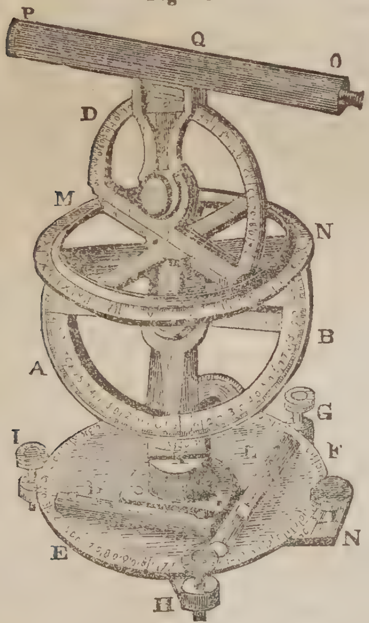
The basis of all equatorial instruments is a revolving axis, placed parallel to the axis of the earth, by which an attached telescope is made to follow a star or other celestial body in the arc of its diurnal revolution, without the trouble of repeated adjustments for changes of elevation, which quadrants and circles with vertical and horizontal axes require. Such an instrument is not only convenient for many useful and interesting purposes in celestial observations, but is essentially requisite in certain cases, particularly in examining and measuring the relative positions of two contiguous bodies, or in determining the diameters of the planets, when the spider's-line micrometer is used.

Christopher Scheiner is supposed to have been the first astronomer who, in the year 1620, made use of a polar axis, but without any appendage of graduated circles. It was not, however, until the middle of the last century that any instruments of this description, worthy of the name, were attempted to be constructed. In 1741, Mr. Henry Hindley, a clockmaker in York, added to the polar axis an equatorial plate, a quadrant of altitude, and declination semicircle; but when this piece of mechanism was sent to London for sale in 1748, it remained unsold for the space of 13 years. Mr. Short, the optician, published in the Philosophical Transactions for 1750 a "description of an equatorial telescope," which was of the reflecting kind, and was mounted over a combination of circles and semicircles, which were strong enough to support a tube, and a speculum of the Gregorian construction 18 inches in focal length. This instrument consisted of a somewhat cumbersome and expensive piece of machinery, a representation of which may be seen in vol. iii, of Martin's "*Philosophia Britannica*, or System of the Newtonian Philosophy." Various modifications of this instrument have since been made by Nairne, Dollond, Ramsden, Troughton, and other artists; but even at the present period it has never come into very general use, though it is one of the most pleasant and useful instruments connected with astronomical observations.

As many of these instruments are somewhat complicated and very expensive, I shall direct the attention of the reader solely to one which I consider as the most simple, which may be purchased at a moderate expense, and is sufficiently accurate for *general* observations.

The instrument consists of the following parts: *A horizontal circle, E F* (fig. 86), divided into four quadrants of 90 degrees each. There is a fixed nonius at *N;* and the circle is capable of being turned round on an axis. In the center of the horizontal circle is fixed a strong upright pillar, which supports the center of a vertical semicircle, *A B*, divided into two quadrants of 90 degrees each. This is called the *semicircle of altitude*, and may, at any time, serve the purpose of a quadrant in measuring either altitudes or depressions. It has a nonius plate at *K*. At right angles to the plane of this semicircle, the *equatorial circle, M N*, is firmly fixed. It represents the equator, and is divided into twice twelve hours, every hour being divided into twelve parts of five minutes each. Upon the equatorial circle moves another circle, with a chamfered edge, carrying a nonius, by which the divisions on the equatorial may be read off to single minutes; and at right angles to this movable circle is fixed the *semicircle of declination, D*, divided into two quadrants of 90 degrees each. The telescope, *P O*, is surmounted above this circle, and is fixed to an index movable on the semicircle of declination, and carries a nonius opposite to *Q*. The telescope is furnished with two or three Huygenian eyepieces and likewise with a diagonal eyepiece for viewing objects near the zenith. Lastly, there are two spirit levels fixed on the horizontal circle at right angles to each other, by means of which this circle is made perfectly level when observations are to be made.

Fig. 86.



To adjust the Equatorial for Observations.—Set the instrument on a firm support; then, *to adjust the levels and the horizontal circle*, turn the horizontal circle until the beginning *O* of the divisions coincides with the middle stroke of the nonius, or near it. In this situation, one of the levels will be found to lie either in a right line joining the two footscrews which are nearest the nonius, or else parallel to such a right line. By means of the last two screws, cause the bubble in the level to become stationary in the middle of the glass; then turn the horizontal circle half round by bringing the other *O* to the nonius; and if the bubble remains in the middle as before, the level is well adjusted; if it does not, correct the position of the level by turning one or both of the screws which pass through its ends until the bubble has moved half the distance it ought to come to reach the middle, and cause it to move the other half by turning the foot-screws already mentioned; return the horizontal circle to its first position, and if the adjustments have been well made, the bubble will remain in the middle; if otherwise, the process must be repeated until it bears this proof of its accuracy; then turn the horizontal circle until 90° stands opposite to the nonius; and by the foot-screw immediately opposite the other 90°, cause the bubble of the same level to stand in the middle of the glass; lastly, by its own proper screws set the other level so that its bubble may occupy the middle of its glass.

To adjust the Line of Sight.—Set the nonius on the *declination* semicircle at *O*, the nonius on the horary circle at VI, and the nonius on the semicircle of altitude at 90; look through the telescope toward some part of the horizon where there is a diversity of remote objects; level the horizontal circle, and then observe what object appears in the center of the cross-wires, or in the center of the field of view if there be no wires; reverse the semicircle of altitude so that the other 90° may apply to the nonius, taking care, at the same time, that the other three noniuses continue at the same parts of their respective graduations as before. If the remote object continues to be seen on the center of the cross-wires, the line of sight is truly adjusted.

To find the Correction to be applied to Observations by the Semicircle of Altitude.—Set the nonius on the declination semicircle to 0, and the nonius on the horary circle to XII; direct the telescope to any fixed and distant object by moving the horizontal circle and semicircle of altitude, and nothing else; note the degree and minute of altitude or depression; reverse the declination semicircle by directing the nonius on the horary circle to the opposite XII; direct the telescope again to the same object, by means of the horizontal circle and semicircle of altitude, as before. If its altitude or depression be the same as was observed in the other position, no correction will be required; but if otherwise, half the difference of the two angles is the correction to be added to all observations made with that quadrant, or half of the semicircle which shows the least angle, or to be subtracted from all the observations made with the other quadrant, or half of the semicircle. When the levels and other adjustments are once truly made, they will be preserved in order for a length of time, if not deranged by violence; and the correction to be applied to the semicircle of altitude is a constant quantity.

Description of the Nonius.—The nonius—sometimes called the *Vernier*—is a name given to a device for subdividing the arcs of quadrants and other astronomical instruments. It depends on the simple circumstance that if any line be divided into equal parts, the length of each part will be greater the fewer the divisions; and contrariwise, it will be less in proportion as those divisions are more numerous. Thus, in the equatorial now described, the distance between the two extreme strokes on the nonius is exactly equal to eleven degrees on the limb, only that it is divided into twelve equal parts. Each of these last parts will therefore be shorter than the *degree* on the limb in the proportion of 11 to 12, that is to say, it will be 1-12th part, or five minutes shorter; consequently, if the middle stroke be set precisely opposite to any degree, the relative positions of the nonius and the limb must be altered five minutes of a degree before either of the two adjacent strokes next the middle on the nonius can be brought to coincide with the nearest stroke of a degree; and so likewise the second stroke on the nonius will require a change of ten minutes, the third of fifteen, and so on to thirty, when the middle line of the nonius will be seen to be equidistant between two of the strokes on the limb; after which, the lines on the opposite side of the nonius will coincide in succession with the strokes on the limb. It is clear from this that whenever the middle stroke of the nonius does not stand precisely opposite to any degree, the odd minutes, or distance between it and the degree immediately preceding, may be known by the *number* of the stroke marked on the nonius, which coincides with any of the strokes on the limb.* In some instruments the nonius-plate has its divisions fewer than the number of parts on the limb to which it is equal; but when once a clear idea of the principle of any nonius is obtained, it will be easy to transfer it to any other mode in which this instrument is contrived.

To find by this Equatorial the Meridian Line, and the Time, from one Observation of the Sun.—In order to this, it is requisite that the sun's declination and the latitude of the place be known. The declination of the sun may be found for every day in the Nautical Almanac, or any other astronomical ephemeris; and the latitude of the place may be found by means of the semicircle of altitude, when the telescope is directed to the sun or a known fixed star. It is likewise requisite to make the observation when the azimuth and altitude of the sun alter quickly, and this is generally the case the farther that luminary is from the meridian; therefore at the distance of three or four hours either before or afternoon (in summer), adjust the horizontal circle; set the semicircle of altitude so that its nonius may stand at the colatitude of the place; lay the plane of the last-mentioned semicircle in the meridian by estimation, its 0 being directed toward the depressed pole; place the nonius of the declination semicircle to the declination, whether north or south; then direct the telescope toward the sun, partly by moving the declination semicircle on the axis of the equatorial circle, and partly by moving the horizontal circle on its own axis. There is but one position of these which will admit of the sun being seen in the middle of the field of view. When this position is obtained, the nonius on the equatorial circle shows *the apparent time, and the circle of altitude is in the plane of the meridian.* When this position is ascertained, the meridian may be settled by a landmark at a distance.

With an equatorial instrument nearly similar to that now described, I formerly made a series of "*day observations* on the celestial bodies," which were originally published in vol. xxxvi, of "Nicholson's Journal of Natural Philosophy," and which occupy twenty pages of that journal. Some of these observations I shall lay before the reader, after having explained the manner in which they are made.

The instrument was made by Messrs. W. and S. Jones, opticians, Holborn, London. The telescope which originally accompanied the instrument was an achromatic refractor, its object-glass being 8½ inches focal distance, and one inch in diameter. This telescope, not admitting sufficiently high magnifying powers for the observations intended, was afterward thrown aside for another telescope having an object-glass 20 inches focal length and 1¾ inches in diameter, which was attached to the equatorial machinery in place of the small telescope. It was furnished with magnifying powers of 15, 30, 45, 60, and 100 times. The instrument was placed on a firm pedestal about three feet high. The feet of this pedestal had short iron pikes, which slipped into corresponding holes in the floor of the apartment adjacent to a south window, so that when the direction of the meridian was found, and the circles properly adjusted, the instrument was in no danger of being shifted from this position. Though this instrument generally stood fronting the southern part of the heavens, yet the equatorial part along with the telescope, could occasionally be removed to another position fronting the north and north-west, for observing the stars in those quarters.

Manner of observing Stars and Planets in the Day-time by the Equatorial.—Before such observation can be made, the semicircle of altitude must be placed in the meridian, and the degree and minute pointed out by the nonius on the horizontal circle, when in this position, noted down in a book, so that it may be placed again in the same position, should any derangement afterward happen. The semicircle of altitude must be set to the colatitude of the place, that is, to what the latitude wants of 90°. Suppose the latitude of the place of observation be 52° 30′ north, this latitude subtracted from 90° leaves 37° 30′ for the colatitude, and therefore the semicircle of altitude on which the equatorial circle is fixed, must be elevated to 37° 30′, and then the equatorial circle on the instrument coincides with the equator in the heavens. Lastly, the telescope must be adjusted on the declination semicircle so as exactly to correspond with the declination of the heavenly body to be viewed. If the body is in the equator, the telescope is set by the index at 0 on the semicircle of declination, or at the middle point between the two quadrants, and then, when the telescope along with the semicircle of declination, is moved from right to left, or the contrary, it describes an arc of the equator. If the declination of the body be north, the telescope is elevated to the northern division of the semicircle; if south, to the southern part of it.

---

* **Adams's Introduction to Practical Astronomy.**

These adjustments being made, take the difference between the right ascension of the sun and the body to be observed, and if the right ascension of the body be greater than that of the sun, subtract the difference from the time of observation; if not, add to the time of observation.* The remainder in one case, or the sum in the other, will be the hour and minute to which the nonius on the equatorial circle is to be set; which being done, the telescope will point to the star or planet to whose declination the instrument is adjusted. When the heavenly body is thus found, it may be followed, in its diurnal course, for hours, or as long as it remains above the horizon; for as the diurnal motion of a star is parallel to the equator, the motion of the telescope on the equatorial circle will always be in the star's diurnal arc; and should it have left the field of the telescope for any considerable time, it may be again recovered by moving the telescope onward according to the time which elapsed since it was visible in the field of view. We may illustrate what has been now stated by an example or two: Suppose on the 30th of April, 1841, at one o'clock, P. M., we wished to see the star *Aldebaran:* the right ascension of this star is 4h 27m., and the sun's right ascension for that day at noon, as found in "White's Ephemeris" or the "Nautical Almanac," is 2h. 30m.; subtract this last number from 4h. 27m., and the remainder 1h. 57m., shows that the star comes to the meridian on that day at 57 minutes past 1 o'clock P. M.; and as the time of observation is 1 P. M., the nonius which moves on the equatorial circle must be set to three minutes past XI, as the star is at that hour 57 minutes from the meridian. The declination of Aldebaran is 16° 11′ north, to which point on the semicircle of declination the telescope must be adjusted, and then the star will be visible in the field of view. Again : suppose we wished to observe the planet Venus on 1st of Jan., 1842, at 12 o'clock noon: the sun's right ascension on that day is 18h. 46m., and that of Venus 17h. 41m., from which the sun's right ascension being subtracted, the remainder is 22h. 55m., or 55 minutes past 10, A. M. Here, as the right ascension of Venus is too small to have the sun's right ascension taken from it, we borrow 24 hours, and reckon the remainder from XII, at noon. As the planet at 12 at noon is one hour and five minutes past the meridian, the nonius on the equatorial circle must be set to that point, and the telescope adjusted to 23° 6′ of south declination, which is the declination of Venus for that day, when this planet will appear in the field of view.

OBSERVATIONS ON THE FIXED STARS AND PLANETS, MADE IN THE DAY-TIME BY THE EQUATORIAL.

For the purpose of illustrating the descriptions now given, and for affording some information, respecting celestial day observations, I shall select a few of the observations above alluded to, which I formerly published in Nicholson's Journal, along with a few others which have been since made. These observations were made with a view to determine the following particulars: 1. What stars and planets may be conveniently seen in the day-time when the sun is above the horizon? 2. What degrees of magnifying power are requisite for distinguishing them? 3. How near their conjunction with the sun they may be seen? and, 4. Whether the diminution of the aperture of the object-glass of the telescope, or the increase of magnifying power, conduces most to render a star or a planet visible in daylight. Having never seen such observations recorded in books of astronomy or in scientific journals, I was induced to continue them, almost every clear day, for nearly a year, in order to determine the points now specified. Some of the results are stated in the following pages.

Observations on Fixed Stars of the first Magnitude.—April 23, 1813, at 10h. 16m., A. M., the sun being 5½ hours above the horizon, saw the star *Vega*, or α Lyræ, very distinctly with a power of 30 times. Having contracted the aperture of the object-glass to 9-10ths of an inch, saw it on a darker ground, but not more plainly than before. Having contracted the aperture still further to half an inch, I perceived the star, but not so distinctly as before. The sky being very clear, and the star in a quarter of the heavens nearly opposite to the sun, I diminished the magnifying power to 15, and could still perceive the star, but indistinctly; it was just perceptible. August 23, at 0h. 12m., P. M. saw the star *Capella* or α *Aurigæ*, with a power of 60, and immediately afterward with a power of 30, the aperture undiminished. With this last power it appeared extremely distinct, but not so brilliant and splendid as with the former power. Having diminished the aperture to 9-10ths of an inch, it appeared on a darker ground, though in the former case it was equally perceptible. A few minutes afterward, could distinguish it with a power of 15, the aperture being contracted to half an inch. It appeared very small; it was with difficulty the eye could fix upon it in the field of the telescope; but when it was once perceived, its motion across the field of view could be readily followed. It could not be perceived when the diminished aperture was removed. The sun was then shining in meridian splendor.

August 10th, 9h. 30m., A. M., saw the star Sirius with a power of 60, the aperture contracted to 9-10ths of an inch; saw it likewise when the aperture was diminished to half an inch, but not so distinctly as through the aperture of 9-10ths of an inch. Having put on a power of 30, could distinguish it distinctly enough through each of the former apertures, and likewise when they were removed, but somewhat more distinctly with the apertures of 9-10ths and a half inch than without them. At this time the star was 2h. 42m. in time of right ascension west of the sun, having an elevation above the horizon of about 17° 10′, the sun shining bright, and the sky very much enlightened in that quarter of the heavens where the star appeared. There was also a considerable undulation of the air, which is generally the case in the hot mornings of summer, which renders a star more difficult to be perceived than in the afternoon, especially when it is viewed at a low altitude. June 4th, 1h. 30m., P. M., saw Sirius with a power of 30 with great distinctness, the aperture not contracted. The star was then within 1h. 50m. in time of right ascension east from the sun. August 24th, 9h. 5m., A M., saw the star *Procyon, α Canis Minoris*, distinctly with a power of 60, the aperture not contracted. When diminished to 9-10ths of an inch, it appeared rather more distinct, as the ground on which it was seen was darker. With a power of 30, and the aperture contracted to 9-10ths of an inch, could perceive it, but somewhat indistinctly. When the equatorial motion was performed in order to keep it in the field of view, it was some time before the eye could again fix upon it. When the aperture was diminished to half an inch, it could not be perceived. Saw it when both the apertures were removed, but rather more distinctly with the aperture of 9-10ths of an inch. The difference in the result of this observation from that of Capella above stated was owing to the star's proximity to the sun, and the consequent illumination of the sky in that quarter where it appeared. Its difference in right ascension from that of the sun was then about 2h. 5m. of time, and its difference of declination about 4° 50'.* This star may be considered as one of those which rank between the first and second magnitudes.

---

*Or find the sun's right ascension for the given day; subtract this from the star or planet's right ascension, and the remainder is the approximate time of the star's coming to the meridian. The difference between this time and the time of observation will then determine the point to which the telescope is to be directed.

Similar observations to the above were made and frequently repeated on the stars Rigel, Aldebaran, Betelguese, Cor Leonis, and other stars of the first magnitude, which gave nearly the same results. The stars Altares and Fomalhaut are not so easily distinguished, on account of their great southern declination, and consequent low elevation above the horizon. The following observation on *Arcturus* may be added. June 3d, observed Arcturus very distinctly a little before seven in the evening,—the sun being about 1h. 40m. above the horizon, and shining bright—with a power of 15, the aperture not contracted. It appeared very small, but distinct. This star is easily distinguishable at any time of the day with a power of 30.

Observations on Stars of the Second Magnitude.—May 5, 1813, at 6h., P. M., the sun being an hour and three-quarters above the horizon, saw *Alphard*, or α Hydræ, a star of the second magnitude, with a power of 60, the aperture diminished to 9-10ths of an inch. A few minutes afterward could perceive it, but indistinctly, with a power of 30, the aperture contracted as above. It could not be seen very distinctly with this power until about half an hour before sunset. It was then seen rather more distinctly when the aperture was contracted than without the contraction. May 7th, saw the star *Deneb*, or β *Leonis*, distinctly with a power of 60, about an hour and a half before sunset. August 20th, saw Ras Alhague, or α *Ophiuchi*, at 4h. 40m., P. M., with a power of 100, the sun being nearly three hours above the horizon, and shining bright. Perceived it about an hour afterward with a power of 60, with the aperture contracted to 9-10ths of an inch, and also when this contraction was removed. The star was seen nearly as distinctly in the last case as in the first. August 27, 5h., P. M., the same star appeared quite distinct with a power of 60, the aperture not contracted. It did not appear more distinct when the aperture was contracted to 9-10ths of an inch. The sun was then more than two hours above the horizon. August 28th, saw the star *Pollux*, or β *Gemini*, two hours after sunrise, with a power of 60, aperture undiminished. November 12th, 1h. 30m., P. M., saw the star *Altair*, or α *Aquilæ*, with an 8½ inch telescope, one inch aperture, carrying a power of 45, the aperture not contracted. Having contracted the aperture a little, it appeared somewhat less distinct. This star is reckoned by some to belong to the class of stars of the first magnitude, but in White's "Ephemeris" and other almanacs it is generally marked as being of the second magnitude. It forms a kind of medium between stars of the first and second magnitude.

Similar observations, giving the same results, were made on the stars Bellatrix, Orion's Girdle, α Andromedæ, α Pegasi, Alioth, Benetnasch, North Crown, or α Coronæ Borealis, and various other stars of the same magnitude.

From the above and several hundreds of similar observations, *the following conclusions* are deduced:

1. That a magnifying power of 30 times is sufficient for distinguishing a fixed star of the first magnitude, even at noonday, at any season of the year, provided it have a moderate degree of elevation above the horizon, and be not within 30° or 40° of the Sun's body; also, that by a magnifying power of 15, a star of this class may be distinguished when the sun is not more than an hour and a half above the horizon; but, in every case, higher powers are to be preferred. Powers of 45 or 60, particularly the last, were found to answer best in most cases, as with such powers the eye could fix on the star with ease as soon as it entered the field of the telescope.

2. That most of the stars of the second magnitude may be seen with a power of 60 when the sun is not much more than two hours above the horizon; and, at any time of the day, the brightest stars of this class may be seen with a power of 100 when the sky is serene, and the star not too near the quarter in which the sun appears.

3. That, in every instance, an increase of magnifying power has the principal effect in rendering a star easily perceptible; that diminution of aperture, in most cases, produces a very slight effect—in some cases none at all; and, when the aperture is contracted beyond a certain limit, it produces a hurtful effect. The cases in which a moderate contraction is useful are the two following: 1 When the star appears in a bright part of the sky, not far from that quarter in which the sun appears. 2. When an object-glass of a large aperture and a small degree of magnifying power is used. In almost every instance, the contraction of the object-glass of the 8½ inch telescope with a power of 45 had a hurtful effect; but when the 20 inch telescope carried a power of only 15, the contraction served to render the object more perceptible.

OBSERVATIONS ON THE PLANETS MADE IN THE DAY-TIME.

Some of the planets are not so easily distinguished in the day-time as the fixed stars of the first magnitude. The one which is most easily distinguished at all times is the planet Venus.

1. *Observations on Venus.*—My observations on this planet commenced about the end of August, 1812, about three or four weeks after its inferior conjunction. About that period, between ten and eleven in the forenoon, with a power of 45, it appeared as a beautiful crescent, quite distinct and well-defined, with a luster similar to that of the

---

* The right ascensions, declinations, longitudes, &c., stated in these memoranda, which were noted at the time of observation, are only approximations to the truth; perfect accuracy in these respects being of no importance in such observations. They are, however, in general, within a minute or two of the truth. The *times* of the observations, too, are noted in reference, not to the *astronomical*, but to the *civil* day. The astronomical day commences at 12 noon, and the hours are reckoned, without interruption, to the following noon. The civil day commences at 12 midnight

moon about sunset, but of a whiter color. The view of its surface and phase was fully more distinct and satisfactory than what is obtained in the evening after sunset; for, being at a high elevation, the undulation near the horizon did not affect the distinctness of vision. The planet was then very distinctly seen with a power of seven times, when it appeared like a star of the first or second magnitude. I traced the variation of its phases almost every clear day until the month of May, 1813. As at that time it was not far from its superior conjunction with the sun, I wished to ascertain how near its conjunction with that luminary it might be seen, and particularly whether it might not be possible, in certain cases, to see it at the moment of its conjunction.

The expressions of all astronomical writers previous to this period, when describing the phases of Venus, either directly assert, or at least imply, that it is *impossible* to see that planet, in any instance, at the time of its superior conjunction. This is the language of Dr. Long, Dr. Gregory, Dr. Brewster, Ferguson, Adams, B. Martin, and most other writers on the science of Astronomy. How far such language is correct will appear from the following observations and remarks.

April 24, 1813, 10h. 50m., A. M., observed Venus with a power of 30, the aperture not contracted. She was then about 31 minutes of time in right ascension distant from the sun, their difference of declination 3° 59′. She appeared distinct and well-defined. With a power of 100, could distinguish her gibbous phase. May 1st, 10h. 20m., A. M., viewed this planet with a power of 60, the aperture not contracted. It appeared distinct. Saw it about the same time with a power of 15, the aperture being contracted to 9-10ths of an inch. Having contracted the aperture to half an inch, saw it more distinctly. When the contracted apertures were removed, the planet could with difficulty be distinguished, on account of the direct rays of the sun striking on the inside of the tube of the telescope. The sun was shining bright, and the planet about 25′ of time in R. A. west of his center, their difference of declination being 3° 7′. May 7th, 10h., A. M., saw Venus distinctly with a power of 60, the sun shining bright. It was then about 19′ of time in R. A., and 4° 27′ in longitude west of the sun, their difference of declination being 2° 18′. I found a diminution of aperture particularly useful when viewing the planet at this time, even when the higher powers were applied. This was the last observation I had an opportunity of making prior to the conjunction of Venus with the sun, which happened on May 25th, at 9h. 3m., A. M. Its geocentric latitude at that time being about 16′ south, the planet must have passed almost close by the sun's southern limb. Cloudy weather for nearly a month after the last observation prevented any further views of the planet, when it was in that part of the heavens which was within the range of the instrument. The first day that proved favorable after it had passed the superior conjunction was June 5th. The following is the memorandum of the observation then taken:

June 5th, 9h., A. M., adjusted the equatorial telescope for viewing the planet Venus, but it could not be perceived on account of the direct rays of the sun entering the tube of the telescope. I contrived an apparatus for screening his rays, but could not get it conveniently to move along with the telescope, and therefore determined to wait until past eleven, when the top of the window of the place of observation would intercept the solar rays. At 11h. 20m., A. M., just as the sun had passed the line of sight from the eye to the top of the window, and his body was eclipsed by it, I was gratified with a tolerably distinct view of the planet, with a power of 60, the aperture being contracted to 9-10ths of an inch. This distinctness increased as the sun retired, until, in two or three minutes, the planet appeared perfectly well-defined. Saw it immediately afterward with a power of 30, the aperture contracted as before. Saw it also quite distinctly with a power of 15; but it could not be distinguished with this power when the contracted aperture was removed. At this time Venus was just 3° in longitude, or about 13′ in time of R. A. east of the sun's center, and of course only about 2¾th degrees from his eastern limb; the difference of their declination being 27′, and the planet's latitude 11′ north.

Several years afterward I obtained views of this planet when considerably nearer the sun's margin than as stated in the above observation, particularly on the 16th of October, 1819, at which time Venus was seen when only six days and nineteen hours past the time of the superior conjunction. At that time its distance from the sun's eastern limb was only 1° 28′ 42″. A subsequent observation proved that Venus can be seen when only 1° 27′ from the sun's margin, which I consider as approximating to the nearest distance from the sun at which this planet is distinctly visible. I shall only state further the two or three following observations.

June 17th, 1813, 10h., A. M., saw Venus with a power of 60, the aperture being contracted to 9-10ths of an inch, the direct rays of the sun *not being intercepted by the top of the window.* The aperture having been farther contracted to half an inch, could perceive her, but not quite so distinctly. When the contractions were removed, she could scarcely be seen. She was then 3° 33′ in longitude, and nearly 15 minutes in time of R. A. distant from the sun's center. Some fleeces of clouds having moved across the field of view, she was seen remarkably distinct in the interstices, the sun at the same time being partly obscured by them. August 19th, 1h. 10m., P. M., viewed Venus with a magnifying power of 100. Could perceive her surface and gibbous phase almost as distinctly as when the sun is below the horizon. She appeared bright, steady in her light, and well-defined, without that glare and tremulous appearance she exhibits in the evening when near the horizon. She was then nearly on the meridian. On the whole, such a view of this planet is as satisfactory, if not preferable, to those views we obtain with an ordinary telescope in the evening, when it is visible to the naked eye.

All the particulars above stated have been confirmed by many subsequent observations continued throughout a series of years. I shall state only two recent observations, which show that Venus may be seen somewhat nearer the sun than what is deduced from the preceding observations, and at the point of its superior conjunction. March 10th, 1842, observed the planet Venus, then very near the sun, at 19 minutes past 11, A. M. It had passed the point of its superior conjunction with the sun on the 5th of March, at 1h 19m., P. M. The difference of right ascension between the sun and the planet was then about 6½ minutes of time, or about 1° 37½′, and it was only about 1° 21′ distant from the sun's eastern limb. It appeared quite distinct and well-defined, and might perhaps have been seen on the preceding day, had the observation been then made. The following observation shows that Venus may be seen still nearer the sun than in the preceding observations, and even *at the moment of its superior conjunction.* On the 2d of October, 1843, this planet passed the point of its superior conjunction with the sun at 4h. 15m., P. M. At two o'clock, P. M., only two hours before the conjunction, I perceived the planet distinctly, and kept it in view for nearly ten minutes, until some dense clouds intercepted the view. It appeared tolerably distinct and well-defined, though not brilliant, and with a round, full face, and its apparent path was distinctly traced several times across the field of view of the telescope. I perceived it afterward, about half past four, P. M., only a few minutes after it had passed the point of conjunction, on which occasion it appeared less distinct than in the preceding observation, owing to the low altitude of the planet, being then only a few degrees above the horizon. The observations, in this instance, were made, not with an equatorial instrument, which I generally use in such observations, but with a good achromatic telescope of $44\frac{1}{2}$ inches focal distance, mounted on a common tripod, with a terrestrial power of 95 times. A conical tube about ten inches long was fixed on the object-end of the telescope, at the extremity of which an aperture $1\frac{1}{2}$ inches in diameter was placed, so as to intercept, as much as possible, the direct ingress of the solar rays. The top of the upper sash of the window of the place of observation was likewise so adjusted as to intercept the greater part of the sun's rays from entering the tube of the telescope. The sun's declination at that time was $3^\circ\ 26'$ south, and that of Venus 2° $12'$ south; consequently, the difference of declination was $1^\circ\ 14' =$ the distance of Venus from the sun's center; and as the sun's diameter was about $16'$, Venus was then only $58'$ from the sun's northern limb, or $6'$ less than two diameters of the sun.

This is the nearest approximation to the sun at which I have ever beheld this planet, and it demonstrates that Venus may be seen even within a degree of the sun's margin; and it is, perhaps, the nearest position to that luminary in which this planet can be distinctly perceived. It shows that the light reflected from the surface of Venus is far more brilliant than that reflected from the surface of our moon; for no trace of this nocturnal luminary can be perceived, even when at a much greater distance from the sun, nor is there any other celestial body that can be seen within the limit now stated. This is the first observation, so far as my information extends, of Venus having been seen at the time of her superior conjunction.*

The practical conclusion from this observation is, that at the superior conjunction of this planet, when its distance from the sun's margin is not less than $58'$, *its polar and equatorial diameter may be measured* by a micrometer, when it will be determined whether or not Venus be of a *spheroidal* figure. The Earth, Mars, Jupiter, and Saturn are found to be, not spheres, but *spheroids*, having their polar shorter than their equatorial diameters. But the true figure of Venus has never yet been ascertained, because it is only at the superior conjunction that she presents a full, enlightened hemisphere, and when both diameters can be measured, except at the time when she transits the sun's disc, which happens only twice in the course of 120 years.†

The following conclusions are deduced from the observations on Venus:

1. That this planet may be seen distinctly, with a moderate degree of magnifying power, *at the moment of its superior conjunction with the sun*, when its geocentric latitude, either north or south, at the time of conjunction, is not less than 1° $14'$, or when the planet is about $58'$ from the

---

* This observation is inserted in the "Edinburgh Philosophical Journal" for January, 1844.

† The late Dr. Benjamin Martin, when describing the nature of the solar telescope, in his "*Philosophia Britannica*," vol. iii, p. 85, gives the following relation: "I cannot here omit to mention a very *unusual phenomenon* that I observed about ten years ago in my darkened room. The window looked toward the west, and the spire of Chichester Cathedral was before it at the distance of 50 or 60 yards. I used very often to divert myself by observing the pleasant manner in which the sun passed behind the spire, and was eclipsed by it for some time; for the image of the sun and of the spire were very large, being made by a lens of 12 feet focal distance; and once, as I observed the occultation of the sun behind the spire, just as the disc disappeared, I saw several small, bright, round bodies or balls running toward the sun from the dark part of the room, even to the distance of 20 inches. I observed their motion was a little irregular, but rectilinear, and seemed accelerated as they approached the sun. These luminous globules appeared also on the other side of the spire, and preceded the sun, running out into the dark room, sometimes more, sometimes less, together, in the same manner as they followed the sun at its occultation. They appeared to be, in general, one-twentieth of an inch in diameter, and therefore must be very large, luminous globes in some part of the heavens, whose light was extinguished by that of the sun, so that they appeared not in open daylight; but whether of the meteor kind, or what sort of bodies they might be, I could not conjecture." Professor Hansteen mentions that, when employed in measuring the zenith distances of the pole-star, he observed a somewhat similar phenomenon, which he described as "a luminous body which passed over the field of the universal telescope; that its motion was neither perfectly equal nor rectilinear, but resembled very much the unequal and somewhat serpentine motion of an ascending rocket;" and he concluded that it must have been "a meteor" or "shooting star" descending from the higher regions of the atmosphere. (See Edinburgh Philosophical Journal for April, 1825, No. XXIV.)

In my frequent observations on Venus, to determine the nearest positions to the sun in which that planet could be seen, I had several times an opportunity of witnessing similar phenomena. I was not a little surprised, when searching for the planet, frequently to perceive a body pass across the field of the telescope, apparently of the same size as Venus, though sometimes larger and sometimes smaller, so that I frequently mistook that body for the planet, until its rapid motion undeceived me. In several instances *four or five* of these bodies appeared to cross the field of view, sometimes in a perpendicular, and at other times in a horizontal direction. They appeared to be luminous bodies, somewhat resembling the appearance of a planet when viewed in the day-time with a moderate magnifying power. Their motion was nearly rectilinear, but sometimes inclined to a waving or serpentine form, and they appeared to move with considerable rapidity—the telescope being furnished with a power of about 70 times. I was for a considerable time at a loss what opinion to form of the nature of these bodies; but, having occasion to continue these observations almost every clear day for nearly a twelvemonth, I had frequent opportunities of viewing this phenomenon in different aspects, and was at length enabled to form an opinion as to the cause of at least *some* of the appearances which presented themselves. In several instances, the bodies alluded to appeared much larger than usual, and to move with a more rapid velocity; in which case I could plainly perceive that they were nothing else than *birds* of different sizes, and apparently at different distances, the convex surface of whose bodies, in certain positions, strongly reflected the solar rays. In other instances, when they appeared smaller, their true shape was undistinguishable, by reason of their motion and their distance.

Having inserted a few remarks on this subject in No. XXV, of the Edinburgh Philosophical Journal for July, 1825, particularly in reference to Professor Hansteen's opinion, that article came under the review of M. Serres, sub-prefect of Embrun, in a paper inserted in the *Annales de Chimie* for October, 1825, entitled "Notices regarding fiery meteors seen during the day." (See Edinburgh Philosophical Journal for July, 1826, p. 114.) In the discussion of this subject, M. Serres admits that the light reflected very obliquely from the feathers of a bird is capable of producing an effect similar to that which I have now described, but that "the explanation ought not to be *generalized.*" He remarks, that while observing the sun at the repeating circle, he frequently perceived, even through the colored glass adapted to the eyepiece, large luminous points which traversed the field of the telescope, and which appeared too well-defined not sun's limb This conclusion is deduced from the observation of October 2, 1843,* stated above.

2. Another conclusion is, that during the space of 583 days, or about 19 months—the time this planet takes in moving from one conjunction with the sun to a like conjunction again—when its latitude at the time of its superior conjunction exceeds 1° 14′, it may be seen with an equatorial telescope every clear day without interruption, except about the period of its *inferior* conjunction, when its dark hemisphere is turned toward the earth, and a short time before and after it. When its geocentric latitude is less than 1° 14′, it will be hid only about four days before, and the same time after its superior conjunction. During the same period it will be invisible to the naked eye, and consequently no observations can be made upon it with a common telescope for nearly six months, and sometimes more, according as its declination is north or south, namely, about two or three months before, and the same time after its superior conjunction, except where there is a very free and unconfined horizon. In regard to the time in which this planet can be hid about the period of its *inferior* conjunction, I have ascertained from observation that it can never be hid longer than during a space of 2 days 22 hours, having seen Venus, about noon, like a fine, slender crescent, only 35 hours after she had passed the point of her inferior conjunction; and in a late instance she was seen when little more than a day from the period of conjunction. The longest time, therefore, that this planet can be hid from view during a period of 583 days, is only about ten days; and when its latitude at the time of the superior conjunction equals or exceeds 1° 14′, it can be hid little more than two days. This is a circumstance which cannot be affirmed of any other celestial body, the sun only excepted.

3. That every variation of the phases of this planet, from a slender crescent to a full enlightened hemisphere, may, on every clear day, be conveniently exhibited by means of the equatorial telescope. This circumstance renders this instrument peculiarly useful in the instruction of the young in the principles of astronomy; for if the phase which Venus should exhibit at any particular time be known, the equatorial telescope may be directed to the planet, and its actual phase in the heavens be immediately exhibited to the astronomical pupil.

4. Since it is only at the period of the superior conjunction that this planet presents a full enlightened hemisphere, and since it is only when this phase is presented that both its diameters can be measured, it is of some importance that observations be made on it at the moment of conjunction, by means of powerful telescopes furnished with micrometers, so as to determine the difference (if any) between its polar and equatorial diameters.

5. Another conclusion from the observations on Venus is, that a moderate diminution of the aperture of the object-glass of the telescope is useful, and even necessary, in viewing this planet when near the sun. Its effect is owing in part to the direct solar rays being thereby effectually excluded, for when these rays enter directly into the tube of the telescope, it is very difficult, and almost impossible, to perceive this planet, or any other celestial body when in the vicinity of the sun.

OBSERVATIONS ON JUPITER AND OTHER PLANETS.

This planet is very easily distinguished in the day-time with a very moderate magnifying power, when it is not within 30° or 35° of the sun. The following extract from my memorandums may serve as a specimen: May 12, 1813, 1h. 40m., P. M., saw Jupiter with a power of 15 times, the aperture not contracted. The planet appeared so distinct with this power that I have reason to believe it would have been perceived with a power of six or seven times. When the aperture was contracted to 9-10ths of an inch, and afterward to half an inch, there was little perceptible difference in its appearance. It was then about 58° in longitude east of the sun.

Though Jupiter, when at a considerable distance from the sun, and near his opposition, appears to the naked eye with a brilliancy nearly equal to that of Venus, yet there is a very striking difference between them in respect of luster when viewed in daylight. Jupiter, when viewed with a high magnifying power in the day-time, always exhibits a very dull, cloudy appearance, whereas Venus appears with a moderate degree of splendor. About the end of June, 1813, between five and six in the evening, having viewed the planet Venus, then within 20° of the sun, and which appeared with a moderate degree of luster, I directed the telescope to Jupiter, at that time more than 32° from the sun, when the contrast between the two planets was very striking, Jupiter appearing so faint as to be just discernible,

---

admit them to be distant, and subtended too large angles to imagine them birds. In illustration of this subject, he states the following facts: On the 7th of September, 1820, after having observed for some time the eclipse of the sun which happened on that day, he intended to take a walk in the fields, and on crossing the town, he saw a numerous group of individuals of every age and sex, who had their eyes fixed in the direction of the sun. Farther on, he perceived another group, having their eyes in like manner turned toward the sun. He questioned an intelligent artist who was among them to learn the object that fixed his attention. He replied, "We are looking at the stars which are detaching themselves from the sun." "You may look yourself; that will be the shortest way to learn the fact." He looked, and saw, in fact, not stars, but balls of fire, of a diameter equal to the largest stars, which were projected in various directions from the upper hemisphere of the sun, with an incalculable velocity; and although this velocity of projection appeared the same in all, yet they did not all attain the same distance. These globes were projected at unequal and pretty short intervals. Several were often projected at once, but always diverging from one another. Some of them described a right line, and were extinguished in the distance: some described a parabolic line, and were in like manner extinguished; others, again, after having removed to a certain distance, in a right line, retrograded upon the same line, and seemed to enter, still luminous, into the sun's disc. The ground of this magnificent picture was a sky-blue, somewhat tinged with brown. Such was his astonishment at the sight of so majestic a spectacle, that it was impossible for him to keep his eyes off it until it ceased, which happened gradually as the eclipse wore off and the solar rays resumed their ordinary luster. It was remarked by one of the crowd that "the sun projected most stars at the time when it was palest;" and that the circumstance which first excited attention to this phenomenon was that of a woman, who cried out, "Come here! come and see the flames that are issuing from the sun!"

I have stated the above facts because they may afterward tend to throw light upon certain objects or phenomena with which we are at present unacquainted. The phenomenon of "falling stars" has of late years excited considerable attention, and it seems now to be admitted that at least certain species of these bodies descend from regions far beyond the limits of our atmosphere. This may be pronounced as certain with regard to the "November Meteors." May not some of the phenomena described above be connected with the fall of meteoric stones—the showers of falling stars seen on the 12th and 13th of November, or other meteoric phenomena whose causes we have hitherto been unable to explain? Or, may we conceive that certain celestial bodies, with whose nature and destination we are as yet unacquainted, may be revolving in different courses in the regions around us, some of them opaque and others luminous, and whose light is undistinguishable by reason of the solar effulgence?

* For an explanation of the manner of viewing Venus at her superior conjunction, see "Celestial Scenery."

though his apparent magnitude was nearly double that of Venus. In this observation a power of 65 was used. In his approach toward the sun, about the end of July, I could not perceive him when he was within 16° or 17° of his conjunction with that luminary. *These circumstances furnish a sensible and popular proof,* independently of astronomical calculations, *that the planet Jupiter is placed at a much greater distance from the sun than Venus,* since its light is so faint as to be scarcely perceptible when more than 20 degrees from the sun, while that of Venus is distinctly seen amid the full splendor of the solar rays, when only about a degree from the margin of that luminary. With a power of 65 I have been enabled to distinguish the *belts* of Jupiter before sunset, but could never perceive any of his satellites until the sun was below the horizon. There are no observations which so sensibly and strikingly indicate the different degrees of light emitted by the different planets as those which are made in the day-time. To a common observer, during night, Jupiter and Venus appear, in a clear sky, nearly with equal brilliancy, and even Mars, when about the point of his *opposition* to the sun, appears with a luster somewhat similar, though tinged with a ruddy hue; but when seen in daylight their aspect is very dissimilar. This circumstance evidently indicates, 1. That these planets are placed at different distances from the sun, and consequently are furnished with different degrees of light proportional to the square of their distances from that luminary; and, 2. That there are certain circumstances connected with the surfaces and atmospheres of the planetary bodies which render the light they emit more or less intense, independently of their different distances from the central luminary; for Mars, though much nearer to the sun than Jupiter, is not so easily distinguished in the day-time, and even in the night-time appears with a less degree of luster.

My observations on *Saturn* in daylight have not been so frequent as those on Jupiter. I have been enabled to distinguish his ring several times before sunset with a power of 65, but his great southern declination, and consequent low altitude, at the periods when these observations were made, were unfavorable for determining the degree of his visibility in daylight; for a planet or a star is always more distinctly perceptible in a *high* than in a low altitude, on account of the superior purity of the atmosphere through which a celestial object is seen when at a high elevation above the horizon. This planet, however, is not nearly so distinctly visible in daylight as Jupiter, and I have chiefly seen it when the sun was not more than an hour or two above the horizon, but never at noonday, although it is probable that with powerful instruments it may be seen even at that period of the day. The planet *Mars*, is seldom distinctly visible in the day-time, except when at no great distance from its opposition to the sun. The following is a memorandum of an observation on Mars, when in a favorable position: October 24, 1836, saw the planet Mars distinctly with a power of about 60, at 40 minutes past 9, A. M., the sun having been above the horizon nearly three hours. It appeared tolerably distinct, but scarcely so brilliant as a fixed star of the first magnitude, though with apparently as much light as Jupiter generally exhibits when viewed in daylight. It could not be traced longer at the time, so as to ascertain if it could be seen at midday, on account of the interposition of the western side of the window of the place of observation. The ruddy aspect of this planet—doubtless caused by a dense atmosphere with which it is environed—is one of the causes which prevents its appearing with brilliancy in the day-time. With respect to the planet *Mercury*, I have had opportunities of observing it several times after sunrise and before sunset, about 10 or 12 days before and after its greatest elongation from the sun, with a power of 45. I have several times searched for this planet about noon, but could not perceive it. The air, however, at the times alluded to, was not very clear, and I was not certain that it was within the field of the telescope, and therefore I am not convinced but that, with a moderately high power, it may be seen even at noonday.

Such are some of the specimens of the observations I have made on the heavenly bodies in the day-time, and the conclusions which may be deduced from them. I have been induced to communicate them from the consideration that the most minute facts in relation to any science are worthy of being known, and may possibly be useful. They may at least gratify the astronomical tyro with some information which he will not find in the common treatises on Astronomy, and may perhaps excite him to prosecute a train of similar observations for confirming or correcting those which have been noted above.

Beside the deductions already stated, the following general conclusions may be noted: 1. That a celestial body may be as easily distinguished at noonday as at any time between the hours of nine in the morning and three in the afternoon, except during the short days in winter. 2. They are more easily distinguished at a high than at a low altitude—in the afternoon than in the morning, especially if their altitudes be low—and in the northern region of the heavens than in the southern. The difficulty of perceiving them at a low altitude is obviously owing to the thick vapors near the horizon. Their being less easily distinguised in the morning than in the afternoon is owing to the undulations of the atmosphere, which are generally greater in the morning than in the afternoon. This may be evidently perceived by looking at distant land objects at those times, in a hot day, through a telescope which magnifies about 40 or 50 times, when they will be found to appear tremulous and distorted in consequence of these undulations, especially if the sun be shining bright. In consequence of this circumstance, we can seldom use a high terrestrial power with effect on land objects except early in the morning and a short time before sunset. Their being more easily distinguished in the northern region of the heavens is owing to that part of the sky being of a deeper azure, on account of its being less enlightened than the southern with the splendor of the solar rays.

UTILITY OF CELESTIAL DAY OBSERVATIONS.

The observations on the heavenly bodies in the day-time, to which I have now directed the attention of the reader, are not to be considered as merely gratifications of a rational curiosity, but may be rendered subservient to the promotion of astronomical science. As to the planet Venus: when I consider the degree of brilliancy it exhibits, even in daylight, I am convinced that useful observations might frequently be made on its surface in the day-time, to determine some of its physical peculiarities and phenomena. Such observations might set at rest any disputes which may still exist respecting the period of rotation of this planet. Cassini, from observations on a bright spot, which advanced 20° in 24h. 34m., determined the time of its rotation to be 23 hours 20 minutes. On the other hand, Bianchini, from similar observations, concluded that its diurnal period was 24 days and 8 hours. The difficulty of deciding between these two opinions arises from the short time in which observations can be made on this planet, either before sunrise or after sunset, which prevents us from tracing with accuracy the progressive motion of its spots for a sufficient length of time; and, although an observer should mark the motion of the spots at the same hour on two succeeding evenings, and find they had moved forward 15° in 24 hours, he would still be at a loss to determine whether they had moved only 15° in all since the preceding observation, or had finished a revolution and 15° more. If, therefore, any spots could be perceived on the surface of Venus in the day-time, their motion might be traced, when she is in north declination, for 12 hours or more, which would completely settle the period of rotation. That it is not improbable that spots fitted for this purpose may be discovered on her disc in the day-time, appears from some of the observations of Cassini, who saw one of her spots when the sun was more than eight degrees above the horizon.* The most distinct and satisfactory views I have ever had of this planet were those which I obtained in the day-time, in summer, when it was viewed at a high altitude with a 44½ inch achromatic telescope, carrying a power of 150. I have at such times distinctly perceived the distinction between the shade and color of its margin and the superior luster of its central parts, and some spots have occasionally been seen, though not so distinctly marked as to determine its rotation. Such distinct views are seldom to be obtained in the evening after sunset, on account of the undulations of the atmosphere, and the dense mass of vapors through which the celestial bodies are viewed when near the horizon.

Nor do I consider it altogether improbable that its *satellite* (if it have one, as some have supposed) may be detected in the day-time, when this planet is in a favorable position for such an observation, particularly when a pretty large portion of its enlightened surface is turned toward the earth, and when its satellite, of course, must present a similar phase. About the period of its greatest elongation from the sun, and soon after it assumes a crescent phase in its approach to the inferior conjunction, may be considered as the most eligible times for prosecuting such observations. If this supposed satellite be about one-third or one-fourth of the diameter of its primary, as Cassini, Short, Baudouin, Montbarron, Montaigne, and other astronomers supposed, it must be nearly as large as Mercury, which has been frequently seen in daylight. If such a satellite have a real existence, and yet undistinguishable in daylight, its surface must be of a very different quality for reflecting the rays of light from that of its primary; for it is obvious to every one who has seen Venus with a high power in the day-time, that a body of equal brilliancy, though four times less in diameter, would be quite perceptible, and exhibit a visible disc. Such observations, however, would be made with much greater effect in Italy and other southern countries, and particularly in tropical climates, such as the southern parts of Asia and America, and in the West India islands, where the sky is more clear and serene, and where the planet may be viewed at higher altitudes and for a greater length of time, without the interruption of clouds, than in our island.

Again, the apparent magnitudes of the fixed stars, the quantity of light they respectively emit, and the precise class of magnitude which should be assigned to them, might be more accurately determined by day observations than by their appearance in the nocturnal sky. All the stars which are reckoned to belong to the *first magnitude* are not equally distinguishable in daylight. For example, the stars *Aldebaran* and *Procyon* are not so easily distinguished, nor do they appear with the same degree of luster by day, as the stars *α Lyræ* and *Capella*. In like manner, the stars *Altair*, *Alphard*, *Deneb*, *Ras Alhague*, considered as belonging to the *second* magnitude, are not equally distinguishable by the same aperture and magnifying power, which seems to indicate that a different quantity of light is emitted by these stars, arising from a difference either in their magnitude, their distance, or the quality of the light with which they are irradiated.

The following are likewise practical purposes to which celestial day observations may be applied. In accurately adjusting circular and transit instruments, it is useful, and even necessary, for determining the exact position of the meridian, to take observations of certain stars which differ greatly in zenith distance, and which transit the meridian nearly at the same time. But as the stars best situated for this purpose cannot, at every season, be seen in the evenings, we must, in certain cases, wait for several months before such observations can be made, unless we make them in the day-time, which can very easily be done if the instrument have a telescope adapted to it, furnished with such powers as those above stated, or higher powers if required. I have likewise made use of observations on the stars in the day-time for adjusting a clock or watch to mean time, when the sun was in a situation beyond the range of the instrument, or obscured by clouds, and when I did not choose to wait until the evening. This may, at first view, appear to some as paradoxical, since the finding of a star in daylight depends on our knowing its right ascension from the sun, and this last circumstance depends, in some measure, on our knowing the true time. But if a watch or clock is known not to have varied above seven or eight minutes from the time, a star of the first magnitude may easily be found by moving the telescope a little backward or forward until the star appear; and when it is once found, the exact variation of the movement is then ascertained by comparing the calculations which were previously necessary with the time pointed out by the nonius on the equatorial circle; or, in other words, by ascertaining the difference between the time assumed and the time indicated by the instrument when the star appears in the center of the field of view. All this may be accomplished in five or six minutes.

Beside the practical purposes now stated, the equatorial telescope is perhaps the best instrument for instructing a learner in the various operations of practical astronomy, and particularly for enabling him to distinguish the names and positions of the principal stars; for when the right ascension and declination of any star is known from astronomical tables, the telescope may be immediately adjusted to point to it, which will infallibly prevent his mistaking one star for another. In this way, likewise the precise position of the planets *Mercury*, *Uranus*, *Vesta*, *Juno*, *Ceres*, *Pallas*, a small comet, a nebula, a double star or any other celestial body not easily distinguishable by the naked eye, may be readily pointed out, when its right ascension and declination are known to a near approximation.

---

* See Long's Astronomy, vol. ii, p. 487, and Encyclopedia Britannica, vol. ii, p. 436, 3d edition.

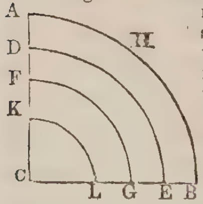
In conclusion, I cannot but express my surprise that the equatorial telescope is so little known by many of the lovers of astronomical science. In several respectable academies in this part of Britain, and, if I am not misinformed, in most of our universities, this instrument is entirely unknown. This is the more unaccountable, as a small equatorial may be purchased for a moderate sum, and as there is no single instrument so well adapted for illustrating all the operations of practical astronomy. Where very great accuracy is not required, it may occasionally be made to serve the general purposes of a *transit instrument* for observing the passages of the sun and stars across the meridian. It may likewise be made to serve as a *theodolite* for surveying land and taking horizontal angles—as a *quadrant* for taking angles of altitude—as a *level*—as an *equal altitude instrument*—an *azimuth instrument* for ascertaining the sun's distance from the north or south points of the horizon—and as an accurate universal sundial, for finding the exact *mean* or *true* time on any occasion when the sun is visible. The manner of applying it to these different purposes will be obvious to every one who is in the least acquainted with the nature and construction of this instrument.

The price of a small equatorial instrument, such as that described p. 125, is about 16 guineas, exclusive of some of the eyepieces, which were afterward added for the purpose of making particular observations. Instruments of a larger size, and with more complicated machinery, sell from 50 to 100 guineas and upward. Messrs. W. and S. Jones, Holborn, London, construct such instruments.

ON THE QUADRANT.

Every circle being supposed to be divided into 360 equal parts or degrees, it is evident that 90 degrees, or the fourth part of a circle, will be sufficient to measure all angles between the horizon of any place and the line perpendicular to it which goes up to the zenith. Thus, in fig. 87, the line *C B* represents the plane of the horizon. *A C B H*, the quadrant; *A C* the perpendicular to the horizon; and *A*, the zenith point. If the lines *B C* and *C A* represent a pair of compasses with the legs standing perpendicular to each other, and the curved lines *A B*, *D E*, and *F G*, the quarter of as many circles of different sizes, it is evident that although each of these differs from the others in size, yet that each contains the same portion of a circle, namely, a quadrant or fourth part; and thus it would be from the smallest to the largest quadrant that could be formed—they would all contain exactly 90 degrees each. By the application of this principle, the comparative measure of angles may be extended to an indefinite distance. By means of an instrument constructed in the form of a quadrant of a circle, with its curved edge divided into 90 equal parts, the altitude of any object in the heavens can at any time be determined.

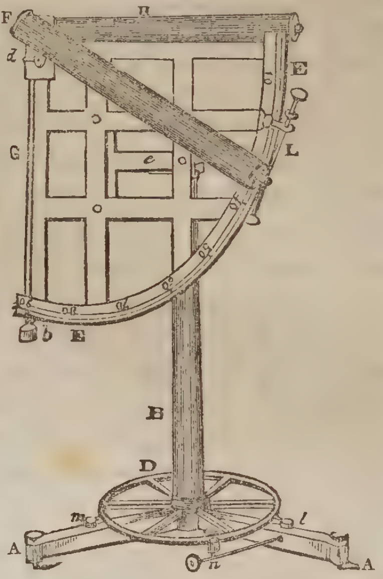
Fig. 87.



There are various constructions of this instrument, some of them extremely simple, and others considerably complex and expensive, according to the degree of accuracy which the observations require The following is a description of the *Pillar Quadrant*, as it was made by Mr. Bird for the Observatory of Greenwich, and several Continental observatories.

This instrument consists of a quadrant, *E E H G L* (fig. 88,) mounted on a pillar *B*, which is supported by a tripod, *A A*, resting on three foot-screws. The quadrant, the pillar, and the horizontal circle all revolve round a vertical axis. A telescope, *H*, is placed on the horizontal radius, and is directed to a meridian mark previously made on some distant object for placing the plane of the instrument in the meridian, and also for setting the zero, or beginning of the scale, truly horizontal. This is sometimes done by a level instead of a telescope, and sometimes by a plumb-line, *G*, suspended from near the center, and brought to bisect a fine dot made on the limb, where a microscope is placed to examine the bisection. The weight or plummet at the end of the plumb-line is suspended in the cistern of water *b*, which keeps it from being agitated by the air. A similar dot is made for the upper end of the plumb-line upon a piece of brass, adjustable by a screw, *d*, in order that the line may be exactly at right angles to the telescope when it is placed at 0. The quadrant is screwed by the center of its frame against a piece of brass, *e*, with three screws, and this piece is screwed to the top of the pillar *B* with other three screws. By means of the first three screws the plane of the quadrant can be placed exactly parallel to the vertical axis, and by the other screws the telescope *H*, can be placed exactly perpendicular to it. The nut of the delicate screw *L* is attached to the end of the telescope *F* by a universal joint. The collar for the other end is jointed in the same manner to a clamp, which can be fastened to any part of the limb. A similar clamp screw and slow motion is seen at *n* for the lower circle, which is intended to hold the circle fast and adjust its motion. The divisions of the lower, or horizontal circle, are read by verniers, or noniuses, fixed to the arms of the tripod at

Fig. 88.



l and *m;* and, in some cases, three are used to obtain greater accuracy.

In using this quadrant, the axis of the telescope *H* is adjusted to a horizontal line, and the plane of the quadrant to a vertical line by the means already stated. The screw of the clamp *L* is then loosened, and the telescope directed to the star or other object whose altitude is required. The clamp-screw being fixed, the observer looks through the telescope, and with the nut of the screw *L* he brings the telescope into a position where the star is bisected by the intersection of the wires in the field of the telescope. The divisions are then to be read off upon the vernier, and the altitude of the star will be obtained. By means of the horizontal circle *D*, all angles in the plane of the horizon may be accurately measured, such as the amplitudes and azimuths of the celestial bodies.

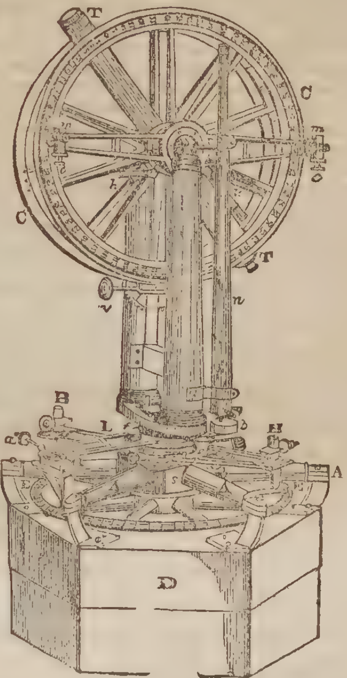
Quadrants of a more simple construction than the above may be occasionally used, such as Gunter's, Cole's, Sutton's, and others; but none of these is furnished with telescopes or telescopic sights, and therefore an altitude cannot be obtained by them with the same degree of accuracy as with that which has been now described.

By means of the quadrant, not only the altitudes of the heavenly bodies may be determined, but also the distances of objects on the earth by observations made at two stations; the altitude of fireballs and other meteors in the atmosphere; the hight of a cloud by observation on its altitude and velocity; and numerous other problems, the solution of which depends upon angular measurements. A *Mural Quadrant* is the name given to this instrument when it is fixed upon a wall of stone, and in the plane of the meridian, such as the quadrant which was erected by Flamstead in the Observatory at Greenwich. Although the quadrant was formerly much used in astronomical observations, yet it may be proper to state that its use has now been almost completely superseded by the recent introduction of *Astronomical Circles,* of which we shall now give the reader a very short description, chiefly taken from Troughton's account of the instrument he constructed, as found in Sir D. Brewster's Supplement to Ferguson's Astronomy.

THE ASTRONOMICAL CIRCLE.

An astronomical circle is a *complete circle* substituted in place of the quadrant, and differs from it only in the superior accuracy with which it enables the astronomer to make his observations. The large vertical or declination circle *C C* (fig. 89) is composed of two complete circles, strengthened by an edge-bar on their inside, and firmly united at their extreme borders by a number of short braces or bars, which stand perpendicular between them, and which keep them at such a distance as to admit the achromatic telescope *T T*. This double circle is supported by 16 conical bars, firmly united, along with the telescope to a horizontal axis. The exterior limb of each circle is divided into degrees and parts of a degree, and these divisions are divided into seconds by means of the micrometer microscopes *m m*, which read off the angle on opposite sides of each circle. The cross wires in each microscope may be moved over the limb, until they coincide with the nearest division of the limb, by means of the micrometer screws *c c*, and the space moved through is ascertained by the divisions on the graduated head above *c*, assisted by a scale within the microscope. The microscopes are supported by two arms proceeding from a small circle concentric with the horizontal axis, and fixed to the vertical columns. This circle is the center upon which they can turn round nearly a quadrant for the purpose of employing a new portion of the divisions of the circle, when it is reckoned prudent to repeat any delicate observations upon any part of the limb. At *h* is represented a level for placing the axis in a true horizontal line, and at *k* is fixed another level parallel to the telescope for bringing the zero of the divisions to a horizontal position. The horizontal axis to which the vertical circle and the telescope are fixed is equal in length to the distance between the vertical pillars, and its pivots are supported by semicircular bearings placed at the top of each pillar These two vertical pillars are firmly united at their bases to a crossbar, *f*. To this crossbar is also fixed a vertical axis about three feet long, the end of which, terminating in an obtuse point, rests in a brass conical socket firmly fastened at the bottom of the hollow in the stone pedestal *D*, which receives the vertical axis. This socket supports the whole weight of the movable part of the instrument. The upper part of the vertical axis is supported by two pieces of brass, one of which is seen at *e*, screwed to the ring *i*, and containing a right-angle, or *Y*. At each side of the ring, opposite to the points of contact, is placed a tube containing a heliacal spring, which, by a constant pressure on the axis, keeps it against its bearings, and permits it to turn, in these four points of contact, with an easy and steady motion. The two bearings are fixed upon two rings capable of a lateral adjustment; the lower one by the screw *d*, to incline the axis to the east or west, while the screw *b* gives the upper one, *i*, a motion in the plane of the meridian. By this means the axis may be adjusted to a perpendicular position

Fig. 89.



as exactly as by the usual method of the tripod with foot-screws. These rings are attached to the center-piece *s*, which is firmly connected with the upper surface of the stone by six conical tubes *A*, *A*, *A*, &c., and brass standards at every angle of the pedestal. Below this frame lies the azimuth circle, *E E*, consisting of a circular limb, strengthened by ten hollow cones firmly united with the vertical axis, and consequently turning freely along with it. The azimuth circle, *E E*, is divided and read off in the same manner as the vertical circle. The arms of the microscopes, *B B*, project from the ring *i*, and the microscopes themselves are adjustable by screws, to bring them to zero and to the diameter of the circle. A little above the ring *i* is fixed an arm, *L*, which embraces and holds fast the vertical axis with the aid of a clamp-screw. The arm *L* is connected at the extremity with one of the arms *A*, by means of the screw *a*, so that by turning this screw a slow motion is communicated to the vertical axis and the azimuth circle.

In order to place the instrument in a true vertical position, a plumb-line, made of fine silver wire, is suspended from a small hook at the top of the vertical tube *n*, connected by braces with one of the large pillars. The plumb-line passes through an angle in which it rests, and by means of a screw may be brought into the axis of the tube. The plummet at the lower end of the line is immersed in a cistern of water, *t*, in order to check its oscillations, and is supported on a shelf proceeding from one of the pillars. At the lower end of the tube *n* are fixed two microscopes, *o* and *p*, at right-angles to one another, and opposite to each is placed a small tube containing a lucid point. The plumb-line is then brought into such a position by the screws *d b*, and by altering the suspension of the plumb-line itself, that the image of the luminous point, like the disc of a planet, is formed on the plumb-line, and accurately bisected by it. The vertical axis is then turned round, and the plumb-line examined in some other position. If it still bisects the luminous point, the instrument is truly vertical; but if it does not, one half of the deviation must be corrected by the screws *d b*, and the other half, by altering the suspension of the line until the bisection of the circular image is perfect in every position of the instrument.

It is not many years since circular repeating instruments came into general use. The principle on which the construction of a repeating circle is founded appears to have been first suggested by Professor Mayer, of Gottingen, in 1758; but the first person who applied this principle to measure round the limb of a divided instrument was Borda, who about the year 1789, caused a repeating circle to be constructed that would measure with equal facility horizontal and vertical angles. Afterward Mr. Troughton greatly improved the construction of Borda's instrument by the introduction of several contrivances, which insure, at the same time, its superior accuracy and convenience in use; and his instruments have been introduced into numerous observatories. Circular instruments, on a large scale, have been placed in the Royal Observatory of Greenwich, and in most of the principal observatories on the Continent of Europe. Although it is agreed on all hands that greater accuracy may be obtained by a repeating circle than by any other having the same radius, yet there are some objections to its use which do not apply to the altitude and azimuth circle. The following are the principal objections, as stated in vol. i, of the Memoirs of the Astronomical Society of London:" 1. The origin of the repeating circle is due to *bad dividing*, which ought not to be tolerated in any instrument in the present state of the art. 2. There are three sources of fixed error which cannot be exterminated, as they depend more on the materials than on the workmanship; first, the zero of the level changes with variations of temperature; secondly, the resistance of the center work to the action of the tangent screws; and, thirdly, the imperfection of the screws in producing motion and in securing permanent positions. 3. The instrument is applied with most advantage to slowly moving or circumpolar stars; but in low altitudes these stars are seen near the horizon, where refraction interferes. 4. Much time and labor are expended, first in making the observations, and again in reducing them. 5. When any one step in a series of observations is bad, the whole time and labor are absolutely lost. 6. When the instrument has a telescope of small power, the observations are charged with errors of vision which the repeating circle will not cure. 7. This instrument cannot be used as a transit instrument, nor for finding the exact meridian of a place.

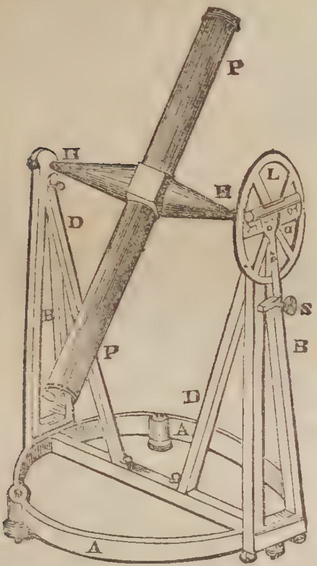
A great variety of directions is necessary in order to enable the student of practical astronomy thoroughly to understand and to apply this instrument to practice, which the limited nature of the present work prevents us from detailing. As this instrument consists of a variety of complicated pieces of machinery, it is necessarily somewhat expensive. A six-inch brass astronomical circle for altitudes, zenith or polar distances, azimuths, with achromatic telescopes, &c., is marked in Messrs. W. and S. Jones's catalogue of astronomical instruments at £27 6*s*. A circle 12 inches in diameter, from £36 15*s*. to £68 5*s*. An 18 inch ditto, of the best construction, £105. The larger astronomical circles for public observatories, from 100 to 1000 guineas and upward, according to their size, and the peculiarity of their construction.

THE TRANSIT INSTRUMENT.

A transit instrument is intended for observing celestial objects as they pass across the meridian. It consists of a telescope fixed at right angles to a horizontal axis, which axis must be so supported that what is called *the line of collimation*, or the line of sight of the telescope, may move in the plane of the meridian. This instrument was first invented by Romer, in the year 1689, but has since received great improvements by Troughton, Jones, and other modern artists. Transit instruments may be divided into two classes, *Portable* and *Fixed*. The portable instrument, when placed truly in the meridian, and well adjusted, may be advantageously used as a stationary instrument in an observatory, if its dimensions be such as to admit of a telescope of 3½ feet focal length; but when the main tube is only from 20 to 30 inches long, with a proportional aperture, it is more suited for a traveling instrument to give the exact time; and, when carried on board a ship in a voyage of discovery, may be taken on shore at any convenient place for determining the solar time of that place, and for correcting the daily rate of the chronometer, giving the time at the first meridian, so that the longitude of the place of observation may be obtained from the difference of the observed and indicated times, after the proper corrections have been made.

The following is a brief description of one of Mr. Troughton's portable transit instruments. In fig. 90, *P P* is an achromatic telescope firmly fixed by the middle to a double conical and horizontal axis *H H*, the pivots of which rest on angular bearings called *Y's*, at the top of the standards *B B*, rendered steady by oblique braces *D D*, fastened to the central part of the circle *A A*. In large fixed instruments, the pivots and angular bearings are supported on two massive stone pillars, sunk several feet into the ground, and are sometimes supported by mason-work, to secure perfect stability. The axis *H H* has two adjustments, one for making it exactly level, and the other for placing the telescope in the meridian. A graduated circle, *L*, is fixed to the extremity of the pivot, which extends beyond one of the *Y's* and the two radii that carry the verniers, *a a*, are fitted to the extremities of the pivot in such a way as to turn round independent of the axis. The double verniers have a small level attached to them, and a third arm, *b*, which is connected with the standard *B* by means of a screw, *s*. If the verniers are placed, by means of the level, in a true horizontal position, when the axis of the telescope is horizontal, and the arm *b* screwed by the screws to the standard *B*, the verniers will always read off the inclination of the telescope, and will enable the observer to point it to any star by means of its meridian altitude. The whole instrument rests on three foot-screws entered into the circle *A A*. In the field of view of the telescope there are several parallel vertical wires, crossed at right angles with a horizontal one, and the telescope is sometimes furnished with a diagonal eyepiece for observing stars near the zenith. A level likewise generally accompanies the instrument, in order to place it horizontal by being applied to the pivots of the axis.

Fig. 90.



In order to fix the transit instrument exactly in the meridian, a good clock regulated to sidereal time is necessary. This regulation may be effected by taking equal altitudes of the sun or a star before and after they pass the meridian, which may be done by small quadrants or by a good sextant. The axis *H* of the instrument is then to be placed horizontal by a spirit level, which accompanies the transit, and the greatest care must be taken that the axis of vision describes in the heavens a great circle of the sphere. To ascertain whether the telescope be in the plane of the meridian, observe by the clock when a circumpolar star seen through the telescope transits both above and below the pole, and if the times of describing the eastern and western parts of its circuit be equal, the telescope is then in the plane of the meridian; otherwise, certain adjustments must be made. When the telescope is at length perfectly adjusted, a landmark must be fixed upon at a considerable distance, the greater the better. This mark must be in the horizontal direction of the intersection of the cross wires, and in a place where it can be illuminated, if possible, in the night-time, by a lantern hanging near it; which mark being on a fixed object, will serve at all times afterward for examining the position of the telescope.

Various observations and adjustments are requisite in order to fixing a transit instrument exactly in the plane of the meridian. There is the adjustment of the *level;* the horizontal adjustment of the axis of the telescope; the placing of the parallel lines in the focus of the eyeglass, so as to be truly vertical, and to determine the equatorial value of their intervals; the collimation in *azimuth*, so that a line passing from the middle vertical line to the optical center of the object-glass is at right angles with the axis of the telescope's motion; the collimation in *altitude*, so that the horizontal line should cross the parallel vertical lines, not only at right angles, but also in the optical center of the field of view, with various other particulars, but of which our limited space will not permit us to enter into details. Those who wish to enter into all the minute details in reference to the construction and practical application of this and the other instruments above described, as well as all the other instruments used by the practical astronomer, will find ample satisfaction in perusing the Rev. Dr. Pearson's Introduction to Practical Astronomy, 4to, vol. ii.

A portable transit instrument, with a cast-iron stand, the axis 12 inches in length, and the achromatic telescope about 20 inches, packed in a case sells at about 16 guineas; with a brass-framed stand and other additions, at about 20 guineas. Transit instruments of larger dimensions are higher in proportion to their size, &c.

CHAPTER III.

ON OBSERVATORIES.

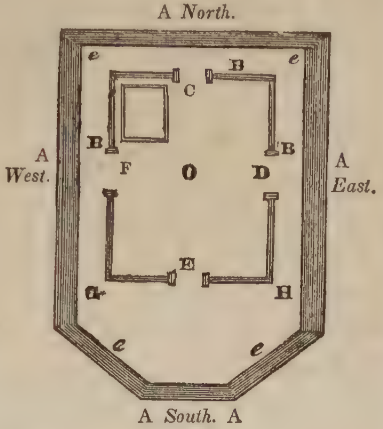
In order to make observations with convenience and effect on the heavenly bodies, it is expedient that an *observatory*, or place for making the requisite observations, be erected in a proper situation. The following are some of the leading features of a spot adapted for making celestial observations: 1. It should command an extensive visible horizon all around, particularly toward the south and the north. 2. It should be a little elevated above surrounding objects. 3. It should be, if possible, at a considerable distance from manufactories, and other objects which emit much smoke or vapor, and even from chimney-tops where no sensible smoke is emitted, as the heated air from the top of funnels causes undulations in the atmosphere. 4. It should be at a distance from swampy ground or valleys that are liable to be covered with fogs and exhalations. 5. It should not, if possible, be too near public roads, particularly if paved with stones, and frequented by heavy carriages, as in such situations undulations and tremulous motions may be produced injurious to the making of accurate observations with graduated instruments. 6. It is expedient that the astronomical observer should have access to some distant field within a mile of the observatory, on which a meridian mark may be fixed after his graduated instruments are properly adjusted. The distance at which a meridian mark should be erected will depend in part on the focal length of the telescope generally used for making observations on the right ascensions and declinations of the stars. It should be fixed at such a distance that the mark may be distinctly seen without altering the focus of the telescope when adjusted to the sun or stars, which, in most cases, will require to be at least half a mile from the place of observation, and more if it can be obtained.

Observatories may be distinguished into public and private. A *private* observatory may be comprehended in a comparatively small building, or in the wing of a building of ordinary dimensions for a family, provided the situation is adapted to it. Most of our densely peopled towns and cities, which abound in narrow streets and lanes, are generally unfit for good observatories, unless at an elevated position at their extremities. Public observatories, where a great variety of instruments is used, and where different observers are employed, require buildings of larger dimensions, divided into a considerable number of apartments. The observatory of *Greenwich* is composed principally of two separate buildings, one of which is the observatory properly so called, where the assistant lives and makes all his observations; the other is the dwelling-house in which the astronomer royal resides. The former consists of three rooms on the ground-floor, the middle of which is the assistant's sitting and calculating room, furnished with a small library of such books only as are necessary for his computations, and an accurate clock made by the celebrated Graham, which once served Dr. Halley as a transit clock. Immediately over this is the assistant's bedroom, with an alarum to awake him to make his observations at the proper time. The room on the eastern side of this is called the *transit*-room, in which is an eight feet transit instrument, with an axis of three feet, resting on two pieces of stone, made by Mr. Bird, but successively improved by Messrs. Dollond, Troughton, and others. Here is also a chair to observe with, the back of which lets down to any degree of elevation that convenience may require. On the western side is the *quadrant-room*, with a stone pier in the middle running north and south, having on its eastern face a mural quadrant of eight feet radius, by which observations are made on the southern quarter of the meridian, through an opening in the roof of three feet wide, produced by means of two sliding shutters. On the western face is another mural quadrant of eight feet radius, the frame of which is of iron and the arch of brass, which is occasionally applied to the north quarter of the meridian. In the same room is the famous zenith sector, twelve feet long, with which Dr. Bradley made the observations which led to the discovery of the nutation of the earth's axis and the aberration of the light of the fixed stars. Here are also Dr. Hooke's reflecting quadrant, and three time-keepers by Harrison. On the south side of this room a small wooden building is erected for the purpose of observing the eclipses of Jupiter's satellites, occultations of stars by the moon, and other phenomena which require merely the use of a telescope, and the true or mean time. It is furnished with sliding shutters on the roof and sides to view any part of the hemisphere from the prime vertical down to the southern horizon. It contains a forty inch achromatic with a triple object-glass, and also a five feet achromatic by Messrs. John and Peter Dollond, a two feet reflecting telescope by Edwards, and a six feet reflector by Herschel. Above the dwelling-house is a large octagonal room, which is made the repository for certain old instruments, and for those which are too large to be used in the other apartments. Among many other instruments, it contains an excellent ten feet achromatic by Dollond, and a six feet reflector by Short. Upon a platform, in an open space, is erected the great reflecting telescope constructed by Mr. Ramage of Aberdeen, on the Herschelian principle, which has a speculum of 15 inches diameter and 25 feet focal length, remarkable for the great accuracy and brilliancy with which it exhibits celestial objects. Various other instruments of a large size and of modern construction have of late years been introduced into this observatory, such as the large and splendid transit instrument constructed by Troughton, in 1816, the two large mural circles by Troughton and Jones, the transit clock by Mr. Hardy, and several other instruments and apparatus which it would be too tedious to enumerate and describe.

Every observatory, whether public or private, should be furnished with the following instruments: 1. A transit instrument for observing the meridian passage of the sun, planets, and stars. 2. A good clock, whose accuracy may be depended upon. 3. An achromatic telescope of at least 44 inches focal distance, with powers of from 45 to 180, for viewing planetary and other phenomena; or a good reflecting telescope at least three feet long, and the speculum five inches in diameter. 4. An equatorial instrument, for viewing the stars and planets in the day-time, and for finding the right ascension and declination of a comet, or any other celestial phenomenon. Where this instrument is possessed, and in cases where no great degree of accuracy is required, the equatorial may be made to serve the general purposes of a transit instrument.

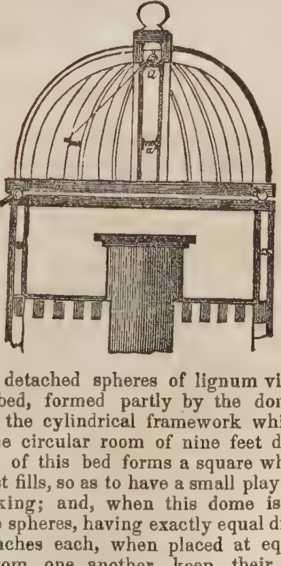
A private observatory might be constructed in any house which has a commanding view of the heavens, provided there is an apartment in it in which windows may be placed, or openings cut out fronting the north, the south, the east, and the west. The author of this work has a small observatory erected on the top of his house, which commands a view of 20 miles toward the east, 30 miles toward the west and north-west, and about twenty miles toward the south, at an elevation of more than 200 feet above the level of the sea and the banks of the Tay, which are about half a mile distant. The apartment is 12½ feet long by 8½ wide, and 8½ feet between the floor and the roof. It has an opening on the north, by which observations can be made on the pole-star; a window on the south, by which the meridian passages of the heavenly bodies may be observed; another opening toward the east, and a fourth opening, consisting of a door, toward the west. There is a pavement of lead on the outside, all around the observatory-room, inclosed by a stone parapet 3½ feet high, the upper part of which is coped with broad flat stones, in certain parts of which grooves or indentations are made for receiving the feet of the pedestal of an achromatic telescope, which form a steady support for the telescope in the open air, when the weather is calm and serene, and when observations are intended to be made on any region of the heavens. By placing an instrument on this parapet, it may be directed to any point of the celestial canopy except a small portion near the northern horizon, which is partly intercepted by a small hill. In the following ground plan, fig. 91, *A A A* is the parapet surrounding the observatory room; *B B B*, a walk around it nearly three feet broad, covered with lead. *O* is the apartment for the observatory, having an opening, *C*, to the north; another opening, *D*, to the east; *E* is a window which fronts the south, and *F* is a door fronting the west, by which an access is obtained to the open area on the outside. *G H I* is an area on the outside, toward the south, covered with lead, 15 feet long from *G* to *H*, and 6½ feet from *E* to *I*, from which a commanding view of the southern, eastern, and western portions of the heavens may be obtained: *e e e e* are positions on the top of the parapet where a telescope may be conveniently placed, when observations are intended to be made in the open air. The top of this parapet is elevated about 30 feet from the level of the ground. On the roof of the observatory, about 12 feet above its floor, on the outside, is a platform of lead, surrounded by a railing six feet by five, with a seat, on which observations either on celestial or terrestrial objects may occasionally be made. *K* is a door or hatchway, which forms an entrance into the observatory from the apartments below, which folds down, and forms a portion of the floor.

Fig. 91.



In public observatories, where zenith or polar distances require to be measured, it is necessary that there should be a dome, with an opening across the roof, and down the north and south walls. Should an altitude or azimuth circle, or an equatorial instrument be used, they will require a revolving roof with openings and doors on two opposite sides, to enable an observer to follow a heavenly body across all the cardinal points. The openings may be about 15 inches wide, and the roof need not be larger than what is requisite for giving room to the observer and the instrument, lest its bulk and weight should impede its easy motion. There have been various plans adopted for revolving domes. Fig. 92 represents a section of the rotatory dome constructed at East Sheen by the Rev. Dr. Pearson. This dome turns round on three detached spheres of lignum vitæ, in a circular bed, formed partly by the dome, and partly by the cylindrical framework which surrounds the circular room of nine feet diameter. A section of this bed forms a square which the sphere just fills, so as to have a small play to allow for shrinking; and, when this dome is carried round, the spheres, having exactly equal diameters of 4¼ inches each, when placed at equal distances from one another, keep their relative places, and move together in a beautifully smooth manner. These spheres act as friction rollers in

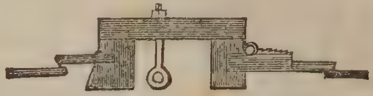
Fig. 92.



two directions at the four points of contact, in case any obstacle is opposed to their progressive motion by the admission of dirt, or by any change of figure of the wood that composes the rings of the dome and of the gangway. No groove is here made but what the weight of the roof resting on the hard sphere occasions. The dome itself moves twice round for the balls once, and has, in this way, its friction diminished. The wood of this dome is covered by Wyatt's patent copper, one square foot of which weighs upward of a pound; and the copper is so turned over the nails that fix it at the parts of junction that not a single nail is seen in the whole dome. This covering is intended to render the dome more permanent than if it had been made of wood alone. At the observatory at Cambridge the dome is made chiefly of iron. In the figure, *a a* represents one of the two oblong doors that meet at the apex of the cone, and a piece of sheet-copper, bent over the upper end of the door which shuts last, keeps the rain from entering at the place of junction. The two halves of the dome are united by brass rods passing through the door-cheeks of wainscot at *a* and *a* by means of nuts that screw upon their ends, which union allows the dome to be separated into two parts when there may be occasion to displace it. The wooden plate *b b*, which appears in a straight line, is a circular broad ring, to which the covering wainscot boards are made fast above the eaves, and *c c* is a similar ring forming the wall-plate or gangway on which the dome rests and revolves.

Fig. 92* shows a small door that lies over the summit of the dome, and may be separately opened for zenith observations; the rod of metal, with a ring at the lower end passing through it; serves to open and shut this door, and at the same time carries upon its upper end a large ball, which falls back on the roof when the door is open, and keeps the door in a situation to be acted upon by the hook of a handle that is used for this purpose The doors *a a*, being curved, are made to open in two halves, the upper one being opened first, on account of its covering the end of the other; and the observer may open one or two doors, as may best suit his purpose. The weight of this dome is such that a couple of wedges, inserted by a gentle blow between the rings *b b* and *c c*, will keep it in its situation under the influence of the strongest wind.

Fig. 92.*



It may not be improper to remark, that in all observatories, and in every apartment where celestial observations are made, there should, if possible, be a uniform temperature; and, consequently, a fire should never be kept in such places, particularly when observations are intended to be made, as it would cause currents of air through the doors and other openings which would be injurious to the accuracy of observations. When a window is opened in an ordinary apartment where a fire is kept, there is a current of heated air which rushes out at the top, and a current of cold air which rushes in from below, producing agitations and undulations which prevent even a good telescope from showing celestial objects distinct and well-defined; and I have no doubt that many young observers have been disappointed in their views of celestial phenomena from this circumstance, when viewing the heavenly bodies from heated rooms in cold winter evenings, as the aerial undulations before the telescope prevent distinct vision of such objects as the belts of Jupiter, the spots of Mars, and the rings of Saturn.

CHAPTER IV.

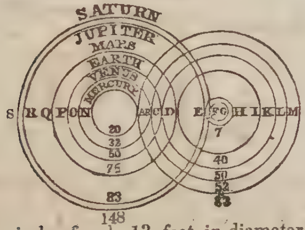
ON ORRERIES OR PLANETARIUMS.

An orrery is a machine for representing the order, the motions, the phases, and other phenomena of the planets. Although orreries and planetariums are not so much in use as they were half a century ago, yet, as they tend to assist the conceptions of the astronomical tyro in regard to the motions, order, and positions of the bodies which compose the solar system, it may not be inexpedient shortly to describe the principles and construction of some of these machines.

The reason why the name *Orrery* was at first given to such machines is said to have been owing to the following circumstance: Mr. Rowley, a mathematical instrument-maker, having got one from Mr. George Graham, the original inventor, to be sent abroad with some of his own instruments, he copied it, and made the first for the Earl of Orrery. Sir R. Steele, who knew nothing of Mr. Graham's machine, thinking to do justice to the first encourager, as well as to the inventor of such a curious instrument, called it an *Orrery*, and gave Mr. Rowley the praise due to Mr. Graham. The construction of such machines is not a modern invention. The hollow sphere of Archimedes was a piece of mechanism of this kind, having been intended to exhibit the motions of the sun, the moon, and the five planets, according to the Ptolemaic system. The next orrery of which we have any account was that of Posidonius, who lived 80 years before the Christian era, of which Cicero says, "If any man should carry the sphere of Posidonius into Scythia or Britain, in every revolution of which the motions of the sun, moon, and five planets were the same as in the heavens each day and night, who in those barbarous countries could doubt of its being finished, not to say actuated, by perfect reason?" The next machine of this kind which history records was constructed by the celebrated Boethius, the Christian philosopher, about the year of Christ 510, of which it was said "that it was a machine pregnant with the universe—a portable heaven—a compendium of all things." After this period we find no instances of such mechanism of any note until the 16th century, when science began to revive and the arts to flourish. About this time the curious clock in Hampton Court Palace was constructed, which shows not only the hours of the day, but the motions of the sun and moon through all the signs of the zodiac, and other celestial phenomena. Another piece of mechanism of a similar kind is the clock in the Cathedral of Strasburg, in which, beside the clock part, is a celestial globe or sphere with the motions of the sun, moon, planets, and the firmament of the fixed stars, which was finished in 1574.

Among the largest and most useful pieces of machinery of this kind is the great sphere erected by Dr. Long, in Pembroke Hall, in Cambridge. This machine, which he called the *Uranium*, consists of a planetarium, which exhibits the motion of the earth and the primary planets, the sun, and the motion of the moon around the earth, all inclosed within a sphere. Upon the sphere, beside the principal circles of the celestial globe, the zodiac is placed, of a breadth sufficient to contain the apparent path of the moon, with all the stars over which the moon can pass; also the ecliptic, and the heliocentric orbits of all the planets. The Earth in the planetarium has a movable horizon, to which a large movable brass circle within the sphere may be set coincident, representing the plane of the horizon continued to the starry heavens. The horizons, being turned round, sink below the stars on the east side, and make them appear to rise, and rise above the stars on the west side, and make them appear to set. On the other hand, the earth and the horizon being at rest, the sphere may be turned round to represent the apparent diurnal motion of the heavens. In order to complete his idea on a large scale, the doctor erected a sphere of 18 feet diameter, in which above 30 persons might sit conveniently, the entrance to which is over the south pole by six steps. The frame of the sphere consists of a number of iron meridians, the northern ends of which are screwed to a large round plate of brass with a hole in the center of it; through this hole, from a beam in the ceiling, comes the north pole, a round iron rod about three inches long, and which supports the upper part of the sphere to its proper elevation for the latitude of Cambridge, so much of it as is invisible in England being cut off, and the lower or southern ends of the meridians terminate on, and are screwed down to, a strong circle of oak 13 feet in diameter, which, when the sphere is put in motion, runs upon large rollers of lignum vitæ, in the manner that the tops of some windmills turn round. Upon the iron meridians is fixed a zodiac of tin painted blue, on which the ecliptic and heliocentric orbits of the planets are drawn, and the stars and constellations traced. The whole is turned round with a small winch, with as little labor as it takes to wind up a jack, although the weight of iron, tin, and the wooden circle is above a thousand pounds. This machine, though now somewhat neglected, may still be seen in Pembroke Hall, Cambridge, where I had an opportunity of inspecting it in November, 1839. The essential parts of the machine still remain nearly in the same state as when originally constructed in 1758.

Fig. 93.

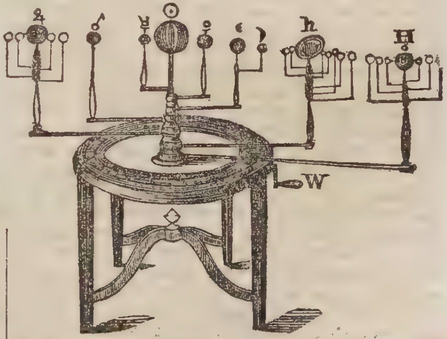


The machine which I shall now describe is of a much smaller and less complex description than that which has been noticed above, and may be made for a comparatively small expense, while it exhibits with sufficient accuracy the motions, phases, and positions of all the primary planets, with the exception of the new planets, which cannot be accurately represented on account of their orbits crossing each other. In order to the construction of the planetarium to which I allude, we must compare the proportion which the annual revolutions of the primary planets bear to that of the Earth. This proportion is expressed in the following table, in which the first column is the time of the Earth's period in days; the second, that of the planets; and the third and fourth are numbers very nearly in the same proportion to each other:

365¼	:	88	: :	83	:	20 for Mercury.
365¼	:	224⅔	: :	52	:	32 for Venus.
365¼	:	687	: :	40	:	75 for Mars.
365¼	:	4332½	: :	7	:	83 for Jupiter.
365¼	:	10759⅓	: :	5	:	148 for Saturn.
365¼	:	30686	: :	3	:	253 for Uranus.

On account of the number of teeth required for the wheel which moves Uranus, it is frequently omitted in planetariums, or the planet is placed upon the arbor which supports Saturn. If we now suppose a spindle or arbor with six wheels *fixed* upon it in a horizontal position, having the number of teeth in each corresponding to the numbers in the third column, namely, the wheel *A M* (fig. 93) of 83 teeth, *B L* of 52, *C K* of 50, for the earth, *D I* of 40, *E H* of 7, and *F G* of 5; and another set of wheels moving freely about an arbor having the number of teeth in the fourth column, namely, *A N* of 20, *B O* of 32, *C P* of 50, for the earth, *D Q* of 75, *E R* of 83, and *F S* of 148; then, if these two arbors of fixed and movable wheels be made of the size and fixed at the distance here represented, the teeth of the former will take hold of those of the latter, and turn them freely when the machine is in motion. These arbors, with their wheels, are to be placed in a box of a proper size, in a perpendicular position; the arbor of fixed wheels to move in pivots at the top and bottom of the box, and the arbor of the movable wheels to go through the top of the box, and having on the top a wire fixed, and bent at a proper distance into a right angle upward, bearing on the top a small round ball representing its proper planet. If, then, on the

Fig. 94.



lower part of the arbor of fixed wheels be placed a pinion of screw-teeth, a winch turning a spindle with an endless screw, playing in the teeth of the arbor, will turn it with all its wheels, and these wheels will turn the others about, with their planets, in their proper and respective periods of time; for while the fixed wheel *C K* moves its equal *C P* once round, the wheel *A M* will move *A N* a little more than four times round, and will consequently exhibit the motion of Mercury; the wheel *E H* will turn the wheel *E R* about 1-12th round, representing the proportional motion of Jupiter; and the wheel *F G* will turn the wheel *F S* about 1-29.5th round, and represent the motion of Saturn, and so of all the rest.

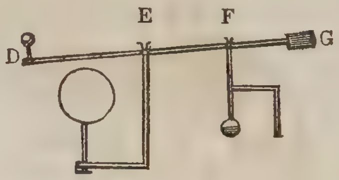
The foregoing figure (94) represents the appearance of the instrument when completed. Upon the upper part of the circular box is pasted a zodiacal circle divided into 12 signs, and each sign into 30 degrees, with the corresponding days of the month. The wheelwork is understood to be within the box, which may either be supported by a tripod, or with four feet, as here represented. The moon and the satellites of Jupiter, Saturn, and Uranus, are movable only by the hand. When the winch *W* is turned, then all the primary planets are made to move in their respective velocities. The ball in the center represents the Sun, which is either made of brass, or of wood gilded with gold.

By this planetarium, simple as its construction may appear, a variety of interesting exhibitions may be made and problems performed, which may be conducive to the instruction of young students of Astronomy. I shall mention only a few of these as specimens.

1. When the planets are placed in their respective positions by means of an ephemeris or the Nautical Almanac, the relative positions of those bodies in respect to each other, the quarters of the heavens where they may be observed, and whether they are to be seen in the morning before sunrise or in the evening after sunset, may be at once determined. For example, on the 19th of December, 1844, the *heliocentric* places of the planets are as follows: Uranus, 2° of Aries; Saturn, 8° 24′ of Aquarius; Jupiter, 7° 4′ of Aries; Mars, 12° 45′ of Libra; the Earth, 27° 46′ of Gemini; Venus, 29° 48′ of Virgo, Mercury, 7° 53′ of Pisces. When the planets are placed on the planetarium in these positions, and the eye placed in a line with the balls representing the Earth and the Sun, all those situated to the left of the sun are to the east of him, and are to be seen in the evening, and those on the right in the morning. In the present case, Uranus, Saturn, Jupiter, and Mercury are evening stars, and Mars and Venus can only be seen in the morning. Jupiter is in an aspect nearly *quartile*, or three signs distant from the sun, and Uranus is nearly in the same aspect. Saturn is much nearer the sun, and Mercury is not far from the period of its greatest *eastern* elongation. Mars is not far from being in a quartile aspect *west* of the sun, and Venus is near the same point of the heavens, approaching to the period of its greatest *western* elongation, and consequently will be seen before sunrise as a beautiful morning star. Jupiter and Uranus, to the east of the sun, appear nearly directly opposite to Venus and Mars, which are to the west of the sun. The phase* of Venus is nearly that of a half moon, and Mercury is somewhat gibbous, approaching to a half moon phase. If, now, we turn the machine by the winch until the index of the earth point at the 8th of August, 1845, we shall find the planets in the following positions: Mars and Saturn are nearly in opposition to the sun; Venus and Mercury are evening stars, at no great distance from each other, and Jupiter is a morning star. In like manner, if we turn the machine until the index point to any future months, or even succeeding years, the various aspects and positions of the planets may be plainly perceived. When the planets are moved by the winch in this machine, we see them all *at once* in motion around the sun, with the same respective velocities and periods of revolution which they have in the heavens. As the planets are represented in the preceding positions, Mercury, Jupiter, and Mars are evening stars, and Venus, Saturn, and Uranus morning stars, if we suppose the earth placed in a line with our eye and the sun.

2. By this instrument, the truth of the Copernican or solar system is clearly represented. When the planets are in motion, we perceive the planets Venus and Mercury to pass both before and behind the sun, and to have two conjunctions. We observe Mercury to be never more than a certain angular distance from the sun as viewed from the earth, namely, 27°, and Venus 47°. We perceive that the superior planets, particularly Mars, will be sometimes much nearer to the earth than at others, and therefore must appear larger at one time than at another, as they actually appear in the heavens. We see that the planets cannot appear from the earth to move with uniform velocity; for when nearest they appear to move faster, and slower when most remote. We likewise observe that the planets appear from the earth to move sometimes *direct*, or from west to east; then become retrograde, or from east to west, and between both to be *stationary;* all which particulars exactly correspond with celestial observations. For illustrating these particulars, there is a simple apparatus, represented by fig. 95, which consists of a hollow wire with a slit at top, which is placed over the arm of Mercury or Venus at *E*. The arm *D G* represents a ray of light coming from the planet at *D* to the earth at *F*. The planets being then in motion, the planet *D*, as seen in the heavens from the earth at *F*, will undergo the several changes of position which we have described above, sometimes appearing to go backward, and at other times forward. The wire prop, now supposed to be placed over Mercury at *E*, may likewise be placed over any of the other planets, particularly Mars, and similar phenomena will be exhibited.

Fig. 95.



This machine may likewise be used to exhibit the falsity of the Ptolemaic system, which places the earth in the center, and supposes the sun and all the planets to revolve around it. For this purpose, the ball representing the Sun is removed, and placed on the wire or pillar which supports the Earth, and the ball representing the Earth is placed in the center. It will then be observed that the planets Mercury and Venus, being both within the orbit of the sun, cannot at any time be seen to go behind it, whereas in the heavens we as often see them go behind as before the sun. Again, it shows that as the planets move in circular orbits about the central earth, they ought at all times to appear of the same magnitude, while, on the contrary, we observe their apparent magnitudes in the heavens to be very variable, Mars, for example, appearing sometimes nearly as large as Jupiter, and at other times only like a small fixed star. Again, it is here shown that the planets may be seen at all distances from the sun; for example, when the sun is setting, Mercury and Venus, according to this arrangement, might be seen, not only in the south, but even in the eastern quarter of the heavens: a phenomenon which was never yet observed in any age, Mercury never appearing beyond 27° of the sun, nor Venus beyond 48°. In short, according to the system thus represented, it is seen that the motions of the planets should all be regular, and uniformly the same in every part of their orbits, and that they should all move the same way, namely, from west to east; whereas in the heavens they are seen to move with variable velocities, sometimes appearing stationary, and sometimes moving from east to west, and from west to east: all which circumstances plainly prove that the Ptolemiac cannot be the true system of the universe.

---

* The balls which represent the different planets on this machine have their hemispheres painted black, with the white side turned directly to the sun, so that if the eye be placed in a line with the earth and the planet, particularly Mercury and Venus, its phase in the heavens at that time, as viewed with a telescope, may be distinctly perceived.

A planetarium such as that now described might be constructed with brass wheel-work for about five guineas. The brass wheel-work of one which I long since constructed cost about three guineas, and the other parts of the apparatus about two guineas more. The following are the prices of some instruments of this kind as made by Messrs. Jones, 30 Lower Holborn, London:—"An orrery, showing the motions of the Earth, Moon, and inferior planets, Mercury, and Venus, by wheel-work, the board on which the instrument moves being 13 inches diameter, £4. 14*s.* 6*d.* A planetarium, showing the motions of all the primary planets by wheel-work with 1½ inch or three inch papered globes, according to the wheel-work and the neatness of the stands, from £7 17*s.* 6*d.* to £10 10*s.* Ditto, with wheel-work to show the parallelism of the Earth's axis, the motions of the Moon, her phases, &c., £18 18*s.* Ditto, with wheel-work to show the Earth's diurnal motion, on a brass stand in mahogany case, £22 1*s.* A small *tellurion*, showing the motion of the Earth and Moon, &c., £1 8*s.*"

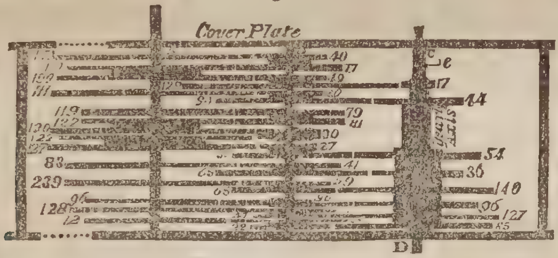
HENDERSON'S PLANETARIUM.

The following is a description of the most complete and accurate planetarium I have yet seen. The calculations occupied more than eight months. For this article I am indebted to my learned and ingenious friend, Dr. Henderson, F.R.A.S., who is known to many of my readers by his excellent astronomical writings.

Section of the wheel-work of a planetarium for showing with the utmost degree of accuracy the mean tropical revolutions of the planets round the sun, calculated by E. Henderson, LL. D., &c.

In the section the dark horizontal lines represent the wheelwork of the planetarium, and the annexed numerals the numbers of teeth in the given wheel. The machine has three axes or arbors, indicated by the letters *A B C*. Axis "*C*," the "yearly axis," is assumed to make one revolution in 365,242,236 days, or in 365 days 5h. 48m. 49.19′, and is furnished with wheels, 17, 44, 54, 36, 140, 96, 127, 86, which wheels are all firmly riveted to said axis, and consequently they turn round with it in the same time. Axle "*B*" is a fixture; it consists of a steel rod, on which a system of pairs of wheels revolve; thus wheels 40 and 77 are made fast together by being riveted on the same collet, represented by the thick, dark space between them, as also of the rest: the several wheels on this axis may be written down thus: $\frac{40}{77}$, $\frac{49}{129}$, $\frac{20}{94}$, $\frac{79}{81}$, 30, $\frac{27}{50}$, $\frac{41}{65}$, $\frac{59}{65}$, 96, $\frac{77}{47}$, $\frac{67}{42}$. On axis *A*, a system of wheels, furnished with tubes, revolve, and these tubes carry horizontal arms, supporting perpendicular stems with the planets. The wheels on this axis are 173, $\frac{117}{190}$, 111, 119, $\frac{122}{130}$, $\frac{123}{127}$, 83, 239, 96, 128, 72. From the following short description, the nature of their several actions will, it is presumed, be readily understood, viz:

Fig. 96.



MERCURY'S PERIOD. On the axis "*C*" at the bottom is wheel 86, which turns round in 365 days 5h. 48m. 49.19s. This wheel impels a small wheel of 22 teeth, to which is made fast wheel 67, both revolving together at the foot of axis *B;* wheel 67 drives a wheel of 72 once round in the period of 87 days 23h. 14m. 36.1s.: this last mentioned wheel has a long tube, which turns on the steel axis *A*, and carries a horizontal arm with the planet Mercury round the sun in the time above noted.

VENUS'S PERIOD. On axis "*C*" is wheel 127, which drives wheel 47, to which is riveted a wheel of 77 teeth, which impels a wheel of 128 teeth on axis *A*, and causes it to make a revolution in 224 days 16h. 41m. 31.1s., and is furnished with a tube, which revolves over that of Mercury, and ascends through the cover of the machine, and bears an arm on which is placed a small ball representing this planet in the time stated.

THE EARTH'S PERIOD The motion of the Earth round the Sun is simply effected as follows: the assumed value of axis "*C*" the "yearly axis," is 365 days 5h. 48m. 49.19s.; hence a system of wheels having the same number of teeth, or, at all events, the first mover and last wheel impelled, must be equal in their numbers of teeth. In this machine three wheels are employed, thus: a wheel having 96 teeth is made fast to the yearly axis *C*, and of course moves round with it in a mean solar year, as above noted; this wheel impels another wheel of 96 teeth on axis *B*, and this, in its turn, drives a third wheel of 96 teeth on axis *A*, and is furnished with a long tube which revolves over that of Venus, and ascends above the cover-plate of the machine, and bears a horizontal arm which supports a small terrestrial globe, which revolves by virtue of said wheels once round the sun in 365 days 5h. 48m. 49.19s.

MARS'S PERIOD. The revolution of this planet is effected as follows: a wheel of 140 teeth is made fast to the yearly axis *C*, and drives on axis *B* a wheel of 65 teeth, to which is fixed a wheel of 59 teeth, which impels a large wheel of 239 teeth on axis *A* once round the sun in 686 days 22h. 18m. 33.6s.: this last mentioned wheel is also furnished with a tube which revolves over that of the earth, and carries a horizontal arm bearing the ball representing Mars, and causes it to complete a revolution round the sun in the period named.

THE ASTEROIDS. VESTA'S PERIOD. The period of Vesta is accomplished thus, viz: on the yearly axis *C* is made fast a wheel of 36 teeth, which drives a wheel of 65 teeth, on axis *B*, to which is fixed a wheel of 41 teeth, which impels a wheel of 83 teeth on axis *A* once round in 1336 days 0h. 21m. 19.8s.; the tube of which last wheel ascends on that of Mars, and, like the rest, bears an arm supporting a ball representing this planet.

JUNO'S PERIOD. For the revolution of Juno, the yearly axis *C* is furnished with a wheel of 54 teeth, which impels a wheel of 50 teeth on axis *B*, to which is made fast a wheel of 27 teeth, which turns a wheel of 127 teeth on axis *A* once round in 1590 days 17h. 35m. 2.7s., and the tube of which ascends on that of Vesta, and supports a horizontal arm which carries a small ball representing this planet in the period named.

CERES'S PERIOD. The revolution of Ceres is derived from the period of Juno, because wheelwork taken from the unit of a solar year was not sufficiently accurate for the purpose, therefore on Juno's wheel of 127 teeth is fixed a wheel of 123 teeth, which drives a thick little bevel sort of wheel of 30 teeth on axis *B*: the reason of this small wheel being beveled is to allow its teeth to suit both wheels $\frac{123}{130}$; wheel 30 drives wheel 130 on axis *A* once round in 1681 days 6h. 17m. 22.4s., and the tube of wheel 130 turns on the tube of Juno, and ascends in a similar manner with the rest, and carries a horizontal arm supporting a small ball representing this planet, and is caused to revolve round the Sun in the above-mentioned period (the period of Ceres to that of Juno is as 130 is to 123: hence the wheels used)

PALLAS'S PERIOD. The period of Pallas could not be derived from the solar year with sufficient accuracy, and recourse was had to an engrafted fraction on the period of Ceres, thus: on wheel 130 of Ceres is made fast a wheel of 122 teeth, which drives a wheel of 81 teeth on axis *B*, to which is fixed a wheel 79, which impels a wheel of 119 teeth on axis *A*, and is furnished with a tube which ascends, and turns on that of Ceres, and supports a horizontal arm, which bears a small ball representing this planet, which by virtue of the above train of wheels is caused to complete a revolution round the Sun in 1681 days 10h. 28m. 25.1s.

JUPITER'S PERIOD. The motion of this planet is derived from the period of a solar year, from the "yearly axis," thus: on this axis is made fast a wheel of 44 teeth, which turns a wheel of 94 teeth on axis *B*, to which is riveted a small wheel of 20 teeth, which impels a wheel on axis *A* having 111 teeth, which is furnished with an ascending tube which revolves over that of Pallas, and bears a horizontal arm which supports a ball representing this planet, which by the said train of wheels is caused to revolve round the Sun in 4330 days 14h. 39m. 35.7s.

SATURN'S PERIOD. The periodic revolution of Saturn is also taken from the solar year, viz: a small wheel of 17 teeth is fixed to the "yearly axis" near its top, and drives a wheel of 129 teeth on axis *B*, to which is made fast a wheel of 49 teeth, which turns a wheel of 190 teeth on axis *A*, whose tube ascends and revolves on that of Jupiter's tube, and supports an arm, having a ball representing Saturn and its rings, and which by the train of wheels is caused to perform a revolution round the Sun in the period of 10,746 days 19h. 16m. 50.9s.

URANUS'S PERIOD. The revolution of this planet could not be attained with sufficient accuracy from the period of a solar year: the period is engrafted on that of Saturn's, thus: a wheel of 117 teeth is made fast to wheel 190 of Saturn, and consequently revolves in Saturn's period. This wheel of 117 teeth drives a wheel on axis *B* having 77 teeth, to which is fixed a wheel of 40 teeth, which turns on axis *A* a large wheel of 173 teeth, whose tube ascends and revolves over that of Saturn, and carries a horizontal arm which supports a ball representing this planet, which is caused to complete its revolution by such a train of wheels in the period of 30,589 days 8h. 26m. 58.4s. Such is a brief description of the motions of this comprehensive and very accurate machine.

The axis *A*, on which the planet tubular wheels revolve, performs a rotation in 25 days 10 hours by virtue of the following train of wheels, $\frac{61}{14}+\frac{70}{12}$ of 24 hours, that is, a pinion of 14 is assumed to revolve in 24 hours, and to drive a wheel of 61 teeth, to which is fixed a pinion of 12, which turns the wheel 70 in the period noted; to this wheel-axis it is made fast, and by revolving with it exhibits the Sun's rotation.

DIURNAL HAND. The machine is turned by a handle or winch, which is assumed to turn round in 24 hours, and from this rotation of 24 hours a train of wheel-work is required to cause the "yearly axis" *C* to turn once round in 365 days 5h. 48m. 49.19s., which is effected in the following manner, viz: the train found by the process of the reduction of continuous fractions is $\frac{61}{14}+\frac{144}{18}+\frac{241}{23}$, that is, in the train for turning the Sun, the same pinion 14 turns the same wheel 61, and turns a pinion of 18 leaves, to which is fixed a wheel of 144 teeth, having a pinion of 23 leaves, which impels a large wheel of 241 teeth once round in 365.242236 days, or 365d. 5h. 48m. 49.19s. The last mentioned wheel of 241 teeth is made fast to the under part of the "yearly axis" *C* at *D*, the handle having a pinion of 14 leaves therefor, and, transmitting its motion through the above train, causes the yearly axis to revolve in the same period.

REGISTRATING DATES. The planetarium is also furnished with a system of wheels for registrating dates for either 10,000 years past or to come. The arrangement is not shown in the engraving (to prevent confusion), but it might be shortly described thus: near the top of the yearly axis is a hooked piece, *e*, which causes the tooth of a wheel of 100 teeth to start forward yearly; consequently, 100 starts of said wheel will cause it to revolve in 100 solar years; and it has a hand, which points on a dial on the cover of the machine the years: thus, for the present year, this hand will be over the number 45. This last-named wheel of 100 teeth has a pin, which causes a tooth of another wheel of 100 teeth to start once in 100 years; hence this last wheel will complete one revolution in 10,000 years; and it is for this purpose the former index or hand moves over a number yearly. The second index will pass over a number every 100 years; for the present year, the second-hand or index will be over the number 18, and will continue over it until the first index moves forward to 99; then both indexes will move at one time, viz: the first index to *O O* on the first concentric circle of the dial, and the second index to 19, denoting the year 1900, and so of the rest. By the ecliptic being divided in a series of four spirals, the machine makes a distinction between common and leap years, and indicates the common year as containing 365 days, and the leap year 366 days, by taking in a day in February every fourth year; thus, for any given period for 10,000 years past or to come, the various situations and aspects of the planets may be ascertained by operating with this machine, and this for thousands of years without producing a sensible error either in space or time. This planetarium wheel-work is inclosed in an elegant mahogany box of twelve sides; is about five feet in diameter by ten inches in depth. At each of the twelve angles, or sides, small brass pillars rise, and support a large ecliptic circle, on which are engraven the signs, degrees, and minutes of the ecliptic, the days of the month, &c. This mahogany box with the wheel-work is supported by a tripod stand three feet in hight, and motion is communicated to the several balls representing the planets by turning the handle as before described. A planetarium of this complicated sort costs sixty guineas.

The foregoing is a tabular view of the wheel-work, periods, &c.

In the month of October last year, Dr. Henderson made a series of calculations for a new planetarium for the use of schools. It shows with considerable accuracy for 700 days the mean tropical revolutions of the planets round the sun. The machine consists of a system of brass wheels peculiarly arranged, and is inclosed in a circular case three feet in diameter, the top of which has the signs and degrees of the ecliptic laid down on it, as also the days of the months, &c. This planetarium costs only 45*s*., or, on a tripod stand, table-high, 55*s*.: the machine is put in motion by a handle on the outside. To the teachers and others connected with education, this planetarium must be of great importance, for without a proper elucidation of the principles of astronomy, that of Geography must be but confusedly understood. This planetarium is at present made by Mr. Dollond, 9 White Conduit Grove, Islington, London.

The *Tellurion* is a small instrument which should be used in connection with the planetarium formerly described. This instrument is intended to show the annual motion of the earth, and the revolution of the moon around it. It also illustrates the moon's phases and the motion of her nodes, the inclination of the Earth's axis, the causes of eclipses, the variety of seasons, and other phenomena. It consists of about eight wheels, pinions, and circles. A small instrument of this description may be purchased for about £1 8*s*., as stated on page 143.

ON THE VARIOUS OPINIONS WHICH WERE ORIGINALLY FORMED OF SATURN'S RING.

The striking and singular phenomenon connected with the planet Saturn, though now ascertained beyond dispute to be a ring or rings surrounding its body at a certain distance, was a subject of great mystery, and gave rise to numerous conjectures and controversies for a considerable time after the invention of the telescope by which it was discovered. Though it was first discovered in the year 1610, it was nearly 50 years afterward before its true form and nature were determined. Galileo was the first who discovered anything uncommon connected with Saturn: through his telescope he thought he saw that planet appear like two smaller globes on each side of a larger one; and after viewing the planet in this form for two years, he was surprised to see it becoming quite round, without its adjoining globes, and some time afterward to appear in the triple form. This appearance is represented in fig. 1 of the following engraving. In the year 1614, Scheiner, a German astronomer, published a representation of Saturn, in which this planet is exhibited as a large central globe, with two smaller bodies, one on each side, partly of a conical form, attached to the planet, and forming a part of it, as shown fig. 2. In the years 1640 and 1643, Ricciolus, an Italian mathematician and astronomer, imagined he saw Saturn as represented in fig. 3, consisting of a central globe, and two conical-shaped bodies completely detached from it, and published an account of it corresponding to this view. Hevelius, the celebrated astronomer of Dantzig, author of the *Selenographia* and other works, made many observations on this planet about the years 1643, 1649, and 1650, in which he appears to have obtained different views of the planet and its appendages, gradually approximating to the truth, but still incorrect. These views are represented in figures 4, 5, 6, and 7. Fig. 4 nearly resembles two hemispheres, one on each side of the globe of Saturn. The other figures very nearly resemble the extreme parts of the ring as seen through a good telescope, but he still seems to have considered them as detached from each other as well as from Saturn. Figures 8 and 9 are views given by Ricciolus at a period posterior to that in which he supposed Saturn and his appendages in the form delineated in fig. 3. In these last delineations the planet was supposed to be inclosed in an elliptical ring, but this ring was supposed to be *fixed* to its two opposite sides.

Fig. 97.

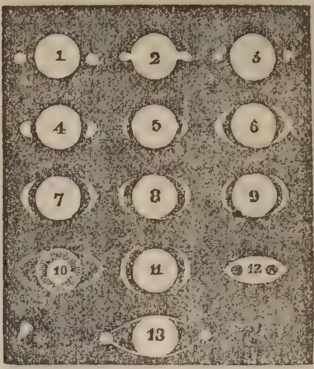

Fig. 10 is a representation by Eustachius Divini, a celebrated Italian optician at Bologna. The shades represented on Saturn and the elliptical curve are incorrect, as this planet presents no such shadowy form. The general appearance here presented is not much unlike that which the ring of Saturn exhibits, excepting that the upper side of the ring should appear covering a portion of the orb of Saturn; but Divini seems to have conceived that the curve on each side was attached to the body of Saturn, for when Huygens published his discovery of the ring of Saturn in 1659, Divini contested its truth, because he could not perceive the ring through his own telescopes; and he wrote a treatise on the subject in opposition to Huygens in 1660, entitled "Brevis Annotatio in Systema Saturnium." Huygens immediately replied to him, and Divini wrote a rejoinder in 1661. Fig. 11 is the representation given by Francis Fontana, a Neapolitan Astronomer. This figure represents Saturn as having two crescents, one on each side, attached to its body, with intervals between the planet and the crescents. Fig. 12 is a view delineated by Gassendus, a celebrated French philosopher. It represents the planet as a large ellipsoid, having a large circular opening near each end, and if this representation were the true one, each opening would be at least 30,000 miles in diameter. Fig 13, which is perhaps the most singular of the whole, is said to be one of the views of this planet given by Ricciolus. It represents two globes, each of which, in the proportion they here bear to Saturn, must be more than 30,000 miles in diameter. These globes were conceived as being attached to the body of Saturn by curves or bands, each of which, in the proportion represented, must have been at least 7000 miles in breadth, and nearly 40,000 miles long. This would have exhibited the planet Saturn as a still more singular body than what we have found it to be; but no such construction of a planet has yet been found in the universe, nor is it probable that such a form of a planetary body exists.

It is remarkable that only two general opinions should have been formed respecting the construction of Saturn, as appears from these representations: either that this planet was composed of three distinct parts, separate from each other, or that the appendage on each side was *fixed* to the body of the planet. The idea of a ring surrounding the body of the planet at a certain distance from every part of it seems never to have been thought of until the celebrated Huygens, in 1655, 1656, and 1657, by numerous observations made on this planet, completely demonstrated that it is surrounded by a solid and permanent ring, which never changes its situation, and, without touching the body of the planet, accompanies it in its revolution around the sun. As the cause of all the erroneous opinions above stated was owing to the imperfection of the telescopes which were then in use, and their deficiency in magnifying power, this ingenious astronomer set himself to work in order to improve telescopes for celestial observations. He improved the art of grinding and polishing object-glasses, which he finished with his own hands, and produced lenses of a more correct figure, and of a longer focal distance, than what had previously been accomplished. He first constructed a telescope 12 feet long, and afterward one 23 feet long, which magnified about 95 times; whereas Galileo's best telescope magnified only about 33 times. He afterward constructed one 123 feet long, which magnified about 220 times. It was used without a tube, the object-glass being placed upon the top of a pole, and connected by a cord with the eye-piece. With such telescopes this ingenious artist and mathematician discovered the fourth satellite of Saturn, and demonstrated that the phenomenon which had been so egregiously misrepresented by preceding astronomers consisted of an immense ring surrounding the body, and completely detached from it. His numerous observations and reasonings on this subject were published in Latin in 1659, in a quarto volume of nearly 100 pages, entitled "*Systema Saturnium, sive de causis mirandorum Saturni Phenomenon, et Comite ejus Planeta Nova,*" from which work the figures and some of the facts stated above have been extracted.

ON THE SUPPOSED DIVISIONS OF THE EXTERIOR RING OF SATURN.

From the period in which Huygens lived until the time when Herschel applied his large telescopes to the heavens, few discoveries were made in relation to Saturn. Cassini, in 1671, discovered the fifth satellite of this planet; in 1672, the third; and the first and second in March, 1684. In 1675, Cassini saw the broad side of its ring bisected quite round by a dark elliptical line, of which the inner part appeared brighter than the outer. In 1722, Mr. Hadley, with his five feet Newtonian reflector, observed the same phenomenon, and perceived that the dark line was stronger next the body, and fainter toward the upper edge of the ring. Within the ring he also discovered two belts across the disc of Saturn; but it does not appear that they had any idea that this dark line was empty space separating the ring into two parts. This discovery was reserved for the late Sir W. Herschel, who made numerous observations on this planet, and likewise ascertained that the ring performs a revolution round the planet in ten hours and thirty minutes.

Of late years, some observers have supposed that the exterior ring of Saturn is divided into several parts, or, in other words, that it consists of two or more concentric rings. The following are some of the observations on which this opinion is founded. They are chiefly extracted from Captain Kater's paper on this subject which was read before the Astronomical Society of London.

The observations, we are told, were made in the years 1825 and 1826, and remained unpublished from a wish on the part of the observer to witness the appearances again. The planet Saturn has been much observed by Captain Kater for the purpose of trying the light, &c., for which the ring and satellites are good tests. The instruments which were employed in the present investigations were two Newtonian reflectors, one by Watson, of 40 inches focus and 6¼th aperture, and another by Dollond, of 68 inches focus and 6¾ths aperture. The first, under favorable circumstances, gave a most excellent image; the latter is a very good instrument. The following are extracts from the author's journal.

Nov. 25, 1825. The double ring beautifully defined, perfectly distinct all around, and the principal belts well seen. I tried many concave glasses, and found that the image was much sharper than with convex eyeglasses, and the light apparently much greater. Dollond, 259, the best power, 480, a single lens, very distinct. *Nov.* 30, the night very favorable, but not equal to the 25th. The exterior ring of Saturn is not so bright as the interior, and the interior is less bright close to the edge next the planet. The inner edge appears more yellow than the rest of the ring, and nearer in color to the body of the planet. *Dec.* 17. The evening extremely fine. With Dollond I perceived the outer ring of Saturn to be darker than the inner, and the division of the ring all around with perfect distinctness; but with Watson I fancied that I saw *the outer ring separated by numerous dark divisions extremely close, one stronger than the rest, dividing the ring about equally.* This was seen with my most perfect single eyeglass power. A careful examination of some hours confirmed this opinion. *Jan.* 16 and 17, 1826. Captain Kater believed that he saw the divisions with the Dollond, but was not positive. Concave eyeglasses found to be superior to convex. *Feb.* 26, 1826. The division of the outer ring not seen with Dollond. On the 17th Dec., when the divisions were most distinctly seen, Captain Kater made a drawing of the appearance of Saturn and his rings. The phenomena were witnessed by two other persons on the same evening, one of whom saw several divisions in the outer ring, while the other saw one middle division only; but the latter person was short-sighted, and unaccustomed to telescopic observations. It may be remarked, however, that these divisions were not seen on other evenings, which yet were considered very favorable for distinct vision.

It is said that the same appearances were seen by Mr. Short, but the original record of his observations cannot be found. In Lalande's *Astronomy* (3d edition, article 3351) it is said, "Cassini remarked that the breadth of the ring was divided into two equal parts by a dark line having the same curvature as the ring, and the *exterior* portion was the less light. Short *told* me that he observed still more singular phenomena with his large telescope of 12 feet. The breadth of the ansæ, or extremities of the ring, was, according to him, divided into two parts, an inner portion without any break in the illumination, and an outer divided by several lines concentric with the circumference, which would lead to a belief *that there are several rings in the same plane.*" De Lambre and Birt severally state that Short saw the outer ring divided, probably on the authority of Lalande. In Brewster's *Ferguson's Astronomy*, vol. ii, p. 125, 2d edition, there is the following note on this subject: "Mr. Short assures us that with an excellent telescope he observed the surface of the ring divided by several dark concentric lines, which seem to indicate a number of rings proportional to the number of dark lines which he perceived."

In December, 1813, at Paris, Professor Quetelet saw the outer ring divided with the achromatic telescope of ten inches aperture, which was exhibited at the exposition. He mentioned this the following day to M. de la Place, who observed that "those, or even more divisions, were conformable to the system of the world." On the other hand, the division of the outer ring was not seen by Sir W. Herschel in 1792, nor by Sir J. Herschel in 1826, nor by Strûve in the same year; and on several occasions when the atmospheric conditions were most favorable, it has not been seen by Captain Kater. It has been remarked by Sir W. Herschel, Strûve, and others, that the exterior ring is much less brilliant than the interior; and it is asked, May not this want of light in the outer ring arise from its having a very dense atmosphere? and may not this atmosphere in certain states admit of the divisions of the exterior ring being seen, though, under other circumstances, they remain invisible? The above observations are said to have been confirmed by some recent observations by Decuppis at Rome, who announced some years ago, that Saturn's outer ring is divided into two or three concentric rings.

Some of the observations stated above, were they perfectly correct, would lead to the conclusion that Saturn is encompassed with a number of rings concentric with and parallel to each other. But while such phenomena as described above are so seldom seen, even by the most powerful telescopes and the most accurate observers, a certain degree of doubt must still hang over the subject; and we must suspend our opinion on this point until future observations shall either confirm or render doubtful those to which we have referred. Should the Earl of Rosse's great telescope, when finished for observation, be found to perform according to the expectations now entertained, and in proportion to its size and quantity of light, we shall expect that our doubts will be resolved in regard to the supposed divisions of the ring of Saturn.

APPENDIX.

BRIEF DESCRIPTION OF THE EARL OF ROSSE'S TELESCOPE.

This telescope, the largest and most magnificent that ever was attempted, reflects the greatest honor on the genius, the inventive powers, and the scientific acquirements of its noble contriver, as well as on the elevated station in which he is placed. With rank and fortune, and every circumstance that usually unfit men for scientific pursuit, he has set a bright example to his compeers of the dignity and utility of philosophical studies and investigations, and of the aids they might render to the progress of science, were their wealth and pursuits directed in a proper channel.

Previously to his lordship's attempting the construction of his largest, or "Monster Telescope," he had constructed one with a speculum of three feet in diameter, which was considered one of the most accurate and powerful instruments that had ever been made, not excepting even Sir W. Herschel's forty feet reflector. In the account of this telescope published in the Philosophical Transactions for 1840, his lordship speaks of the possibility of a speculum of six feet in diameter being cast. At that time it was considered by some as little short of a chimera to attempt the construction of such a monstrous instrument; but the idea no sooner occurred to this ingenious and persevering nobleman than he determined to put it to the test, and the result has been attended with complete success. The materials of which this speculum is composed are *copper* and *tin*, united very nearly in their atomic proportions, namely, copper 126.4 parts to tin 58.9 parts. This compound has a specific gravity of 8.8, and is found to preserve its luster with more splendor, and to be more free from pores than any other. A foundry was constructed expressly for the purpose of casting the speculum. Its chimney, built from the ground, was 18 feet high, and 16½ square at the base, tapering to four at the top. At each of its sides, communicating with it by a flue, was sunk a furnace 8 feet deep and 5½ square, with a circular opening 4 feet in diameter. About seven feet from the chimney was erected a large crane, with the necessary tackle for elevating and carrying the crucibles from the furnace to the mold, which was placed in a line with the chimney and crane, and had three iron baskets supported on pivots hung round it; and four feet farther on was the annealing oven. The crucibles which contained the metal were each 2 feet in diameter, 2½ deep, and together weighed one ton and a half. They were of cast iron, and made to fit the baskets at the side of the mold. These baskets were hung on wooden uprights, or pivots; to one of these, on each side, was attached a lever, by depressing which it might be turned over, and the contents of the crucible poured into the mold. The bottom of the mold was made by binding together tightly layers of hoop iron, and turning the required shape on them edgewise. This mold conducted the heat away through the bottom, and cooled the metal toward the top in infinitely small layers, while the interstices, though close enough to prevent the metal from escaping, were sufficiently open to allow the air to penetrate. This bottom was 6 feet in diameter and 5½ inches thick, and was made perfectly horizontal by means of spirit levels, and was surrounded by a wooden frame. A wooden pattern, the exact size of the speculum, being placed on the iron, sand was well packed between it and the frame, and the pattern was removed. Each of the crucibles containing the melted metal was then placed in its basket, and everything being ready for discharging their contents, they were at the same instant turned over, and the mold being filled, the metal in a short time safely set into the required figure. While it was red hot, and scarcely solid, the framework was removed, and an iron ring connected with a bar which passed through the oven being placed round it, it was drawn in by means of a capstan at the other side, on a railroad, when charcoal being lighted in the oven, and turf fires underneath it, all the openings were built up, and it was left for sixteen weeks to anneal. It was cast on the 13th of April, 1842, at 9 o'clock in the evening. The crucibles were ten hours heating in the furnaces before the metal was introduced, which in about ten hours more was sufficiently fluid to be poured. When the oven was opened the speculum was found as perfect as when it entered it. It was then removed to the grinding machine, where it underwent that process, and afterward was polished, without any accident having occurred.

This speculum weighed *three tons*, and lost about one-eighth of an inch in grinding. Lord Rosse has since cast another speculum of the same diameter four tons in weight. He can now, with perfect confidence, undertake any casting, so great an improvement has the form of mold which he has invented proved. The speculum was placed on an equilibrium bed, composed of nine pieces, resting on points at their centers of gravity. The pieces were lined with pitch and felt before the speculum was placed on them. The speculum box is also lined with felt, and pitched: this prevents any sudden change of temperature affecting the speculum by means of the bad conducting power of the substances employed. A vessel of lime is kept in connection with the speculum box to absorb the moisture, which otherwise might injure the mirror. The process of grinding was conducted under water, and the moving power employed was a steam-engine of three horse power. The polisher is connected with the machinery by means of a large ring of iron, which loosely encircles it; and instead of either the speculum or the polisher being stationary, both move with a regulated speed. The ring of the polisher, and therefore the polisher itself, has a transverse and a longitudinal motion; it makes 80 strokes in the minute, and 24½ strokes backward and forward for every revolution of the mirror, and at the same time $1\frac{72}{100}$th strokes in the transverse direction. The extent of the latter is $\frac{27}{100}$ths of the diameter of the speculum. The substance made use of to wear down the surface was emery and water: a constant supply of these was kept between the grinder and the speculum. The grinder is made of cast iron, with grooves cut lengthwise, across, and circularly on its face. The polisher and speculum have a mutual action upon each other: in a few hours, by the help of the emery and water, they are both ground truly circular, whatever may have been their previous defects. The grinding is continued until the required form of surface is produced, and this is ascertained in the following manner: there is a high tower over the house in which the speculum is ground, on the top of which is fixed a pole, to which is attached the dial of a watch; there are trap-doors which open, and by means of a temporary eyepiece, allow the figure of the dial to be seen in the speculum brought to a slight polish. If the dots on the dial are not sufficiently well-defined, the grinding is continued; but if they appear satisfactorily, the polishing is commenced. It required six weeks to grind it to a fair surface. The polisher was cut into grooves, to prevent the abraded matter from accumulating in some places more than in others; a thin layer of pitch was spread over it; it was smeared over with rouge and water, and a supply of it kept up until the machinery brought it to a fine black polish. The length of time employed for polishing the three-feet speculum was six hours.*

This large telescope is now completed, or nearly so. The tube is 56 feet long, including the speculum box, and is made of deal one inch thick, hooped with iron. On the inside, at intervals of eight feet, there are rings of iron three inches in depth and one inch broad, for the purpose of strengthening the sides. The diameter of the tube is seven feet. It is fixed to mason-work in the ground by a large universal hinge, which allows it to turn in all directions. At 12 feet distance on each side a wall is built, 72 feet long, 48 high on the outer side, and 56 on the inner, the walls being 24 feet distant from each other, and lying exactly in the meridional line. When directed to the south, the tube may be lowered until it becomes almost horizontal; but when pointed to the north, it only falls until it is parallel with the earth's axis, pointing then to the pole of the heavens. Its lateral movements take place only from wall to wall, and this commands a view for half an hour on each side of the meridian; that is, the whole of its motion from east to west is limited to 15 degrees. At present it is fitted up in a temporary way to be used as a transit instrument; but it is ultimately intended to connect with the tube-end galleries machinery which shall give an automaton movement, so that the telescope shall be used as an equatorial instrument. All the works connected with this instrument are of the strongest and safest kind; all the iron work was cast in his lordship's laboratory by men instructed by himself, and every part of the machinery was made under his own eye by the artisans in his own neighborhood, and not a single accident worth mentioning happened during the whole proceeding.

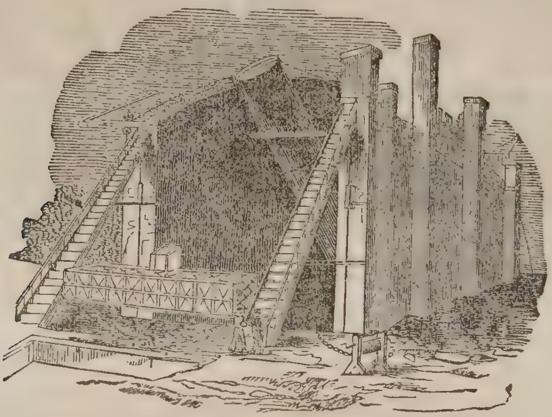
The expense incurred by his lordship in the erection of this noble instrument, was not less than *twelve thousand pounds!* beside the money expended in the construction of the telescope of three feet diameter. Sufficient time has not yet been afforded for making particular observations with this telescope; but from slight trials which have been made, even under unfavorable circumstances, it promises important results. Its great superiority over every telescope previously constructed, consists in the great quantity of light it reflects, and the brilliancy with which it exhibits objects, even when high powers are applied. It has a reflecting surface of 4071 square inches, while that of Herschel's 40 feet telescope had only 1811 square inches on its polished surface, so that the quantity of light reflected from the speculum is considerably more than double that of Herschel's largest reflector. This instrument has already exceeded his lordship's expectations. Many appearances before invisible in the Moon have been perceived, and there is every reason to expect that new discoveries will be made by it in the *Nebulæ*, double and triple stars, and other celestial objects. The following is an extract of a communication from Sir James South on this subject, addressed to the editor of the "*Times;*" "The leviathan telescope on which the Earl of Rosse has been toiling upward of two years, although not absolutely finished, was on Wednesday last directed to the sidereal heavens. The letter which I have this morning received from its noble maker, in his usual unassuming style, merely states that the metal, only just polished, was of a pretty good figure, and that with a power of 500 the nebula known as No. 2 of Messier's catalogue was even more magnificent than the nebula No. 13 of Messier, when seen with his lordship's telescope of three feet diameter and 27 feet focus. Cloudy weather prevented him from turning the leviathan on any other nebulous object. Thus, then, we have all danger of the metal breaking before it could be polished, overcome. Little more, however, will be done with it for some time, as the earl is on the eve of quitting Ireland for England to resign his post at York as president of the British Association. I look forward with intense anxiety to witness its first severe trial, when all its various appointments shall be completed, in the confidence that those who may then be present will see with it what man has never seen before. The diameter of the large metal is six feet, and its focus 54 feet; yet the immense mass is manageable by one man. Compared with it, the working telescopes of Sir William Herschel, which in his hands conferred on astronomy such inestimable service, and on himself astronomical immortality, were but playthings."

---

* The above description has been selected and abridged from a small volume entitled "The Monster Telescope, erected by the Earl of Rosse, Parsontown," and also from the "Illustrated London News" of September 9th, 1843. In the volume alluded to a more particular description will be found, accompanied with engravings.

The following is a more recent account of observations made by this telescope, chiefly extracted from Sir James South's description, inserted in the *Times* of April 16th, 1845, and the "*Illustrated London News*" of April 19:

Fig. 98.

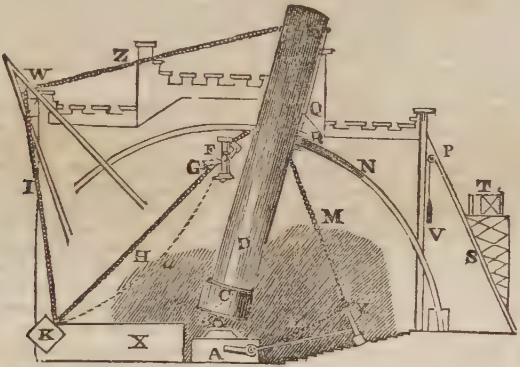


"The night of the 5th of March, 1845, was the finest I ever saw in Ireland. Many nebulæ were observed by Lord Rosse, Dr. Robinson, and myself. Most of them were, for the first time since their creation, seen by us as groups or clusters of stars; while some, at least to my eyes, showed no such resolution. Never, however, in my life did I see such glorious sidereal pictures as this instrument afforded us. Most of the nebulæ we saw I certainly have observed with my own achromatic; but although that instrument, as far as relates to magnifying power, is probably inferior to no one in existence, yet to compare these nebulæ, as seen with it and the six-feet telescope, is like comparing, as seen with the naked eye, the dinginess of the planet Saturn to the brilliancy of Venus. The most popularly known nebulæ observed this night were the ring nebulæ in the *Canes Venatici*, or the 51st of Messier's catalogue, which was resolved into stars with a magnifying power of 548, and the 94th of Messier, which is in the same constellation, and which was resolved into a large globular cluster of stars not much unlike the well-known cluster in Hercules, called also the 13th of Messier." Perfection of figure, however, of a telescope must be tested, not by nebulæ, but by its performance on a star of the first magnitude. If it will, under high power, show the star round and free from optical appendages, we may safely take it for granted it will not only show nebulæ well, but any other celestial object as it ought. To determine this point, the telescope was directed to *Regulus* with the entire aperture, and a power of 800, and "I saw," says Sir James, "with inexpressible delight, the star free from wings, tails, or optical appendages; not indeed, like a planetary disc, as in my large achromatic, but a round image resembling voltaic light, between charcoal points; and so little aberration had this brilliant image, that I could have measured its distance from, and position with any of the stars in the field with a spider's-line micrometer, and a power of 1000, without the slightest difficulty; for not only was the large star round, but the telescope, although in the open air, and the wind blowing rather fresh, was as steady as a rock."

"On subsequent nights, observations of other nebulæ, amounting to some thirty or more, removed most of them from the list of nebulæ, where they had long figured, to that of clusters; while some of these latter, more especially the 5th of Messier, exhibited a sidereal picture in the telescope such as man before had never seen, and which for its magnificence baffles all description Several double stars were seen with various apertures of the telescope, and with powers between 360 and 800; and as the earl had before told us we should—before the speculum was inserted in the tube, in consequence of his having been obliged to quit the superintendence of the polishing at the most critical part of the process—we found that a ring about six inches broad, reckoning from the circumference of the speculum, was not perfectly polished, and to *that* the little irradiation seen about Regulus was unquestionably referrible. The only double stars of the first class which the weather permitted us to examine with it were Xi Ursæ Majoris, and Gamma Virginis, which I could have measured with the greatest confidence. D'Arrest's comet we observed on the 12th of March, with a power of 400, but nothing worthy of notice was detected. Of the Moon a few words must suffice. Its appearance in my large achromatic of 12 inches aperture is known to hundreds of readers; let them then imagine that with it they look *at* the moon, while with Lord Rosse's six-feet they look *into it*, and they will not form a very erroneous opinion of the performance of the leviathan. On the 15th of March, when the moon was seven days old, I never saw her unilluminated disc so beautifully, nor her mountains so temptingly measurable. On my first looking into the telescope, a star of about the seventh magnitude was some minutes of a degree from the moon's dark limb, and its occultation by the moon appeared inevitable. The star, however, instead of disappearing the moment the moon's edge came in contact with it, apparently glided on the moon's dark face, as if it had been seen through a transparent moon, or as if the star were between me and the moon. It remained on the moon's disc nearly two seconds of time, and then disappeared. I have seen this apparent projection of a star on the moon's face several times, but from the great brilliancy of the star, this was the most beautiful I ever saw. The cause of this phenomenon is involved in impenetrable mystery.

The following is a representation of the great Rosse telescope, along with part of the buildings with which it is connected. In the interior face of the eastern wall a very strong iron arc of about 43 feet radius is firmly fixed, provided with adjustments, whereby its surface facing the telescope may be set very accurately in the plane of the meridian. On this bar lines are drawn, the interval between any adjoining two of which corresponds to one minute of time on the equator. The tube and speculum, including the bed on which the speculum rests, weigh about 15 tons. The telescope rests on a universal joint, placed on masonry about six feet below the ground, and is elevated or depressed by a chain and windlass; and although it weighs about 15 tons, the instrument is raised by two men with great facility: of course, it is counterpoised in every direction. The observer, when at work, stands in one of four galleries, the three highest of which are drawn out from the western wall, while the fourth or lowest has for its base an elevating platform, along the horizontal surface of which a gallery slides from wall to wall by a machinery within the observer's reach, but which a child may work. When the telescope is about half an hour east of the meridian, the galleries, hanging over the gap between the walls, present to a spectator below an appearance somewhat dangerous; yet the observer, with common prudence, is as safe as on the ground, and each of the galleries can be drawn from the wall to the telescope's side so readily, that the observer needs no one else to move it for him.

Fig. 99



The foregoing figure (98) represents only the upper part of the tube of the telescope, at which the observer stands when making his observations. The telescope is at present of the Newtonian construction, and, consequently, the observer looks into the side of the tube at the upper end of the telescope; but it is proposed to throw aside the plane speculum, and to adapt it to the *front view*, on the plan already described (see pp. 88, 89, &c.), so that the observer will sit or stand with his back toward the object, and his face looking down upon the speculum; and in this position he will sometimes be elevated between 50 and 60 feet above the ground. As yet, the telescope has no equatorial motion, but it very shortly will; and at no very distant day, clockwork will be connected with it, when the observer will, while observing, be almost as comfortable as if he were reading at a desk by his fireside.

The foregoing figure (99) shows a section of the machinery connected with this telescope. It exhibits a view of the inside of the eastern wall, with all the machinery as seen in section. *A* is the mason work on the ground; *B*, the universal joint, which allows the tube to turn in all directions; *C*, the speculum in its tube; *D*, the box; *E*, the eyepiece; *F*, the movable pulley· *G*, the fixed one; *H*, the chain from the side of the tube; *I*, the chain from the beam; *K*, the counterpoise; *L*, the lever; *M*, the chain connecting it with the tube; *Z*, the chain which passes from the tube to the windlass over a pulley on a trussbeam, which runs from *W* to the same situation on the opposite wall: the pulley is not seen; *X* is a railroad, on which the speculum is drawn either to or from its box: part is cut away, to show the counterpoise. The dotted line *a* represents the course of the weight *R* as the tube rises or falls: it is a segment of a circle, of which the chain *I* is the radius. The tube is moved from wall to wall by the ratchet and wheel at *R;* the wheel is turned by the handle *O*, and the ratchet is fixed to the circle on the wall. The ladders in front, as shown in the preceding sketch, enable the observer to follow the tube in its ascent to where the galleries on the side-wall commence. These side-galleries are three in number, and each can be moved from wall to wall by the observer after the tube, the motion of which he also accomplishes by means of the handle *O*.

I shall conclude the description of this wonderful instrument in the words of Sir James South: "What will be the power of this telescope when it has its Le Mairean form [that is, when it is fitted up with the front view], "it is not easy to divine. What nebulæ will it resolve into stars? in what nebulæ will it not find stars? how many satellites of Saturn will it show us? how many will it indicate as appertaining to Uranus? how many nebulæ never yet seen by mortal eye will it present to us? what spots will it show us on the various planets? will it tell us what causes the variable brightness of many of the fixed stars? will it give us any information as to the constitution of the planetary nebulæ? will it exhibit to us any satellites encircling them? will it tell us why the satellites of Jupiter, which generally pass over Jupiter's face as discs nearly of white light, sometimes traverse it as black patches! will it add to our knowledge of the physical construction of nebulous stars? of that mysterious class of bodies which surround some stars, called, for want of a better name, 'photospheres'? will it show the annular nebulæ of Lyra merely as a brilliant luminous ring, or will it exhibit it as thousands of stars arranged in all the symmetry of an ellipse? will it enable us to comprehend the hitherto incomprehensible nature and origin of the light of the great nebulæ of Orion? will it give us, in easily appreciable quantity, the parallax of some of the fixed stars, or will it make sensible to us the parallax of the nebulæ themselves? finally, having presented to us original portraits of the moon and of the sidereal heavens, such as man has never dared even to anticipate, will it, by Daguerreotype aid, administer to us copies founded upon truth, and enable astronomers of future ages to compare the moon and heavens as they then may be with the moon and heavens as they were? Some of these questions will be answered affirmatively, others negatively, and that, too, very shortly; for the noble maker of the noblest instrument ever formed by man 'has cast his bread upon the waters, and will, with God's blessing, find it before many days.'"

HINTS TO AMATEURS IN ASTRONOMY RESPECTING THE CONSTRUCTION OF TELESCOPES.

As there are many among the lower ranks of the community who have a desire to be possessed of a telescope which will show them some of the prominent features of celestial scenery, but who are unable to purchase a finished instrument at the prices usually charged by opticians, the following hints may perhaps be acceptable to those who are possessed of a mechanical genius.

The lenses of an achromatic telescope may be purchased separately from glass-grinders or opticians, and tubes of a cheap material may be prepared by the individual himself for receiving the glasses. The following are the prices at which achromatic object-glasses for astronomical telescopes are generally sold: Focal length 30 inches, diameter 2¼th inches, from 2 to 3½ guineas. Focal length 42 inches, diameter 2¾ths inches, from 5 to 8 guineas. Focal length 42 inches, diameter 3¼th inches, from 12 to 20 guineas. Focal length 42 inches, diameter 3¾ths inches, from 25 to 30 guineas. Eyepieces, from 10*s.* 6*d* to 18 shillings. The smallest of these lenses, namely, that of 2¼th inches diameter, if truly achromatic, may be made to bear a power of from 80 to 100 times in clear weather for celestial objects, which will show Jupiter's moons and belts, Saturn's ring, and other celestial phenomena. The tubes may be made either of tin plates, *papier maché*, or wood. Wood, however, is rather a clumsy article, and it is sometimes liable to warp, yet excellent tubes have sometimes been made of it. Perhaps the cheapest and most convenient of all tubes, when properly made, are those formed of paper. In forming these, a wooden roller of the proper diameter should be procured, and paper of a proper size, along with bookbinder's paste. About three or four layers only of the paper should be pasted at one time, and when sufficiently dry, it should be smoothed by rubbing it with a smooth stick or ruler; after which another series of layers should be pasted on, and allowed to dry as before, and so on until the tube has acquired a sufficient degree of strength and firmness. In this way I have, by means of a few old newspapers and similar materials, formed tubes as strong as if they had been made of wood. If several tubes be intended to slide into each other, the smallest tube should be made first, and it will serve as a roller for forming the tube into which it is to slide.

An achromatic object-glass of a shorter focal distance and a smaller diameter than any of those stated above, may be fitted up as a useful astronomical telescope when a better instrument cannot be procured. In the pawnbrokers' shops in London and other places, an old achromatic telescope, with an object-glass 20 inches focal distance and about 1½ inch diameter, may be purchased at a price varying from 15 to 20 shillings. By applying an astronomical eyepiece to such a lens, if a good one, it may bear a power for celestial objects of 50 or 60 times. If two plano-convex glasses three-fourths of an inch focal distance be placed with their convex sides near to each other, they will form an eyepiece which will produce a power on such an object-glass of above 50 times, which will show Jupiter's belts and satellites, Saturn's ring, the solar spots, and the mountains and cavities of the moon. I have an object-glass of this description which belonged to an old telescope, which cost me only 12 shillings, and with which I formerly made some useful astronomical observations. It was afterward used as the telescope of a small equatorial instrument, and with it I was enabled to perceive stars of the first and second magnitude, and the planets Venus, Jupiter, and Mars in *the day-time.*

But, should such a glass be still beyond the reach of the astronomical amateur, let him not altogether despair. He may purchase a single lens of three feet focal distance for about a couple of shillings, and by applying an eyeglass of one inch focus, which may be procured for a shilling, he will obtain a power of 36 times, which is a higher power than Galileo was able to apply to his best telescope; and consequently, with such an instrument, he will be enabled to perceive all the celestial objects which that celebrated astronomer first described, and which excited so much wonder at that period in the learned world; but, whatever kind of telescope may be used, it is essentially requisite that it be placed on a firm stand in all celestial observations; and any common mechanic can easily form such a stand at a trifling expense.

There is a certain optical illusion to which most persons are subject in the first use of telescopes, especially when applied to the celestial bodies, on which it may not be improper to make a remark. The illusion to which I allude is this, that they are apt to imagine the telescope does not magnify nearly so much as it really does; they are apt to complain of the small appearance which Jupiter and Saturn, for example, present when magnified 160 or 200 times. With such powers they are apt to imagine that these bodies do not appear so large as the moon to the naked eye; yet it can be proved that Jupiter, when nearest the earth, viewed with such a power, appears about five times the diameter of the full moon, and 25 times larger in surface. This appears from the following calculation: Jupiter, when in opposition, or nearest the Earth, presents a diameter of 47″; the mean apparent diameter of the moon is about 31′; multiply the diameter of Jupiter by the magnifying power, 200, the product is 9400″, or 156′, or 2° 36′, which, divided by 31′, the moon's diameter, produces a quotient of 5, showing that this planet with such a power appears five times larger in diameter than the full moon to the naked eye, and consequently 25 times larger in surface. Were a power of only 50 times applied to Jupiter when nearest the earth, that planet would appear somewhat larger than the full moon; for 47″ multiplied by 50 gives 2350″, or 39′, which is 8′ more than the diameter of the moon; yet with such a power most persons would imagine that the planet does not appear one-third of the size of the full moon.

The principal mode by which a person may be experimentally convinced of the fallacy to which I allude is the following: At a time when Jupiter happens to be within a few degrees of the moon, let the planet be viewed through the telescope with the one eye, and the magnified image of the planet be brought into contact with the moon as seen with the other eye, the one eye looking at the moon, and the other viewing the magnified image of Jupiter through the telescope when brought into apparent contact with the moon; then it will be perceived that with a magnifying power of 50 the image of Jupiter will completely cover the moon as seen by the naked eye; and with a power of 200—when the moon is made to appear in the center of the magnified image of the planet—it will be seen that Jupiter forms a large and broad circle around the moon, appearing at least five times greater than the diameter of the moon. This experiment may be varied as follows: Suppose a person to view the moon through a small telescope or opera-glass magnifying three times, he will be apt to imagine, at first sight, that she is not in the least magnified, but rather somewhat diminished; but let him bring the image as seen in the telescope in contact with the moon as seen with the naked eye, and he will plainly perceive the magnifying power by the size of the image. It may be difficult, in the first instance, to look at the same time at the magnified image and the real object, but a few trials will render it easy

THE

SOLAR SYSTEM:

WITH

MORAL AND RELIGIOUS REFLECTIONS,

IN REFERENCE TO

THE WONDERS THEREIN DISPLAYED.

PREFACE.

The following work is chiefly designed for juvenile readers, and for those who have hitherto acquired but a slender acquaintance with the general facts of astronomical science. With this view, the attention of the reader is, in the first place, directed to the general aspect and the apparent motions of the heavens, in order that he may be induced to contemplate, with his own eyes, the apparent movements of the celestial vault, in all its variety of aspects, as beheld in different countries and at different seasons of the year. Without such observations, the student of astronomy can never acquire a clear and accurate view of the economy of the solar system, and the phenomena it presents; and, therefore, such personal observations are particularly recommended to all the lovers of astronomical science.

This work is a different one from "Celestial Scenery," though in some points there must necessarily be a certain coincidence. The statements of the distances, magnitudes, and general appearances of the planets, must necessarily be the same in both; but the particular descriptions, remarks, and moral and religious reflections, are different. A great variety of subjects likewise is introduced, which are not noticed in "Celestial Scenery," such as the following:—the figure of the Earth—view of its surface, atmosphere, and the method of finding its dimensions—celestial phenomena arising from the annual motion of the earth—the *destination of the earth*, and the final cause of its creation—motions and aspects of the superior planets—general remarks on the solar system—method of acquiring an approximate idea of a million of units—the doctrine of *Eclipses*, with tables and descriptions of the most remarkable eclipses of the sun and moon—descriptions of the seasons of the year, and their characteristics in different countries—Reflections, moral and religious—history of astronomy—explanation of astronomical terms, &c. On these and various other topics, a considerable variety of interesting facts and sketches will be found more or less illustrated.

One great object, which the author has uniformly kept in view, has been to lead the minds of the young from the creature to the Creator, and to direct them to contemplate his attributes as displayed in the motions, magnitudes, and mechanism of the heavens, and to render their views of creation subservient to their moral and spiritual improvement, and to their preparation for a higher sphere of existence—an object which should always be kept in view in our contemplation of the works of God.

CONTENTS.

INTRODUCTION.

PAGE

OBJECT and sublimity of Astronomy. Appearance of the heavens to a common observer. Objects of this science lead to sublime and interesting trains of thought—its relation to religion. The Scriptures direct our attention to this subject. It is our duty to contemplate the works of God Plan of the following work........

CHAPTER I.

ON THE GENERAL ASPECT AND THE APPARENT MOTIONS OF THE HEAVENS.

Preliminary remarks........ 11

SECTION I.

ON THE APPARENT MOTIONS OF THE HEAVENS DURING THE DAY.

Apparent movements of the sun, as seen at different seasons, and as viewed from different regions of the globe. Sun's apparent annual motion—how observed. How the motions of the sun appear in Southern latitudes and at the Poles. Stars above the horizon during the day, and may sometimes be seen while the sun is shining........ 11

SECTION II.

ON THE APPARENT MOTION OF THE HEAVENS DURING THE NIGHT.

General appearance of the starry heavens—how their apparent motions may be perceived. Aspects of the stars in the southern and in the northern regions of the heavens. Positions of the Great Bear at different seasons. Caution to be observed in making observations. Position of the Pole and the Pole-star. Positions of certain stars and constellations in the beginning of January. Appearance of the stars at the Equator and at the North Pole...... 13

SECTION III.

CONCLUSIONS DEDUCED FROM THE PRECEDING FACTS AND OBSERVATIONS.

Earth appears sustained between two hemispheres of the heavens. Rapid and astonishing motions somewhere exist, either in the earth or in the heavens. Reflections on the power of the Deity........ 15

CHAPTER II.

ON THE FIGURE AND MOTION OF THE EARTH.

SECTION I.

ON THE FIGURE OF THE EARTH, AND THE ARGUMENTS WHICH PROVE THAT IT IS NEARLY IN THE SHAPE OF A GLOBE.

Preliminary remarks........ 16

Opinions formerly entertained on this subject. Four arguments, derived from different sources, particularly illustrated. Argument taken from an eclipse of the moon. Consequences which flow from the globular figure of the earth. It is the best adapted to a habitable world. Discovery of the true figure of the earth, an important fact in the history of Providence....... 17

SECTION II.

ON THE MOTIONS OF THE EARTH.

Motion actually exists. Rate of motion in the celestial bodies, were the earth at rest—rate of motion, if the earth move, illustrated by a figure—which of these motions is most probable and correspondent to the wisdom of the Almighty—a certain rate of motion would shatter the universe to atoms. No instance of a larger body revolving round a smaller. Arguments for the earth's motion derived from the wisdom of the Deity.......................... 19

SECTION III.

REFLECTIONS SUGGESTED BY THE MOTIONS OF THE EARTH AND HEAVENS.

At what rate we are carried through the regions of space during the hours of sleep, and from one season of the year to another. Rapid motions of the heavens. Original cause of all motion. Scene of wonders which such motions present. Practical instructions deducible from this subject.. 22

CHAPTER III.

DESCRIPTION OF THE SUN, OF THE INFERIOR PLANETS, AND OF THE EARTH AND MOON.

Introductory remarks.. 23

SECTION I.

THE SUN.

Its general appearance and effects in the visible creation. Its magnitude illustrated, compared with other magnitudes. Displays of the glory of the Creator. Nature and physical constitution of the sun. Description of the solar spots—delineation of some of them. Bright solar spots. Conclusions respecting the constitution of the sun. Beneficial effects produced by this luminary—displays the power and beneficence of the Creator—an emblem of the Sun of Righteousness. 23

SECTION II.

THE PLANET MERCURY.

Arrangement of the planets in the solar system. Amplitude of their orbits. Orbits of comets. Mercury—its distance, size, and the velocity of its motion—its motion and phases. Quantity of light on its surface—its temperature—orbit elliptical—transits of—is probably inhabited... 27

SECTION III.

ON THE PLANET VENUS.

Its distance, magnitude, motion, rotation, etc. Discoveries made on this planet by the telescope. Galileo and the Senators of Venice. Observations of Cassini. Schroeter's observations and discoveries. Mountains on Venus. Apparent motions of this planet—its superior and inferior conjunctions—description and delineation of its phases—periodical revolution—its transits, etc. Reflections on the morning star, as emblematical of intellectual light and joy......... 30

SECTION IV.

THE EARTH CONSIDERED AS A PLANETARY BODY.

(1.) *General View of the Earth's Surface, Atmosphere, Magnitude, and Method of finding its Dimensions.*

Earth a body which reflects light in common with the other planets—its appearance from the moon. Planets dark bodies in themselves. General aspect of the earth's surface—magnitude of its continents, seas, and oceans—its *atmosphere*, and the properties with which it is invested. *Dimensions* of the earth—how ascertained. Its *circumference*—mode of measuring it. Various measurements of a degree of the meridian.. 33

(2.) *Proofs of the annual Motion of the Earth.*

General considerations which render this motion highly probable. Demonstrative arguments. Arguments derived from the aberration of light. Importance of acquiring correct views on this subject in reference to our conceptions of the Divinity.. 36

(3.) *Phenomena arising from the annual Motion of the Earth.*

The sun will appear to move through the circuit of the heavens. Ecliptic explained. Apparent motion of the sun, as seen from other planets. Why we behold different clusters of stars at different seasons.. 37

(4.) *On the Destination of the Earth, or the final Cause of its Creation.*

Matter exists chiefly for the sake of sentient and intelligent beings. The Creator's design in the formation of man—arrangements made for his happiness—restriction in God's transaction

with him. Fall of man from his state of primitive integrity—the mercy of his Creator displayed. The promised Messiah, and preparations for his advent. Extraordinary events which accompanied the sacrifice he offered. Proclamation of pardon and eternal happiness to the inhabitants of the world. Reasons why this proclamation has been withheld from the majority of the nations. Prospect of the regeneration of the world. Importance of studying the material universe in connection with intellectual beings and moral truths. Population of the earth. Numbers passing daily into the invisible world. Population which the earth is capable of sustaining. Numbers of other living beings. Various other facts respecting the earth. 39

SECTION V.

ON THE MOON.

Motions of the moon—illustrated by a diagram. Phases and general appearances of this orb. Illustrations of its phases. How the earth appears as seen from the moon. Proofs that the earth shines upon the moon. Appearance of its continents and seas. Moon presents only one side to the earth. Earth appears in a fixed position as seen from the moon. Moon's distance, diameter, and other dimensions. *Telescopic appearances* of the moon—its circular plains—peculiarity of its mountain scenery—its depressions and cavities—its picturesque and sublime scenery—delineation of certain portions of its surface—various astronomical facts in relation to the moon—is probably inhabited—its beauty and utility in relation to our globe.... 41

CHAPTER IV.

DESCRIPTION OF THE SUPERIOR PLANETS OF THE SOLAR SYSTEM.

SECTION I.

ON THE MOTIONS AND ASPECTS OF THE SUPERIOR PLANETS.

Distinctions, in seven particulars, of the superior and inferior planets. Apparent motion of the superior planets as seen from the earth.......... 47

SECTION II.

ON THE PLANET MARS.

Remarks on its name, and on the atrocity of war—its distance—period of revolution—position in 1845 and 1847—its spots and rotation—inclination of axis—magnitude—telescopic appearance—atmosphere—polar spot—land and water—conclusions respecting its constitution..... 48

SECTION III.

ON THE NEW PLANETS.

Their situation in the system—history of their discovery—their magnitudes and distances—their singularities and anomalies—supposed to be the fragments of a larger planet. Reflections suggested by the state in which these planets now exist.......... 50

SECTION IV.

ON THE PLANET JUPITER.

Its distance—revolution—magnitude, compared with that of the earth—rotation—rate of motion—inclination of axis—direct and retrograde motions, etc.—present position—telescopic appearance—apparent magnitude with different powers. Its belts—their number and appearance Conjectures respecting their nature—improbability of their being produced by winds, etc.—different representations of them. Figure of this planet. Quantity of light—its mass, density, etc.......... 53

SECTION V.

ON THE SATELLITES OF JUPITER.

History of their discovery—form a system of revolving bodies, analogous to the solar system—their revolutions and eclipses—powers requisite for observing them—table of their magnitudes, periods, etc.—representation of their orbits—their utility in finding the longitude—motion of light—sublime phenomena they present to the inhabitants of Jupiter. Reflections on the sublimity and motion of this planet, and on the Omnipotence of the Deity.......... 55

SECTION VI.

ON THE PLANET SATURN.

Its distance and rotation—its motion and present position—telescopic appearance—its magnitude—belts—figure—quantity of light—its satellites, and by whom discovered. Cassini's telescopes—Herschel's. Powers requisite for observing these satellites. Their periods of revolution. Sublime phenomena they present in the firmament of Saturn.......... 57

SECTION VII.

ON THE RINGS OF SATURN.

History of their discovery, and conjectures formed respecting the phenomenon. Dimensions of the rings, according to Sir J. Herschel—their solidity and area—their appearance from the

different regions of the planet—four representations of them—their various aspects as viewed through telescopes at different periods—their occasional disappearance—some of the uses or designs for which they are intended. Supposed division of the outer ring. Reflections on their grandeur, and the power of God.......... 59

SECTION VIII.

ON THE PLANET URANUS.

Former and present supposed dimensions of the solar system. Herschel's telescopes and discoveries. Discovered Uranus—its size and distance—rate of motion—quantity of light and heat. Its satellites—their period and distance—direction of their motions.......... 62

SECTION IX.

GENERAL REMARKS ON THE SOLAR SYSTEM.

Whether other planets may exist within its range. Order and harmony which prevail in the system—unity and mutual relationship of the bodies which compose it. Unity of the Supreme Being. Illustrations of the distances and magnitudes of the planets. Summary view of the solar system.......... 63

METHOD OF ACQUIRING AN APPROXIMATE IDEA OF A MILLION OF UNITS. m

Difficulty of forming an accurate conception of such a number. Various illustrations. Method suggested by Mr. Martin of Chatham, illustrated by a figure. Incomprehensible nature of the universe, as to distances and magnitudes, etc.......... 65

CHAPTER V.

ON COMETS.

Meaning of the term. How comets are distinguished from planets—length of their tails, and opinions respecting them. Form of their orbits. Account of some remarkable comets. Comets of 1807 and 1811. Gambart's and Encke's comets. Numbers of comets. Opinions respecting them in former ages. Whether they may come in contact with the earth. Destination of comets.......... 66

CHAPTER VI.

ON THE ECLIPSES OF THE SUN AND MOON.

Opinions respecting eclipses in former times. Nature of an eclipse, and the different kinds of them. 69

SECTION I.

ON THE ECLIPSES OF THE MOON.

Cause of lunar eclipses. In what circumstances they happen. Figures representing the nature of lunar eclipses. Facts in relation to them. Their duration etc.......... 69

SECTION II.

ON THE ECLIPSES OF THE SUN.

Nature of a solar eclipse, and when it happens. Explanation of a diagram illustrative of solar eclipses. Various facts in relation to solar eclipses. Periods of eclipses. Darkness which accompanied our Saviour's Crucifixion must have been supernatural. Account of a total eclipse of the sun. Description of the phenomena which accompanied the total eclipse of 1724, as seen in England. Total eclipses which will happen in future years. Description of a total eclipse of the sun, at Vienna, in July, 1842. Table of solar eclipses during the present century. Utility of eclipses.......... 71

CHAPTER VII.

ON THE SEASONS, AND THE DIFFERENT LENGTHS OF DAYS AND NIGHTS.

Succession of day and night. Seasons in the frigid, temperate, and torrid zones. Characteristics of the different seasons. Description of spring—of summer—of autumn—of winter. Seasons produced by the operation of simple principles. Change of seasons illustrated by a diagram. General remarks. Why our weather is coldest when the sun is nearest us. Such seasons as we now enjoy are not the same as in the primeval state of man. Various moral reflections in relation to the seasons.......... 74

CHAPTER VIII.

REFLECTIONS, MORAL AND RELIGIOUS, IN REFERENCE TO THE SOLAR SYSTEM.

Astronomy presents to view objects calculated to excite solemn reflections, and to raise our views to the Great Creator. 1. The solar system exhibits a striking display of Almighty power. This power, thus displayed, lays a foundation for the hope and comfort of the Christian. 2. This system displays the wisdom and benevolence of the Creator. Various instances of wisdom and goodness. 3. The facts it exhibits have a tendency to moderate the pride of man, and to promote humility. The wisest and most exalted beings in the universe are characterized by humility. Scriptural declarations respecting it. 4. Astronomy affords a striking view of the condescension of God. 5. The studies connected with astronomy tend to prepare the renewed spirit for the employments of the future world. Moral and spiritual dispositions requisite. The first step to eternal felicity. The course to be prosecuted in order to be fitted for Heaven—the blessed effects of prosecuting this course.......... 79

APPENDIX.

I. New discoveries in the planetary system, 85.—II. Brief sketch of the history of astronomy, 88.—III. Explanation of astronomical terms, 90.—IV. The telescope, 93.

THE SOLAR SYSTEM.

INTRODUCTION.

Of all the sciences which are the subject of human study and investigation, Astronomy must be admitted to be the most interesting and sublime. It teaches us the motions, the magnitudes and distances of the heavenly bodies—their diversified phenomena, the laws by which they are directed in their varied movements, and the grand designs they are intended to fulfill in the vast system of the universe.

The objects with which this science is conversant are so grand and marvelous — surpassing everything that could have been imagined in the infancy of science—that they tend to enlarge the field of human contemplation, to expand to an indefinite extent the conceptions of the human intellect, and to arouse the attention and excite the admiration even of the most incurious and uncultivated minds. The vast magnitude of the heavenly bodies, so far surpassing what could be conceived by their appearance to the unassisted eye ; their incalculable numbers ; the immense velocity of their motions, and the astonishing forces with which they are impelled in their career through the heavens; the attractive influence they exert upon each other, at the distance of hundreds of millions of miles; and the important ends they are destined to accomplish in the universal empire of Jehovah; present to the human imagination a scene, and a subject of contemplation, on which the soul of man might expatiate with increasing wonder and delight, during an indefinite series of ages.

Even to a common observer, the heavens present a sublime and elevating spectacle. He beholds an immense concave hemisphere of unknown dimensions, surrounding the earth in every region, and resting as it were upon the circle of the horizon. From every quarter of this vast expanse—when the shades of night have spread over the earth — he beholds numerous lights displayed, proceeding onward in solemn silence, varying their aspects at different seasons, moving with different degrees of velocity, shining with different degrees of splendor, and all calculated to inspire admiration and awe. Wherever he travels abroad, either on the surface of the land or of the ocean, this celestial vault still appears encompassing this lower world; and, after traveling thousands of miles, it appears still the same, and seems to make no nearer an approach than when the journey commenced. While contemplating this wonderful expanse with the eye of reason and imagination, the mind is naturally led into a boundless train of speculations and inquiries. Where do these mighty heavens begin, and where do they end? Can imagination fathom their depth, or human calculations, or figures, express their extent? Have the highest created beings ever winged their flight across the boundaries of the firmament? Can angels measure the dimensions of those heavens, or explore them throughout all their departments? Is there a boundary to creation beyond which the energies of Omnipotence are unknown, or does it extend throughout the infinity of space ? Is the immense fabric of the universe yet completed, or is Almighty Power still operating throughout the boundless dimensions of space, and new creations still starting into existence?

Such views and inquiries have a tendency to lead the mind to sublime and interesting trains of thought and reflection, and to afford scope for the noblest energies and investigations of the human intellect. A serious contemplation of the heavens opens to the mental eye a glimpse of orbs of inconceivable magnitude and grandeur, and arranged in multitudes which no man can number, which have diffused their radiance on our world during hundreds of generations. It opens a vista which carries our views into the regions of infinity, and exhibits a sensible display of the immensity of space, and of the boundless operations of Omnipotence: it demonstrates the existence of an eternal and incomprehensible Divinity, who presides in all the grandeur of his attributes over an unlimited empire. Amidst the silence and the solitude of the midnight scene, it inspires the soul with a solemn awe, and with reverential emotions ; it excites astonishment, admiration, and wonder, and has a tendency to enkindle the fire of devotion, and to raise the affections to that ineffable Being who presides in high authority over all the movements of the universe. It teaches us the littleness of man, the folly of pride and ambition, and of all that earthly pomp and splendor with which mortals are so enamored —and that our thoughts and affections ought to soar above all the sinful pursuits, and transitory enjoyments, of this sublunary scene.

Such being the views and the tendencies of this science, it ought to be considered as bearing an intimate relation to religion, and worthy the study of every enlightened Christian. It has been said, and justly, by a celebrated poet, that "An undevout astronomer is mad." The evidence of a self-existent and eternal Being, whose wisdom is inscrutable, and whose power is uncontrollable, is so palpably manifested in the arrangement and the motions of the celestial orbs, that it cannot but make an indelible impression on every rational and reflecting mind. Though the heavenly bodies have "no speech nor language," though they move round the earth in silent grandeur, and "their voice is not heard" in articulate sounds, yet "their line is gone throughout all the earth, and their words to the end of the world"—proclaiming to every attentive spectator, that "The hand that made them is Divine" So that there is scarcely a tribe or nation on the face of the earth, so inattentive and barbarous as not to have deduced this conclusion from a survey of the movements of the celestial orbs. "Men," says Plato, "began to acknowledge a Deity, when they saw the stars maintain so great a harmony, and the days and nights throughout all the year, both in summer and winter, to observe their stated risings and settings." Another heathen philosopher, Cicero, thus expresses his sentiments on this point: "What can be so plain and clear as, when we behold the heavens, and view the celestial bodies, that we should conclude there is some Deity of a most excellent mind by whom these things are governed—a present and Almighty God. Which, he that doubts of, I do not understand why he should not as well doubt whether there be a sun that shines, and enlightens the world."

The sacred Scriptures, in numerous instances, direct our attention to this subject. "The heavens," says the Psalmist, "declare the glory of God;" that is, they manifest his wisdom and power, and beneficence to the inhabitants of the world;—"the firmament showeth forth," or publicly declareth, "his handiwork." "Day unto day uttereth speech, and night unto night showeth knowledge. There is no speech nor language where their voice is not heard." In reference to that department of creation which astronomy explores, it may be said with peculiar propriety, in the language of Scripture, "The works of the Lord are great, sought out of all them that have pleasure therein." Throughout the volume of inspiration, our attention is frequently directed to the contemplation of the heavens: "Lift up thine eyes on high, and behold who hath created these things.—The everlasting God, the Lord, the Creator of the ends of the earth, who fainteth not, neither is weary; there is no searching of his understanding.—He bringeth out their host by number, and calleth them all by names: by the greatness of his might, for that he is strong in power; not one faileth.—It is he that sitteth upon the circle of the earth, and the inhabitants thereof are as grasshoppers.—All nations before him are as nothing; and they are counted to him less than nothing, and vanity."—"Hearken unto this, O Job: stand still, and consider the wondrous works of God."

Hence it appears, that it is not to be considered merely as a matter of taste, or as a rational amusement, but as an imperative duty, to contemplate the works of the Most High, and especially the manifestations of his power and Godhead which the heavens display—that we may derive more enlarged conceptions of his glorious attributes, and be enabled to render to him that tribute of adoration and praise which is due to his name. For it is represented as one of the characteristics of the ungodly, that while "the harp, and the viol, and the tabret, and pipe, and wine are in their feasts,—they regard not the work of the Lord, neither consider the operation of his hands;" and consequently "he will destroy them, and not build them up." It is therefore the incumbent duty of the young; of every professing Christian; and of every rational inquirer, not only to study the facts, doctrines, and duties exhibited in the system of Divine revelation, but also to contemplate the manifestations of the Creator as exhibited in the system of creation. They are both revelations of the same almighty and beneficent Being—emanations from the same adorable Divinity; and the views and instructions they respectively unfold, when studied with reverence and intelligence, are in perfect harmony with each other. The study of both combined, is calculated to make the man of God perfect, and "thoroughly furnished unto all good works."

In the following small volume, it shall be our endeavor to direct the general reader in the study of some of those objects which the heavens unfold; and we shall chiefly select those parts of astronomical science which are most level to the comprehension of those who have had little opportunity of engaging in scientific pursuits. In the present volume, it is proposed to confine ourselves chiefly to a description of the Solar System, and the phenomena it exhibits, together with a few instructions as to the best mode of contemplating the apparent motions and the diversified aspects of the firmament. The discoveries which relate to the sidereal heavens—the general arrangement of the fixed stars, their distances and magnitudes—the facts which have been discovered respecting new stars—variable stars—double and triple stars—the Milky Way—the different orders of the nebulæ—and a variety of other topics connected with such objects, will form materials for another volume similar to the present.

In the meantime we may just remark, that all the wonders we behold, both in the heavens above, and in the earth below, demand our serious attention and devout contemplation. They are all the workmanship of that great and adorable Being in whom "we live and move;" who at first "spake, and it was done;" who gave the command, and the whole of this stately fabric of heaven and earth started into being. It is the same God who created the planets and the host of stars, and that conducts them in all their rapid motions; who is also "the God and Father of our Lord Jesus Christ," and "the Author of eternal salvation" to all who obey him. All these works display his infinite power, his unerring wisdom, and the riches of his beneficence; and demand from every beholder that tribute of praise, reverence, and adoration which is due to Him "who created all things, and for whose pleasure they are and were created."

CHAPTER I.

ON THE GENERAL ASPECT, AND THE APPARENT MOTIONS OF THE HEAVENS.

Previous to entering on the study of astronomical science, and the phenomena of the solar system, it is requisite that the young inquirer should be directed to contemplate the general aspect of the heavens, and the apparent motions of the different bodies which present themselves to view in the regions of the firmament. No one can enter with intelligence on the study of astronomy, or acquire an accurate idea of its elementary principles, and of the arrangement and motions of the planetary bodies, unless he has been led to observe, with his own eyes, the apparent and more obvious phenomena and aspects of the celestial orbs, as they present themselves to the view of any common and attentive spectator. For although the real motions of the heavenly bodies are, in many instances, very different from their apparent movements, and although many of them appear to move while they are absolutely at rest, yet it is necessary that their apparent motions and appearances should be accurately inspected, in order that, in the progress of investigation, we may be enabled to determine what bodies are really in motion, and what only appear to be in motion, in consequence of the motions of other bodies. In order to direct the untutored observer on this point, the following observations are stated.

SECTION I.

ON THE APPARENT MOTIONS OF THE HEAVENS DURING THE DAY.

In the first place, let us consider the appearance of the heavens as seen in the day-time. Sometimes it happens for days, and even for weeks together, that the sky is overcast with an assemblage of sable clouds covering the whole face of the firmament. In which case no celestial orb makes its appearance; but the light transmitted through the clouds and reflected from their under surfaces, indicates that some luminous orb, the fountain of light, is above our horizon, and far beyond the upper region of the clouds, though its form and splendor cannot be perceived. At other times the concave of the sky appears of an azure color, where scarcely a speck of cloud is to be seen—like a boundless desert, where no celestial orb makes its appearance—as at the dawning of the morning, when the aurora makes its appearance in the east. This faint light gradually increases, rising higher and higher in its brightness, a prelude of something still more grand and refulgent. The clouds near the horizon are tinged with purple and vermilion, and the mountain tops are clothed with brightness. At length, the disc of the sun disengages itself from the horizon by degrees, until the whole of his orb appears to view, and ascends the heavens with majestic grandeur. The sun is the only object which, during the day, appears conspicuous to the naked eye; for although the moon is frequently visible in the day-time, yet she then appears with no greater brilliancy than a small cloud of the same size, and is scarcely noticed by a common observer.

The apparent movements of the SUN appear very different at different seasons of the year, and in different regions of the globe. In describing these apparent motions, we shall suppose ourselves, in the first instance, in the latitude of fifty-two degrees north, which is nearly the latitude of London and several other large towns in England. The sun's apparent motions in this latitude will be nearly the same as when he is viewed from Holland, Denmark, Scotland, Nova Scotia, Canada, and the northern states of America. Suppose we begin our observations in winter, about the 21st December, when the days in our northern hemisphere are shortest. In this case, turning our eyes to the south-east quarter of the sky, a little after eight o'clock in the morning, we shall see the sun rising nearly on the south-eastern point of the compass, and gradually ascending the celestial vault. In about four hours, he comes to the meridian, or due south, the highest point of his elevation at that season; after which he gradually descends toward the west, and sets in the south-western part of the heavens, about four in the afternoon, having described a comparatively small arc of a circle above the horizon. At this time, when he arrives at the meridian, or the highest point of his diurnal course, he is only about fourteen degrees above the horizon.* If, after this period, the point at which the sun rises be observed, it will be found a little to the northward every day, from the point at which he rose before. On the 21st of March, the sun rises due east, about forty-five degrees to the north of the point at which he rose on the 21st of December. The time of his rising is exactly six in the morning; six hours afterward, he passes the meridian, at an elevation of thirty-eight degrees; and sets due west, at six o'clock in the evening. At this time, the day and the night are of an equal length, namely, twelve hours each.

If again we view the rising sun on the 21st of June, we shall find that he rises near the north-east, forty-five degrees farther to the northward than on the 21st of March. At this period, the sun describes a large circuit around the heavens; rising fifteen minutes before four in the morning, and advancing to an elevation of more than sixty degrees at noon-day; after which he declines toward the west and sets near the north-west quarter of the heavens, about a quarter past eight in the evening The length of the day, at this time, is about sixteen and a half hours; and as his course during the night is not far below the horizon, there is no absolute darkness during the absence of the sun; and his course may be traced by observing the motion of the twilight, or the aurora, gradually proceeding to the northern point of the heavens, and from that point to the north-east, where the solar orb again emerges from the horizon. After this period, the sun begins, every succeeding day, to rise in points nearer the south, and to take less extensive circuits round the heavens, until the 23d of September, when he again rises on the eastern point of the horizon, and sets in the west, which is the time of the autumnal equinox, when day and night are equal. From this period the sun gradually verges to points of the horizon south of the east, at the time of his rising, and the days rapidly shorten, until he again arrives near the south-eastern quarter of the heavens, where he is seen to rise on the 21st of December. Such are some of the apparent motions of the sun, in our quarter of the globe, throughout the different seasons of the year; and every one who resides in the country has an opportunity, every clear day, of observing these diversified movements.

---

* The circumference of the heavens, as well as that of the earth, is divided by astronomers into three hundred and sixty parts called degrees; consequently, the distance from the horizon to the zenith, or the point directly above our heads, is ninety degrees, or the one-fourth of the circumference of a circle. When, therefore, the sun is said to be elevated above the horizon fourteen degrees, it means, that he has risen to an altitude little more than the one-sixth part of the distance from the horizon to the zenith. The apparent breadth of the sun or moon is a very little more than half a degree.

Beside the motions to which we have now adverted, there is another apparent motion of the sun, in a contrary direction, which is seldom noticed by a common observer. Every day the sun has an apparent motion from west to east, at the rate of nearly a degree each day; and in the course of a year, or 365 days, 5h. 48m., and 51s., he makes a complete circuit around the heavens. This motion manifests itself chiefly by the appearance of the heavens during the night. If, in the morning, some time before sunrise, we view those stars which are near the point of the horizon where the sun rises, in a week or two, we shall find that the same stars are more elevated near the time of sun-rising than before, and farther distant from him, indicating that he is moving through the heavens toward the east, and leaving these stars as it were behind him. If, again, in the evening, we mark those stars which are a little above the point of the setting sun, we shall find that every evening they make a nearer approach to the place where the sun goes down; until, after a short period, they approach so near this luminary as to be overpowered with his rays, and can no longer be seen, still indicating that the sun is approaching toward the east.

Perhaps the best way of tracing this is to mark the different positions of the Pleiades, or seven stars, with respect to the sun. About the middle of January, at eight o'clock in the evening, the seven stars are seen nearly on the meridian, which observation should be noted down for the purpose of being compared with future observations. On the 1st of March, at the same hour, these stars will be seen nearly halfway between the meridian and the western horizon, while all the other stars, at the same elevation, will be found to have made a similar progress. About the 15th of April, they will be seen, at the same hour, very near the north-western horizon; and every day after this, they will appear to make a nearer approach to that part of the heavens in which the sun appears, until, being overpowered by the splendor of his rays, they cease to be visible. From these and similar observations, it will be easily perceived that the sun has an apparent motion through the circle of the heavens, and that the revolution is completed in the course of a year. The circle which the sun thus describes is called the ECLIPTIC, and is divided into twelve signs, and three hundred and sixty degrees.

The apparent motions of the sun appear somewhat different, when viewed from different regions of the earth. Were we placed in countries under the equator, such as at Borneo, Sumatra, the Gallipago isles, Quito, and other parts of South America, the sun at noon would shine directly from the zenith, at the time of the equinoxes, at which time objects would have no shadows. At all other times the sun will appear either in the northern or the southern quarter of the heavens. During the one half of the year, he shines from the north, and the shadows of objects fall to the south: during the other half, he shines from the south, and the shadows of objects are projected to the north; a circumstance which can never occur in our country, or in any part of the temperate zones. At the equator, too, there is a perpetual equality of days and nights throughout the year; the twilight is shortest, and the darkness of night rapidly succeeds the setting of the sun

Were we placed in southern latitudes—for example, at the Cape of Good Hope, New South Wales, or Buenos Ayres, in South America—instead of beholding the sun moving along the southern part of the heavens, from the left hand to the right, as in our country, we should see him directing his course along the northern part of the sky, from the right hand to the left. In other respects, his apparent motions would nearly resemble those already described, excepting that when the sun is highest at mid-day to us, he appears lowest to the inhabitants of these countries; their winter happening at the time of our summer. Were we placed in Lapland, Greenland, or other countries within the polar circle, the sun, in winter, would be absent for weeks and even for months together; and in summer he would shine without intermission for a corresponding portion of time; appearing every day to make a complete circle round the heavens, but never descending below the horizon during the lapse of six weeks or even three or four months. Could we suppose ourselves placed at the north pole, the motion of the sun would present a different aspect from any of those now described. On the 21st of March, we should see a portion of the sun's disc appear in the horizon after a long night of six months. This portion of the sun would appear to move quite round the horizon every twenty-four hours; it would gradually rise higher and higher until the whole orb of the sun made its appearance. As the season advanced the sun would appear to rise higher and higher, until on the 21st of June, he attained the altitude of twenty-three and a half degrees above the horizon; after which his altitude would gradually decline until the 23d of September, when he would again appear in the horizon. During the whole of this period of six months, there is perpetual day; the stars are never seen, and the sun appears to go quite round the heavens every twenty-four hours without setting, in circles nearly parallel with the horizon.

Such are some of the motions and aspects of the sun, as viewed at different seasons of the year, and from different parts of the earth. Let it be carefully remembered that these motions are not real, but only apparent. While presenting all these diversified aspects and movements to spectators placed in different positions, it can be proved that the sun is, notwithstanding, a quiescent body in the center of the planetary system. By the rotation of the earth round its axis from west to east every twenty-four hours, and by its revolution round the sun every year, all the apparent motions we have hitherto described are produced, and completely accounted for, as we shall afterward show, when we come to illustrate the evidences which prove that the earth on which we dwell is a moving body.

When we view the sun pursuing his course through the heavens in a clear and serene sky, we are apt to imagine that there are no other celestial bodies diffusing their rays above our horizon. This, however, is far from being the case. In the full blaze of day, there are as many stars, at an average, around us in the firmament, as are beheld in a clear sky at the hour of midnight; but their light is overpowered by the more brilliant splendor of the sun. By means of equatorial telescopes, which can be made to point to any particular part of the heavens, all the larger stars of the firmament may be seen even at noonday, while the sun is shining in all his splendor; nay, there is scarcely a star visible to the naked eye, during night, but may be seen in this way during the blaze of day, and its exact position in the heavens pointed out. During a total eclipse of the sun, when the moon interposes her dark body between us and the sun, some of the planets and the larger stars have appeared as distinctly as at midnight; but the moment the moon has passed a little over the disc of the sun, and a glimpse of his beams has shone out, their feeble light becomes undistinguishable, and they are no longer perceived. Sometimes, too, it happens that stars have been seen from the bottom of deep wells and mines, when large ones happen to pass near the zenith during the day, and the planet Venus, when brightest, has frequently been seen with the naked eye, in the day-time when at no great distance from the sun. Thus it appears that the sun passes through the heavens every day with stars all around him, although invisible to the unassisted eye—just as the moon, during night, is seen surrounded with stars, which the faintness of her light is not sufficient to overpower.* Hence it happens that astronomers can trace the exact path of the sun among the stars every day, during his apparent annual circuit round the heavens. They can tell what stars are near and around the sun; what clusters he is leaving behind him, to what other clusters he is approaching; what stars or planets are near his margin, and what stars are behind his luminous globe, with as much accuracy as if they were all visible to the naked eye, as at midnight.

SECTION II.

ON THE APPARENT MOTIONS OF THE HEAVENS DURING NIGHT.

WHEN a careless observer, on a clear evening, gazes upon the firmament, he beholds a number of shining points, some of them far more brilliant than others, dispersed throughout every region of the sky; but he cannot tell whether they appear to move or to remain in a fixed position; whether they shift their positions with respect to each other; whether they rise and set; whether all the stars visible at six o'clock in the evening are also seen at midnight, or whether the same clusters are to be seen in summer as in winter There are thousands and millions of mankind who have occasionally gazed on the starry vault who could give no reply to such interrogations. Such is the apathy with which the most wonderful works of God are viewed by the great bulk of mankind; although only a few days or hours of serious observation would be sufficient to solve some of the questions to which we allude.

In order to illustrate the apparent motions of the heavens, let us suppose ourselves placed in a situation which commands an extensive view of the sky, about the beginning of January, at eight o'clock in the evening. At this period, on a serene evening, when the sky is destitute of clouds, a sublime and beautiful spectacle presents itself to view, as some of the most brilliant constellations are then above the horizon. We behold a vast hemisphere expanding over our heads, whose center we seem to occupy, and which appears to rest upon our horizon. Above and around us, on every hand, a multitude of brilliant orbs, of various degrees of splendor, display their radiance. But whether they are in motion or at rest, does not appear at the first glance. We must make different observations, and wait for some time until their motion, or rest, be discovered. To ascertain this point, let us fix on a particular star, or a cluster of stars, and bring it in contact with a church spire, a chimney top, the twig of a tree, or any elevated object, and our line of vision, and in a short time we shall find it has moved onward to the west, while we have remained stationary in our position. Or, if we direct a common telescope to any star, and fix the instrument in one position, in a few minutes the star will have passed from the field of view to the westward. If we look at a star near the horizon in the west, in a few minutes it will sink beyond the limits of our view, and disappear. If we mark any particular star just risen above the eastern horizon, in an hour or two it will be seen considerably elevated above its former position, and every minute rising higher and higher. If we look at any bright star rising due east about six o'clock in the evening, at twelve, midnight, it will be on the meridian, or due south, at an elevation of thirty-eight degrees, and at six o'clock next morning, it will be seen setting at the western point of the horizon. In like manner, any other star rising toward the east, north-east, or south-east, if carefully observed, will be found to rise gradually until it come to the meridian, and then decline in a western direction, until it set either in the west, north-west, or south-west. If it rise in the north-east, it will set in the north-west, and if it rise in the south-east it will set in the south-west; in the former case describing a larger, and in the latter, a lesser portion of a circle, in the sphere of the heavens.

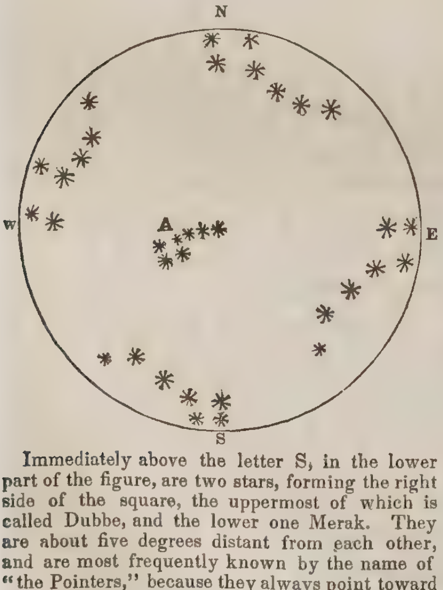
The following are some varieties which may be observed in the apparent motions of the stars. If you look toward the south, you will observe some stars just appearing above the horizon, grazing this circle, as it were; but not rising above it, and then vanishing. If you observe a group a little to the east of the south, you will find them rising above the horizon, making a small arch, and then going down a little to the west of the meridian. If you mark another group rising much farther to the east, you will find these describing a much larger arch, and taking a much longer time before they go down to the westward of the meridian. If you now turn your face to the northern part of the sky, you will find some stars that just skim the horizon, at certain times, near the north point, and then gradually mount up to the top of heaven, until they come nearly over head, and then descend, and again nearly touch the northern horizon; and ascend again without ever disappearing, describing a complete circle above the horizon. Such are the bright stars Vega, Capella, and several others. Other stars that are higher than these, when seen near the northern horizon, likewise describe complete circles in the sky, without approaching the horizon; and these circles gradually diminish, until at last you arrive at a star which seems scarcely to move from the point where it is stationed—all the rest seeming to circulate around it as a center. This is called the Pole Star, which, to a common observer, never seems to vary its position; and, in the latitude we have supposed, is elevated more than fifty degrees above the northern horizon. The time occupied by the stars now alluded to, in completing their circles, is about twenty-four hours, or, more accurately, is twenty-three hours, fifty-six minutes, and four seconds, and they all finish their revolutions in exactly the same period of time.

---

* The author has frequently seen, by the equatorial telescope, in the day-time, not only numerous stars of the first, second, and third magnitudes, in regions of the firmament at a distance from the sun, but has perceived the planet Venus, when immersed in the sun's effulgence, and when it was within a degree of the margin of that luminary.

For the illustration of what has been now stated, let us suppose ourselves to be viewing the northern quarter of the heavens, about the beginning of November, at eight o'clock in the evening. At this time, the Great Bear, or *Ursa Major*, will appear near the lowest part of its course, not far from the northern part of the horizon. I refer to this constellation, because it is generally known, even to common observers, and is sometimes distinguished by the names of "the Plough," and of "Charles's Wain." That part of the constellation which is generally recognized, consists of seven bright stars, of which the four toward the right form a kind of irregular square, and the three stars stretching out from it to the left form a kind of irregular curve. In the following figure (fig. 1), this constellation is represented in four positions.

Fig. 1.



Immediately above the letter S, in the lower part of the figure, are two stars, forming the right side of the square, the uppermost of which is called Dubbe, and the lower one Merak. They are about five degrees distant from each other, and are most frequently known by the name of "the Pointers," because they always point toward the pole-star. The pole-star is represented in the central part of the figure; it is about twenty-nine degrees—or nearly six times the distance of the two pointers—from Dubbe, and in whatever position this constellation may happen to be, these two stars always point to the pole-star, which is the first bright star in a line with the pointers, at the proportional distance exhibited in the engraving; and by attending to this circumstance, the pole-star may at all times be distinguished. Such is the position of this constellation at eight o'clock in the evening of the 1st of November. If now we view this constellation, about eleven o'clock the same evening, or a few evenings afterward, we shall find that it has moved considerably toward the east, and to a higher elevation; and at two o'clock the next morning, it will be seen in the position represented at E, with the pointers still directed to the pole-star. At eight o'clock in the morning, it will be seen at N, when it will appear in the zenith, with the pointers pointing downward toward the pole. At two o'clock in the afternoon, if it could then be seen, it will appear as represented at W, to the west of the pole, and the pointers pointing eastward to the polar star; and again, about eight in the evening it will return nearly to its former position at S.

Again, this constellation appears in different positions, at the same hour, at different seasons of the year. We have seen that, in the beginning of November, at eight o'clock in the evening, it appears as represented at S; in the beginning of February, at the same hour, it will appear as represented at E; in the beginning of May, as exhibited at N; and in the beginning of August, at the same hour, as represented at W.

In order that none of my readers may fall into any mistakes, from what has been now stated, I may be permitted to mention the following anecdote:—A few years ago, I pointed out in the heavens, to a lady of my acquaintance, the constellation of the Great Bear, and showed her how she might mark its positions at different times, and its apparent revolution round the pole-star. About a year afterward, she told me she had carefully made the observations to which I had directed her, and found them to correspond to what I had stated. She appeared, however, to have paid no attention to any other stars, but those of the Great Bear; and on putting several questions to her on the subject, I found that she conceived of the motion of the Great Bear as if it had been a huge monster pursuing its way through the midst of the surrounding stars, as if they had all been at rest, without apparently shifting their position—somewhat like a huge animal pursuing its way through a crowd, whilst every individual of the crowd remained nearly in the same position. Now, that my readers may not fall into the same mistake, let it be carefully remembered that all the stars in the neighborhood of the pole have the same apparent motions and revolutions as the Great Bear, all moving in concert, but some of them describing larger, and others smaller circles, around the polar point, and all completing their revolution in the same time, namely, in twenty four hours.

Having represented the pole-star in the center of the engraving, to prevent mistakes, it may be proper to mention, that this star, although, to a common observer, it appears in a fixed position, is not exactly in the polar point: it is at present one degree and thirty-two minutes from the north pole of the heavens, and revolves around it every day in a circle of about three degrees in diameter. This motion may be perceived by placing a telescope in a fixed position, and directing it to this star, when we shall find that, after an hour or two, it will have moved out of the field of view

There is no star exactly at the polar point, and this is called the polar star, because it is the nearest bright star to the north pole of the heavens. It forms the tip of the tail, or the extremity, of *Ursa Minor*, or the Lesser Bear, which likewise consists of seven stars, arranged very nearly in the shape of the Greater Bear, but in a reverse order. This constellation, which is much nearer the pole than *Ursa Major*, may be seen revolving around it, in the same manner as we have described above, but the stars of which it is composed are much smaller, and not so easily distinguished as those of *Ursa Major*. When the Great Bear is at its lowest position, as at S (fig. 1), the square of the Lesser Bear is considerably to the westward, and the four stars, of which it is composed, are directly above the tail of the Great Bear, at the distance of about twenty degrees, as at A.

Let us now suppose ourselves contemplating the southern, eastern, and western parts of the heavens, about the beginning of January, at nine o'clock in the evening. At this time we shall see the seven stars, a very little to the west of the meridian, and at a very high elevation. Next to this cluster, on the east, but a little lower, is *Aldebaran*, or the Bull's Eye, a ruddy star of the first magnitude, in the constellation of Taurus. South by east of Aldebaran, and considerably below it, is the splendid constellation of Orion, distinguished by four bright stars forming an irregular square, or parallelogram, in the middle of which are three bright stars in a straight line, at equal distances from each other. This is one of the most splendid constellations in the heavens, and is distinguished by almost every common observer by the three stars now mentioned, which form the belt of Orion, or what Job calls "the bands of Orion," and are sometimes known by the names of "the three Kings," "the Yard," and "the Lady's Elwand." South-east from Orion, at a low elevation, is the star Sirius, belonging to *Canis Major*, or the Great Dog, which is considered the most brilliant fixed star in the heavens. North-east from Sirius, at a higher elevation, is Procyon, a bright star in *Canis Minor* or the Little Dog. North from Procyon, at a much higher altitude, are the bright stars Castor and Pollux, belonging to the constellation Gemini. If, then, three hours after having made these observations, or about midnight, we view the face of the heavens, we shall find a considerable alteration in the positions of the stars and constellations to which we have referred. The seven stars will then be found to have moved halfway between the meridian and the western horizon, followed by Aldebaran, which is then a considerable distance past the meridian to the westward. The constellation Orion is likewise westward of the meridian, and the bright star Sirius, which was formerly in the south-east, is now nearly due south. Procyon, and Castor and Pollux, which, at nine o'clock, were a great way toward the east, are, at midnight, not far from the meridian, and at a much higher elevation. All which circumstances show that the various clusters of stars, in the eastern, southern, and western portions of the heavens, have a regular and uniform apparent motion from east to west.

Such are some of the general appearances of the heavens, as viewed in our northern latitude; but, in several other quarters of the globe, their aspects will appear somewhat different. Were we placed under the equator, in the island of Sumatra, or about Quito, in South America, we should behold all the stars in the firmament proceeding in their courses from east to west. All the stars would appear to rise and set, and none of them would describe circles above the horizon, as some of them appear to do in our northern region. The north pole, which in our latitude, is at a high elevation, would appear in the northern point of the horizon, and the south pole would, at the same time, be visible in the opposite quarter of the heavens. In our latitude, we cannot perceive above two-thirds of the stars which may be seen in the firmament; but, at the equator, all the visible stars of heaven may be perceived During the space of twenty-four hours they all pass along above the horizon. The one-half of them, indeed, cannot be seen on account of the light of day, but, in the course of a year, they are all visible. Were we placed in Van Dieman's Land, or at the Cape of Good Hope, we should behold multitudes of stars which are never visible in our latitude, and the constellations of the Great and Little Bears, Cassiopeia, and other clusters, would be no longer visible. Could we take our station at the north pole of the earth, the stars would appear neither to rise or set, nor yet to stand still. All the stars visible from this point would appear to move round the heavens above the horizon, in parallel circles, every twenty-four hours; and all that could ever be seen in such a situation might be perceived every hour and minute, in a clear sky, when the sun is absent. But, from this point, only one-half of the firmament is visible, and none of the stars belonging to the other half ever rise above the horizon.

SECTION III.

CONCLUSIONS DEDUCED FROM THE PRECEDING FACTS AND OBSERVATIONS.

An intelligent spectator, after having observed the various aspects of the heavens above described, will naturally inquire—Whence come those stars which are seen gradually emerging from the eastern horizon? Whither have those stars gone which have sunk beneath the western horizon? And what becomes of those stars during the light of day, which shine with so much splendor during the shades of night? A little reflection on the subject will soon suggest, that the stars which are seen rising above the eastern horizon, come from another hemisphere of the heavens, which is invisible from the point on which we stand, and which we are apt to imagine is below the hemisphere which we behold above us; and when they set in the west, return to that hemisphere again; and that the reason why the stars are not visible during the day, is because their light is overpowered by the more vivid splendor of the sun. We are also naturally led to conclude, from such appearances, that the world in which we dwell is suspended in empty space, and is surrounded on all sides, above and below, by the expanse of the firmament, in which the sun, moon, planets, and stars appear to perform their diversified motions and revolutions. Another conclusion which may be deduced from the preceding observations, is, that the whole sphere of the heavens performs an apparent revolution round our world; carrying, as it were, all the stars along with it in the space of twenty-four hours. Whether this motion be real, or only apparent, requires to be determined by certain rational considerations, and from the harmony and order which appear to be characteristic of the works of the Creator; to which subject we shall particularly direct our attention in the following chapter

In the meantime, we may remark, that such general views of the motions of the starry firmament as we have already taken, have a tendency to expand the intellectual faculties, and to elevate the mind to the contemplation of some Great Invisible Power, by which such mighty movements are conducted. When we behold the vast concave of the sky, with all its radiant orbs, moving in majestic grandeur around our globe, an idea of sublimity and almighty energy irresistibly forces itself upon the mind, which throws completely into the shade the mightiest efforts of human power,—so that the most stupendous machines ever constructed by human art can afford no assistance in forming a conception of that incomprehensible Power, which sustains and carries forward in their course thousands of spacious worlds. The shining orbs which the firmament displays are evidently placed at an immense distance from the earth, and consequently are bodies of an immense size; and if the apparent motions to which we have adverted were real, the swiftness with which they would fly through the regions of space would exceed all human calculation and conception. But whether these motions be real or apparent, we find motions actually existing among the orbs of heaven which astonish and overpower every rational and contemplative mind. The very circumstance, that motions so sublime appear in the expanse of the firmament, is a demonstrative proof that motions of a wonderful and incomprehensible nature exist somewhere; and the ideas of majesty, of grandeur, and of omnipotent energy, which this single circumstance is calculated to inspire, are such as irresistibly to lead the mind to the contemplation of a Being whose perfections are incomprehensible, and whose "ways are past finding out."

It does not require a scientific knowledge of astronomy in order that the mind may be impressed with sentiments of admiration at the movements which appear throughout the universe. For the works of God, when contemplated in any point of view, or on any theory, or hypothesis we may form, appear, like himself wonderful, magnificent, and incomprehensible. The motions to which we have chiefly alluded, are either in the earth or in the heavens. If these motions really exist in the heavens, the mind is overpowered with astonishment at the idea of thousands and tens of thousands of vast globes of light, at immense distances, every day revolving around us with amazing velocity. If the motion chiefly exist in the earth, then we are still overwhelmed with wonder at the idea of a globe containing two hundred millions of square miles, with its mighty continents and oceans, and its numerous population, whirling around its axis every day, at the rate of a thousand miles an hour, and in its course round the sun, flying with a velocity of eleven hundred and thirty miles every minute! There is no alternative but that of admitting either the one or the other of these motions; and whatever view we take of this subject, or in whatever light we contemplate the phenomena of the heavens, we are almost irresistibly led to exclaim, "Great and marvelous are thy works, Lord God Almighty!" "Who can utter the mighty operations of Jehovah!" "The Lord God omnipotent reigneth!" The idea of a Being who thus incessantly displays such amazing energies demands from all his intelligent offspring a tribute of reverence and adoration, of gratitude and praise.

CHAPTER II.

ON THE FIGURE AND MOTION OF THE EARTH.

SECTION I.

ON THE FIGURE OF THE EARTH, AND THE ARGUMENTS WHICH PROVE THAT IT IS NEARLY IN THE SHAPE OF A GLOBE.

In the preceding chapter, we have given a description of the principal motions which appear in the heavens, both by day and by night. Every one, however illiterate, who has a desire to study "the wonderful works of God," has an opportunity, if he please, to observe most of the motions and phenomena to which we have adverted, provided he live in the country, or in a spacious street or square. Those who live in the narrow and dirty lanes and courts of London, Liverpool, Manchester, and other populous cities and towns, have no scope for making such observations, unless they occasionally retire to the open fields; and hence it is that the inhabitants of such places seldom know anything of the general aspects either of the earth or of the heavens. It is, however, the incumbent duty of every man, and particularly of every Christian, to contemplate, with an eye of intelligence and devotion, the operations of the Most High, in order that he may be enabled to "praise Him for his mighty acts," and "according to his excellent greatness." And the man who will not give himself the trouble of occasionally devoting an hour or two to such studies and observations, virtually declares that the works of his Creator are unworthy of his contemplation; and consequently, that he deserves to remain in ignorance of the most sublime objects of creation, and of the most glorious manifestations of the Divinity.

Before proceeding to a particular description of the planetary system, it is requisite that we should acquire clear and definite views of the figure and motions of this earth, on which we reside; without which the general frame of the universe, and the order and arrangement of the solar system, cannot be appreciated or understood.

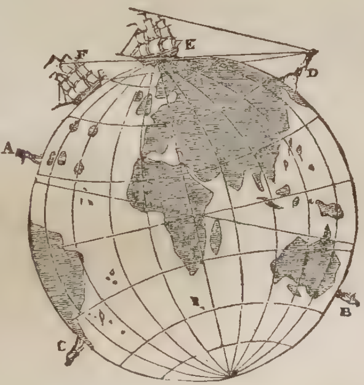
For a long period, during the dark ages, and the infancy of science, the world in which we dwell was considered as the largest body in the universe. It was supposed to be an immense plain, diversified with a few inequalities, caused by the mountains and vales; and that it stretched out in every direction to an unlimited extent, and was bounded on all sides by the sky. What was below this immense mass of land and water, and how it was supported, none could tell; though some of the Christian fathers strenuously asserted that the earth was extended infinitely downward, and established upon several foundations. Such were the absurd and foolish opinions of those who viewed the system of nature through a false medium, and who were ignorant of the facts and principles of modern science. It is only within the period of the last three hundred years that the true figure and dimensions of the earth have been accurately ascertained. This figure is now found to be that of an oblate spheroid, very nearly approaching to the shape of a globe, or sphere. That this is in reality the form of our world will appear from the following considerations.

1. When, on a calm day, we take our station on the sea-shore, we shall perceive that the surface of the water is not quite plane, but a little convex, or rounded; and if we happen to be on one side of an arm of the sea, two or three miles broad, if we place our eyes near the water, and look toward the opposite coast, we shall plainly see the water elevated between our eyes and the opposite coast, so as to prevent our seeing the objects which are near the edge of the water. If we make the same experiment on a lake of two or three miles in extent, a small boat near the end of the lake may be seen by a man who is at some hight above the water; but if we lay our eye near the surface, the view of the boat will be intercepted by the convexity of the water, which shows that the lake is a small segment of a globe.

2. When we view a ship taking its departure from the coast in any direction, as it retires from our view we may perceive the masts and rigging of the vessel when the hull has disappeared, and has sunk, as it were, beyond the boundary of our sight. First we lose sight of the hull, then of the sails, and, last of all, of the topmast. On the other hand, when a ship is approaching the shore, the first part of it which is visible, when at a considerable distance, is the topmast; as it approaches nearer, the sails begin to be seen; and last of all the hull gradually comes within the limits of our sight—but the vessel will pass over several miles of the sea, from the time of our first perceiving the topmast until the hull appears. In order to make such observations with accuracy, it is requisite that a telescope should be used. What is it, then, that prevents the hull of a ship from being perceived when its topmasts are visible? It is evidently the round, or convex surface of the water rising up, as it were, or interposing between our eye and the lower part of the ship, when it has receded a certain distance. Now, as such appearances are observed on every sea and ocean on the face of the earth, it follows that the ocean at large is a convex surface, or a portion of a globe; and if the ocean be globular, so also is the land—notwithstanding that the hills and mountains form a few inequalities on its surface—for the portions of the land are all nearly on a level with the ocean, with the exception of the ranges of elevated mountains.

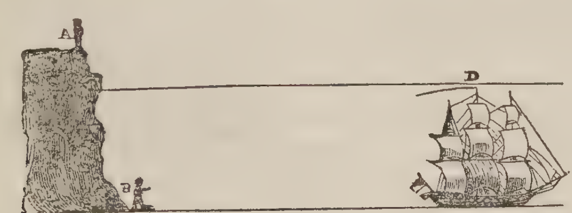
What has been now stated may be illustrated by the following figure (fig. 2), in which the convex surface of the globe is represented. At D a person is represented as standing on the top of a tower; and from that elevation he is enabled to see both the topmast and the hull of the ship E; which is evident, because right lines can be drawn without interruption from the eye, both to the topmast and to the hull. Whereas a line drawn from the eye to the hull of the ship F, which is at a greater distance, is intercepted by the convex surface of the water interposing, and consequently the hull is invisible; but a line drawn from the eye to the higher parts of the vessel shows that the topmasts are visible, because light, when passing through the same medium, flows in straight lines from every object. In conformity with what has been now stated, we find that the higher the eye is placed, the farther will the view be extended. From a lofty mountain we obtain a much more distant and extensive prospect than from the plain below; and hence it is common for sailors to ascend to the top of the ship's mast, when they wish to descry objects at the greatest distance; as from such an elevation they can discover land, or other ships, at a greater distance than when they stand on deck.

Fig. 2.



On the other hand, were the surface of the sea a level plain, as represented in fig. 3, the appearances would be very different. A line might be drawn from any object situate upon it, as the ship D, to the eye, whether it were placed high or low, at A or at B. In this case, any object upon the earth or sea would be visible at any distance which was not so great as to make the appearance of it too faint or small to be perceived. An object would be visible at the same distance whether the eye were high or low. The largest, and not the highest, objects would be visible at the greatest distance. The topmast of a ship would first disappear, and the hull, as being the largest body, would be longest visible; but this is contrary to all experience. The considera-

Fig. 3.



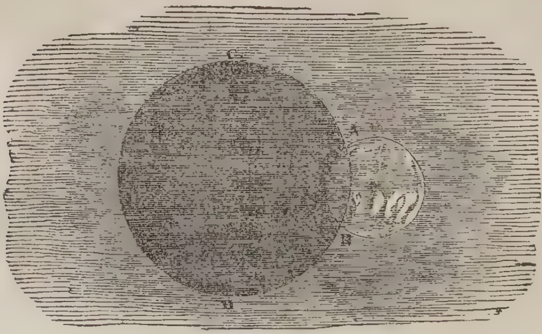
tions now adduced are, therefore, clear and decisive proofs that the earth is not an extended plain, but a globular body; and it is astonishing that such a conclusion was not generally drawn until a few centuries before the present age.

3. That the earth is round from east to west, appears from actual experiment; for many navigators, by sailing in a westerly direction, have gone quite round it from east to west. They have set sail from England, crossed the Atlantic, rounded Cape Horn, sailed along the Great Pacific ocean to the northern coasts of New Holland, crossed the Indian sea, and passing the Cape of Good Hope, have again arrived, by traversing the Atlantic, to the port whence they set out. This experiment therefore shows that the earth is round from east to west; but it does not prove that it is also round from north to south; for it has never been actually circumnavigated in that direction, on account of the obstruction caused to navigation by the immense masses of ice within the polar regions. Had we therefore no other proof of the earth's rotundity than this, we might be apt to suppose it somewhat resembling the shape of a cylinder. But that the earth is in reality round from north to south, appears from the following circumstances. When we travel a considerable distance from north to south, or from south to north, a number of new stars successively appear in the heavens in the quarter to which we are advancing, and many of those in the opposite quarter gradually disappear. For example, in sailing toward the south, when we approach the equator the brilliant constellation called the Cross makes its appearance, which is always invisible in this country; and if we go still farther south, the constellations of the Great Bear, Cassiopeia, and other stars visible in our northern sky, will entirely disappear; which could not happen if the earth were a plane in that direction; for, in this case, all the stars of heaven would be visible in every point from the north pole to the south.

4. Another corroborative proof of the earth's globular figure is this: in cutting for a canal, in order to have the water on a level, certain allowances require to be made for the earth's rotundity. The slope requisite to be made on this account is about eight inches in the mile, thirty-two inches in two miles, and so on, increasing as the square of the distance. If the earth were a plane, no allowances of this kind would be requisite, in order that the water in a long canal might stand on a level.

5. The phenomena exhibited in eclipses of the moon present to the eye a clear demonstration that the earth is of a spherical form. It is well known that an eclipse of the moon is produced by the intervention of the body of the earth between the sun and the moon, which can only happen at the time of full moon, in which case, the shadow of the earth falls upon the moon. This shadow is found in all cases, and in every position of the earth and moon, to be of a circular figure, or the segment of a circle, as the whole shadow cannot be seen at one time. Thus, let A B [fig. 4] represent the moon while an eclipse is going on, and C D the shadow of the earth, which is much larger than the diameter of the moon. In every stage of the progress of an eclipse, the curve A B of the earth's shadow is distinctly perceived passing along the disc of the moon. But the entire shadow of the earth is not seen, because there is no bright object on which the whole of it can fall; only that part of it which covers the moon being visible. But since this shadow always appears a portion of a circle, it proves, incontestably, that the whole mass of land and water, of which the earth is composed, is nearly of a globular form.

Fig. 4.



If, therefore we admit that the earth is of a globular form, it necessarily follows that it may be inhabited on all sides, and consequently, that those who live on the opposite side of the globe must have their feet pointing toward our feet, and their heads pointing in an opposite direction. Thus, in fig. 2, the person standing at A has his feet pointing to the feet of the one standing at B, and their heads pointing to regions of space directly opposite; and therefore if by any motive power, they were to be carried forward in the direction to which their heads point, and the power to be continued, they would never meet through all eternity. The same may be said in reference to the persons supposed to be placed at C and D. It also follows, that, could we suppose a hole bored through the center of the earth, commencing at the point where we now stand, and extending to the opposite side, it would terminate at our *antipodes*, and would measure nearly eight thousand miles. It likewise follows that this globe of land and water is either suspended in empty space, or is moving round its axis every day, or flying with immense velocity round the sun every year. Whichever of these suppositions we hold to be true, a wonderful and sublime idea is conveyed to the mind. If we suppose the earth at rest in empty space, we have presented to view a globe—containing 264 millions of cubical miles, and weighing at least, 2,200,000,000,000,000,000,000, or more than two thousand trillions of tons—resting upon nothing—suspended in the midst of infinite space, and surrounded by the immense bodies of the universe, with no material support but the invisible arm of Omnipotence, poising its immense mass of continents and oceans, and preventing it from sinking into the depths of infinity. If we suppose it to be turning round its axis, and revolving at the same time, round the sun, then we have presented to view a still more astonishing idea—a globe, of the huge dimensions now stated, with its numerous population, flying through the spaces of immensity, without intermitting its speed a single moment, at the rate of sixty-eight thousand miles every hour. So that there is no view we can take of the works of the Almighty, in which we are not irresistibly excited to wonder and admire.

We may here also remark, that the globular figure of the earth is evidently the best adapted to a habitable world. It is the most capacious of all forms, and contains the greatest quantity of area in the least possible space. It is the best adapted to motion, both annual and diurnal, every part of the surface being nearly at the same distance from the center of gravity and motion. Without this figure, there could have been no comfortable and regular alternation of day and night in our world, as we now enjoy; and the light of the sun and the mass of waters could not have been equally distributed. Had the earth been of the figure of a cube, or pentagon, or of any other angular form, some parts would have been comparatively near the center of gravity, and others hundreds or thousands of miles farther from it. Certain countries would have been exposed to furious tempests, which would have overturned and destroyed every object: while others would have been stifled for want of currents and agitation of the air. One part would have been overwhelmed with water, and another entirely destitute of the liquid element; one part might have enjoyed the benign influence of the sun, while another might have been within the shadow of elevations a hundred miles high, and in regions of insufferable cold. In short, while one country might have resembled a paradise, others would have been transformed into a chaos, where nothing was to be seen but barrenness and desolation. But the globular figure which the Creator has given to our world prevents all such inconveniences and evils, and secures to us all the advantages we enjoy from the equable distribution of light and gravity—of the waters of our seas and rivers, and of the winds and motions of the atmosphere. Hence it is that all the bodies of the planetary system are either spherical, or spheroidal bodies; nay, all the great bodies in the universe, so far as our knowledge extends, are found to be of a globular figure; and in this arrangement the wisdom and intelligence of the Almighty Creator are clearly to be perceived.

In short, the discovery of the globular figure of the earth constitutes an important fact in the history of Divine Providence, without which some of the grand designs of the Creator, in reference to our world, would not have been accomplished. It was in consequence of a knowledge of this fact that the continent of America was discovered, and the blessings of civilization, science, and Christianity conveyed to that region of the earth. On a knowledge of the true figure of the earth the art of navigation depends: and in consequence of this, the greater part of the world has been explored, and the way prepared for carrying the tidings of salvation to men of all nations, through faith in the crucified Redeemer. On the knowledge of the true figure of the earth depends our knowledge of its magnitude and dimensions; and on our knowledge of its magnitude, depends our knowledge of the distances of the sun and moon; and on our knowledge of the distance of the sun depends our knowledge of the respective distances of the planets, and the extent of the solar system; and on our knowledge of the extent of this system, depend our conceptions of the distances of the fixed stars, and of the vast magnitude and extent of the material creation; and on our views of the immensity of the universe, depend the enlarged conceptions we are now enabled to form of the attributes of that Almighty Being from whom we derived our existence, and whose "kingdom ruleth over all." Had the first link of this chain —our knowledge of the figure of the earth—been wanting, we should have remained in ignorance of all the important consequences, now stated, which have resulted from this discovery—so intimately connected are all the branches of useful knowledge, both human and Divine.

Had mankind always remained ignorant of this important fact, the circumnavigation of the globe would never have been attempted, vast portions of the habitable world would have remained unknown and unexplored; the intercourses which now subsist among the various tribes and nations of mankind could not have been carried on; the tribes of the greater portion of the heathen world, and the countries in which they reside, would have been unknown; no extensive missionary enterprises could have been carried forward; the knowledge of "the salvation of God" could not have been communicated to all the nations that dwell upon the face of the earth, according to the predictions of ancient prophesy; and our ideas of the majesty and grandeur of the great Creator and Redeemer of men would have remained as low and contracted as in the dark ages, when it was considered, even by ecclesiastics, as a heresy and a crime to maintain that the earth is round like a globe, or ball, and that it may be inhabited on all sides. But now, in consequence of the knowledge we have acquired on this subject, the way is prepared for the accomplishment of the Divine purposes and predictions in relation to our race; our knowledge of creation and the perfections of its Author, is extended; the path to future improvement and discovery is laid open, and everything now appears, notwithstanding many obstacles, to be hastening onward to a glorious consummation.

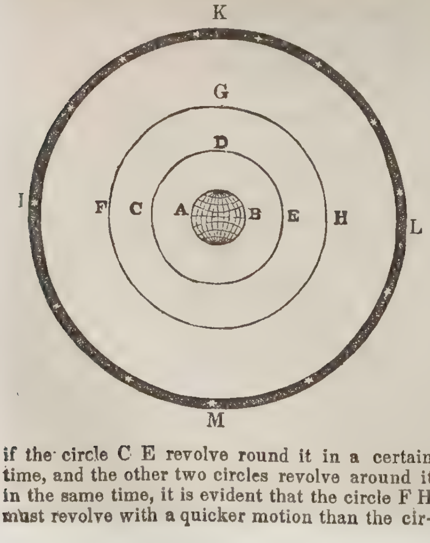
SECTION II

On the motions of the earth.

It is presumed that, in the times in which we live, there are few persons who have any doubts that the world in which we dwell is nearly of the figure of a globe, especially when this position can be proved by so many sensible demonstrations. But there are still many who can scarcely be convinced that it is moving along with immense velocity through the regions of space, in company with the other planets. On this subject, therefore, we shall now offer a few considerations, tending to prove that the world we inhabit—however steadfast it may appear to the eye of sense—is, in reality, a moving body, and that all its inhabitants are carried forward with a velocity far greater than any motions we see around us. There are two different motions considered as connected with the earth:—one, by which it is viewed as turning round its axis every twenty-four hours: and another, by which it wings its flight round the sun once every year. In the meantime, I shall chiefly illustrate those arguments by which its diurnal motion may be demonstrated.

1. In the first place, there is one thing of which we are all certain, that motion does actually exist, either in the earth, or in the heavens. We every day behold the sun apparently moving from the eastern toward the western horizon. We find, likewise, all the stars in the firmament apparently moving in a body round the earth, in the course of twenty-four hours, and in the manner described in the preceding pages. Such observations, which every one has it in his power to make, clearly show, that there is motion somewhere, and the question is—Does this apparent motion really exist in the heavens, or is it the motion of the earth that produces this appearance? Let us suppose, for a moment, that it is the earth which moves. What, then, will be the rate of its motion, in turning round its axis, to produce the apparent revolution of the heavens? For, if the earth really move round its axis from west to east, the heavens will, of course, appear to revolve around us from east to west. The rate of this motion will depend upon the magnitude of the earth. Now, we know that the earth is a globe, somewhat more than 24,000 miles in circumference; and, consequently in turning round every twenty-four hours, some portions of its surface must move at least a thousand miles every hour. This is a motion far more rapid than has ever been produced in the smallest bodies by human art; and, therefore, it may appear incredible to some that such a motion can exist in a globe of such vast dimensions as the earth. But, if such persons deny that the earth thus moves, then they *must admit* that the heavens move. There is no alternative; for motion actually exists, either in the one or in the other. Now, if the motion is to be considered as existing in the heavens, let us consider what the rate of this motion must necessarily be. If a small globe of 18 inches diameter, were supposed to perform a revolution round its axis in two seconds, and a globe of 2000 yards, or 72,000 inches in diameter, to finish a rotation in the same time, this larger globe would move with a velocity four thousand times greater than the other. In fig. 5, if A B, in the center represent the earth, then if the circle C E revolve round it in a certain time, and the other two circles revolve around it in the same time, it is evident that the circle F H must revolve with a quicker motion than the circle C E, and the circle I L with a still greater velocity in proportion to its greater distance from the center of motion, A B.

Fig. 5.



Let us consider, then, what would be the rate of motion of some of the bodies in the heavens, whose distance from the earth is known. The sun is ascertained to be ninety-five millions of miles distant from the earth, and, consequently, were he to move round the earth every day, as he appears to do, he would move along a circumference of 597 millions* of miles every day; that is, at the rate of above twenty-four millions of miles in an hour, 414,000 miles in a minute, and 6900 miles every second. Again, the planet Uranus, at its nearest distance from the earth, is more than 1700 millions of miles distant; and consequently the circumference of its orbit is more than ten thousand six hundred millions of miles. If therefore this planet were supposed to move round the earth every day, its motions would be at the rate of 445 millions of miles in an hour,—seven millions four hundred and twenty thousand miles in a minute,—and one hundred and twenty-three thousand six hundred and seventy-seven miles every second. Again, the nearest fixed stars are known not to be within 20,000,000,000,000, or twenty billions of miles from the earth; and consequently their daily circuit round our globe would measure more than 125,000,000,000,000, or one hundred and twenty-five billions of miles; that is, at the rate of fourteen hundred millions of miles in the space of a single second, or the interval of time which the pendulum of a common clock takes in moving from one side to the other! Stars, at distances a hundred times greater—of which there are many such in our firmament—would move with a rapidity a hundred times swifter; and those still farther removed from us in the depths of immensity, with a velocity far exceeding either human or angelic comprehension; yet all the stars of heaven appear to move round our globe every twenty-four hours. If the circle C D E (fig. 5) represent the supposed diurnal orbit of the sun; F G H that of Uranus; and I K L M that of some of the fixed stars; then it is evident, that in proportion to the distance of the body from the earth will be the velocity of its motion, if it be supposed to move round the earth every day.

If, therefore, there be any reader disposed to reject the motion of the earth, because it appears incomprehensible, he must necessarily admit of motions ten hundred thousand times greater and far more incomprehensible, more especially when we consider that the bodies in the heavens to which we have alluded are incomparably greater than this globe of earth on which we stand,—the planet Uranus being more than eighty times, and the sun more than thirteen hundred thousand times larger than the earth, and the fixed stars, at an average, as large as the sun. Such a rate of motion, in such a number of magnificent luminaries, appears altogether overwhelming, and, I may add altogether incredible.

The question then which we have to decide is, which of the motions to which we have referred is most probable—the motions of the earth, or of the heavens? Is it really necessary that the whole universe, composed of sun, moon, planets, comets, stars, and nebulæ, should move round our globe with such astonishing velocities, in order to produce the alternate succession of day and night? Reason tells us that it is not. We know that the Almighty does nothing in vain, but employs the most simple means, in order to accomplish the most astonishing and important ends. The succession of day and night can be accomplished by a simple rotation of the earth on its axis, which will completely account for all the apparent diurnal revolutions of the celestial bodies. This we find to be actually the case with the other planets of the solar system. The planet Jupiter is fourteen hundred times larger than the earth, and moves round its axis in less than ten hours, at the rate of 28,000 miles an hour, which is a velocity twenty-eight times greater than that of the earth, supposing it to move round its axis. The planet Saturn is nearly a thousand times larger than our globe, and it revolves round its axis in ten hours and a half, at the rate of 24,000 miles an hour, in those places situate near its equator. To a spectator placed on these planets, the heavens would appear to revolve around him every ten hours, as they appear to us to revolve every twenty-four hours, but with an apparently more rapid motion; while he himself might suppose, as we are apt to do, that he is actually at rest. The earth, therefore must be considered as revolving round its axis, in accordance with the arrangements of the other planets of the system to which it belongs; and to suppose otherwise, would be in opposition to all the laws which govern the material universe, and would distort all our ideas of the harmony and order of the works of the Creator.

---

* If the circle C D E represent the circle which the sun apparently describes in revolving round the earth, P C, its distance from the center of the earth, represent 95,000,000 of miles, and the diameter of the circle C E 190,000,000; and, as the proportion of the diameter of a circle to its circumference is nearly as 7 to 22, the circumference of the sun's circle, C D E will be about 597,000,000 of miles, through which he behooved to travel every day, if the earth were at rest.

2. Another consideration which demonstrates the diurnal motion of the earth is this: that such a rate of motion in the heavenly bodies, as has now been stated, though it might be within the limits of Divine power to effect, *would soon shatter the material universe to atoms*, and reduce creation to a chaos. Were a ball of soft wood to be projected from a cannon, at the rate of 800 miles per hour, in a few moments it would be reduced to splinters; and hence the forage and other light substances projected from a piece of ordnance are instantly torn to pieces. What then might be supposed to be the consequences, were a body impelled through the ethereal regions with a velocity of a hundred thousand millions of miles in a minute, as multitudes of the stars behooved to be, were the earth at rest in the center of the universe? It would undoubtedly reduce to atoms the most compact bodies in creation, although they were composed of substances harder than adamant.

3. Another corroborative argument in support of the motion of the earth is this, that *there is no instance known in the universe of a larger body revolving around a smaller.* We do not find such planets as Jupiter and Saturn revolving around their satellites, or moons; but all those satellites which are much smaller than these planets, perform their revolutions around them, as the center of their motions. The earth, which is fifty times greater than the moon, does not revolve around her, but that nocturnal luminary regularly revolves around the earth. The sun does not revolve around the planets Mercury and Venus—which are thousands of times less than that luminary—but they invariably revolve around him as the center of light and influence. As the sun is one million three hundred thousand times larger than the earth, it cannot therefore be supposed for a moment, that such an enormous globe should revolve, with such an inconceivably rapid motion, around so inconsiderable a ball as the earth; and much less that the whole universe should revolve around it every day. Were the earth not revolving around its axis every day, there would be an infraction of all the laws which govern the system of universal nature; and therefore it is absolutely necessary to admit its motion, in order to direct our views, and to produce conviction of the unity of design, and of the harmony of creation.

4. The last argument I shall mention in the meantime, and which I consider as demonstrative on this subject, is this—that if the earth were at rest, and all the heavenly bodies revolving around it with dreadfully rapid motions, *it would confound all our ideas of the wisdom and intelligence of the Deity.* Wisdom is that perfection of an intelligent agent, which enables him to proportionate one thing to another, and to devise the most appropriate means to accomplish important ends. We should reckon that person foolish in the extreme who should construct, at an enormous expense, a huge piece of machinery for carrying round a grate, and the body of a large building to which it is attached, for the purpose of roasting a small fowl, fixed in the center of its motions; instead of making the fowl turn round its different sides to the fire. Were the inhabitants of London or any large town, to attempt to construct machinery to make the whole city move round in a circle, carrying a lamp near the center to throw light and heat over a ball of only one inch in diameter, when the same purpose could have easily been effected by making the ball itself turn round its axis; we should not hesitate a moment in pronouncing such a scheme as a display of consummate folly. But none of these schemes would be half so preposterous as to suppose the vast universe to move round so inconsiderable a globe as the earth, to produce the alternate succession of day and night, when the same object can be effected by the earth's simply revolving around its axis. Such a device, therefore, cannot form any part of the arrangements of Infinite Wisdom. Can we suppose for a moment that what would be considered as the consummation of folly in mankind, is characteristic of the plans and operations of the Divinity, or that the great Source of eternal wisdom is to be leveled below the most foolish of men? Such a thought can never be admitted by any of his intelligent offspring, in relation to Him who is designated "THE ONLY WISE GOD," who "is wonderful in counsel, and excellent in working," and "who hath established the world by his wisdom, and stretched out the heaven by his understanding." If it could be proved that the earth is at rest, and the whole universe in motion around it, I should scarcely admit that the world was framed by that all-wise Being whose character is delineated in the sacred Scriptures, whose wisdom as far transcends that of man as the heavens are high above the earth.

I have been somewhat particular in exhibiting the arguments which prove that the earth is a moving body, because, in some minds, there is a great hesitation in admitting this fact, and in others, a disposition to receive it merely on the testimony of other men, without understanding the foundation on which it rests; and because right views and conceptions of such facts lead to right conceptions of the operations and the attributes of that almighty Being whom we profess to adore. I shall take an opportunity of stating the arguments which prove the annual motion of the globe round the sun, when we come to describe the earth considered as a planet.

SECTION III.

REFLECTIONS SUGGESTED BY THE MOTIONS OF THE EARTH AND HEAVENS.

WE have now endeavored to prove to the intelligent reader, that the world in which we dwell, with all its continents, islands, oceans, and its numerous population, is continually revolving around its axis to bring about the returns of day and night. It is also flying with a still greater velocity around the sun, to produce the various changes of the seasons. What an august and sublime idea does this suggest for our occasional contemplation! While we are apt to imagine we are sitting in absolute rest in our apartments, we are in reality whirling round toward the east at the rate of hundreds of miles an hour; and are, at the same time, carried through the regions of space with a velocity of sixty-eight thousand miles every hour; so that during every moment, or every pulse that beats within us, we are carried nearly twenty miles from that portion of space we occupied before. When we lie down to sleep in the evening, we are seldom aware that, during our seven hours' repose, we have been carried along through the space of four hundred and seventy thousand miles! When, amidst the gloom of winter, we look forward to the cheering scenes of spring, we must be carried forward more than a hundred millions of miles, before we can enjoy the pleasures of that season; and when spring arrives, we must be carried through the voids of space, hundreds of millions more, before we can enjoy the fruits of harvest. During every breath we draw, and every word we speak, we are carried forward in our course thirty, forty, or fifty miles, unconscious of the rapidity of our flight; but the motion is not the less real, because we do not feel it. What should we think if we beheld one of the largest mountains in Scotland flying through the atmosphere, across the island of Great Britain, with a velocity which would carry it from John-o'-Groat's to the Land's End, a distance of seven hundred miles, in seven minutes? It would, doubtless, excite universal wonder and astonishment. But this is not one-tenth part of the velocity with which the great globe of the earth, and all that it contains, flies through the boundless regions of space. Were we placed on a fixed point, a thousand miles distant from the earth, and beheld this mighty globe, with all its magnificent scenery and population, thus winging its flight around the sun, and carrying the moon along with it in its rapid career, such a spectacle would overwhelm us with astonishment inexpressible, and even with emotions of terror, and would present to view a scene of sublimity and grandeur beyond the reach of our present conceptions. To angels, and other superior intelligences, when winging their flight from heaven to earth, and through distant worlds, such august scenes may be frequently presented.

Although the heavens do not in reality move round the earth, as they appear to do, yet there are thousands of globes in the celestial regions whose real motions are more swift and astonishing than even those to which we have now referred. The planet Venus moves in its orbit with a velocity of eighty thousand miles an hour; Mercury at the rate of one hundred and nine thousand miles an hour; and the planet Jupiter, which is one thousand four hundred times larger than the earth, at the rate of nearly thirty thousand miles an hour, carrying along with it in its course, four globes, each larger than our moon. Some of the comets have been found to move more than eight hundred thousand miles in the space of an hour; and some of the fixed stars, though apparently at rest, are moving with a velocity of many thousands of miles an hour. In short, we have every reason to believe that there is not a globe in the universe, nor a portion of matter throughout creation, but is in rapid and perpetual motion through the spaces of infinity, supported by the arm of Omnipotence, and fulfilling the designs for which it was created.

If we inquire into the original cause of these motions, we shall find that no other cause can be assigned but the fiat and the power of that omnipotent Being who at first said, "Let the universe appear," and it started into being. As matter did not make itself, so neither can it move itself; its motion must commence, and can only be continued every moment, by the power of that almighty Being who brought it into existence. He alone who existed from eternity, whose power is uncontrollable, and whose wisdom is unsearchable, is the original Source of all motion, as he is the Source of all life and animation. By his omnipotent arm the planets were at first launched into existence, and impelled in their swift career, and the motion at first communicated, is every moment continued by the incessant agency of the same almighty Power. Were that Power to withdraw its energy, or the subordinate means by which it is appointed to be continued, the universe would soon run into confusion, and creation be transformed into a chaos. But God, who "stretched out the heavens, and laid the foundations of the earth," hath appointed them a decree which they cannot pass, and they continue to this day, according to his ordinances, for all are his servants. Psalm cxix. 91.

What a scene of wonders is presented to view when we contemplate the motions incessantly going forward throughout creation!—that thousands of globes, much larger than our world, are winging their flight with unremitting speed, through the regions of immensity, at a rate which overwhelms the human imagination! What an astonishing idea does this convey of the energies of the Eternal Divinity, who at first launched this earth and all the planetary globes from his powerful hand! He only "spake, and it was done;" and for thousands of years such motions have been continued without intermission! Well may we exclaim, with the inspired writers, "Who can by searching find out God?"—"Who can utter the mighty acts of the Lord? who can show forth all his praise?"

There are certain practical instructions which may be deduced from this subject. The power of God, as displayed in the motions of the earth and heavens, teaches us that nothing can be too hard for Jehovah, and that all the declarations of his word, however wonderful and inexplicable to mortals, shall, in due time, receive their full accomplishment. We are assured, by the declaration of the sacred oracles, that a period is approaching when all the millions of the human race, whose bodies are now putrefying in the grave, and all the succeeding generations of men until the close of time, shall be reanimated from the tomb, and arrayed in more glorious forms than they now wear. We are also assured that this globe, on which we now reside, is destined to undergo an important and universal change, when its elementary parts "shall melt with fervent heat," and "the earth also, and the works that are therein shall be burned up," as to their present constitution and aspect, and that a new arrangement will take place, in reference to the habitation to be allotted to the righteous. We perceive no symptoms of such changes at present; we have never seen any of the dead rise to life, after their bodies had mingled with the dust, and the ashes of some of them been scattered by the winds over different regions of the sea and land; and therefore doubts are apt to arise in the mind, whether such wonderful transformations are possible to be effected. But all such doubts are at once dispelled, when we consider the perfections of Jehovah as displayed in the structure, and particularly in the movements of the universe, which afford us a sensible demonstration, that nothing, however inexplicable to us, can be beyond the range of Omnipotence. Therefore, we may rest assured that, when the time appointed in the decree of Heaven arrives, that power which carries the earth and all the celestial orbs in their rapid motions through the sky, shall be exerted in reanimating all the generations of mankind, now sleeping in the tomb; in producing a most wonderful change in the aspect of this terraqueous globe; and in causing "new heavens and a new earth" to arise, wherein righteousness shall dwell forever. For that power which carries thousands of vast globes through the regions of immensity, with velocities of a hundred thousand miles in the short space of an hour, must be more than adequate to accomplish all the glorious scenes and transformations predicted in the records of the Christian revelation. The Christian may therefore rely with unshaken confidence on all the "great and precious promises" contained in the Scriptures of truth, which are given forth by Him whose faithfulness is established in the very heavens, and who "keepeth covenant and mercy with them that love him and keep his commandments to a thousand generations," and therefore cannot fail of ultimately receiving their full accomplishment. Well, therefore, may the believer in Christ exclaim—

"If my immortal Saviour lives,
Then my immortal life is sure:
His word a firm foundation gives;
Here let me build and rest secure.

"Here let my faith unshaken dwell:
Immovable the promise stands;
Nor all the powers of earth and hell
Can e'er dissolve the sacred bands.

"Here, O my soul, thy trust repose!
If Jesus is for ever mine,
Not death itself, that last of foes,
Shall break a union so divine."

CHAPTER III.

DESCRIPTION OF THE SUN—OF THE INFERIOR PLANETS—AND OF THE EARTH AND MOON.

When we take a particular survey of the starry heavens, we find that the stars, in general, never shift their positions from each other. They appear to move round us in one compact body, as the figures of the constellations do on a celestial globe, when it is turned round its axis; but the stars belonging to one constellation never move toward those of another, nor change their distances from each other. If we direct our attention to the stars of the Great Bear, for example, (see fig. 1), we shall find that, at all hours of the day and night, and at every season of the year, they present the same definite figure, and the same relative position to each other, without any sensible variation of distance or magnitude; and the same may be observed from one year to another. Hence, they are usually denominated "the fixed stars." But when we observe the heavens with still more accuracy and minuteness, we shall occasionally perceive a few bodies, having the appearance of stars, which, when carefully watched, for a few weeks or months, will be found shifting their positions with respect to the surrounding stars. In most cases, their motion is toward the east, but not unfrequently toward the west, and, at certain times, no motion can be observed for a considerable number of days. The bodies which are thus perceived to change their positions among the stars are called PLANETS; which word signifies "wandering stars."

There are ten orbs of this description which have been traced in the heavens, and whose motions have been accurately ascertained. Only five of these bodies are visible to the naked eye: the other five can be seen only with telescopes. The five planets visible to the unassisted eye were known to the ancients, who gave them the following names, derived from the heathen mythology; namely, Mercury, Venus, Mars, Jupiter, and Saturn. The other five were discovered by means of the telescope, within the space of the last seventy years. They are named Vesta, Juno, Ceres, Pallas, and Uranus. By a careful investigation of the motions and other phenomena of these bodies, astronomers have ascertained that they all move round the sun as the center of their motions; and, along with the earth, and nineteen smaller globes, form one grand and harmonious system, with which we who live on the terraqueous globe are intimately connected. The central orb which enlightens these moving bodies, and by its influence preserves them in harmony and order, is the same sun that enlightens our day, and diffuses life and animation among all the animal and vegetable productions of our globe. These bodies, although they sometimes appear in different and even opposite regions of the heavens, occupy but a very small space, as to the range of their motions, compared with that which is occupied by the fixed stars. The whole assemblage of these moving orbs, including the earth, is what is generally denominated THE SOLAR SYSTEM, of which we shall now proceed to give a general description, beginning at the center of the system, and proceeding to the different planets as they lie in order.

SECTION I.

THE SUN.

The sun is the grand center and animating principle of the planetary system, around which all the planets revolve, at different distances, and in different periods of time; and by whose attracting influence they are retained in their respective orbits From this source they all derive light and heat, and all the other influences requisite to fit them for being habitable worlds.

Among all the objects of the visible creation, there is none whose beauty is so much admired, and whose benign influence is so generally appreciated, as the sun. Every day this glorious orb visits us with his cheering beams, dispels the shades of night, and diffuses joy and animation among all the tribes of sensitive existence; without whose powerful energy, our world would soon become a dark and shapeless chaos, without life, order or enjoyment. But the splendor of this luminary, and the benefits it confers, are so common and so regularly continued, that we are apt to view them with indifference; and we seldom contemplate, with the eye of an enlightened understanding, the wonderful nature of that globe on which surrounding worlds depend for all the comforts and beneficial agencies they enjoy. To the vulgar eye, the solar orb appears only like a flat luminous circle of a few inches diameter; and there are thousands of mankind who consider it in no other light than as a brilliant lamp, of no great size, hung up in the firmament to give us light by day, and to enable us to prosecute our daily labors. Even minds of a more elevated and reflecting cast have seldom entered into all the sublime ideas connected with the nature and properties of this august luminary; and it is questionable whether the greatest astronomer now existing is capable of forming a conception of the magnitude and sublimity of the solar orb, corresponding to its vast extent and its real grandeur, as the soul, and center, and connecting principle of mighty worlds.

Of the *magnitude* of this stupendous globe arithmetical numbers can scarcely convey to us an adequate idea; but we may, in the first place, state its dimensions in numbers. Its diameter, or a line passing through its center from one side to another, is found to be 880,000 miles. Its circumference, or a line going quite round it, is 2,764,600 miles. Its surface contains 2,432,800,000,000 of square miles; that is, more than twelve thousand times the number of square miles on our globe. Its solid contents comprehend 356,818,739,200,000,000 or three hundred and fifty-six thousand billions of cubical miles; that is, 1,350,000 times the number of solid miles which the terraqueous globe contains; so that were one million three hundred and fifty thousand globes as large as the earth to be compacted into one globe, it would only equal the size of the sun! Some of these dimensions may be somewhat illustrated as follows: Suppose a person to move round the sun's circumference at the rate of forty-five miles every day, it would require more than one hundred and sixty years before the circuit could be completed. Suppose one were to traverse the whole surface of this luminary, so as to pass over every square mile on its surface, at the rate of sixty miles a day, it would require more than a hundred millions of years before such an object could be accomplished. It is stated that the splendid view from Mount Etna comprehends a circle two hundred and forty miles in diameter, containing 45,240 square miles. Now this is only the fifty-three millionth part of the surface of the sun; so that more than fifty-three millions of landscapes, such as beheld from the top of Etna, must pass before us ere we could contemplate a surface as extensive as that of the sun. Were we to suppose every such landscape to occupy two hours in the contemplation, it would require twelve thousand two hundred and seventy-five years—without the least intermission—or more than double the time which has elapsed since the Mosaic creation, before the whole surface of this immense globe could be, in this rapid manner, surveyed. The magnitude of this luminary may also be illustrated from the following comparison: The earth contains about two hundred and sixty-four thousand millions of cubical miles; the planet Jupiter is fourteen hundred times larger than the earth; Saturn is about a thousand times; and Uranus about eighty times larger than the earth: yet the sun is found to be more than five hundred times larger than those planets, and all the other planets, moons, and comets of the solar system taken together.

If it be asked why the sun appears so small to our eyes, if it is indeed so immense a globe, it is easily answered, that this is owing to its immense distance from our world. This distance is no less than ninety-five millions of miles,—a distance of which the mind can form only a very inadequate conception. It may be somewhat illustrated, however, as follows: A cannon ball, at its utmost speed, when it leaves the mouth of a cannon, is calculated to fly at the rate of about five hundred miles an hour; but it would require such a moving body—though flying continually with this velocity—twenty-one years and two hundred and forty-five days before it could reach the sun. This may be further illustrated by motions with which we are more familiar. Suppose a steam-carriage to set out from the earth in the direction of the sun, and to move, without intermission, at the rate of four hundred and eighty miles every day, it would require five hundred and forty-seven years before it could traverse the space which intervenes between us and that distant luminary. How wonderful, then, that the sun, at such a distance, should exert his attractive power upon the earth—fructify the soil—raise tides in the ocean—and diffuse light, and heat, and color, and animation, over all its regions! And not only so, but even on the remotest planet of the system, at the distance of eighteen hundred millions of miles, similar influences are produced by the agency of this august luminary!

Are we startled at the vast distance and dimensions of the solar orb which we have now stated? and are we apt to doubt whether the representations we have given be accordant with fact? We ought to consider that He who made the sun, and adorned him with the splendor he exhibits, is "THE LORD GOD OMNIPOTENT," the extent of whose power and wisdom none can comprehend; and that the sun required to be of such a magnitude to give stability to the system of which he is the center; and, according to the laws he hath impressed upon the material world, to retain surrounding worlds in the paths prescribed them, and to dispense to them all those influences which they require. If we are astonished at the magnitude of the sun, how must our admiration be raised when we consider that this globe is only one out of millions of similar globes which exist in the universe! For every star that adorns our firmament is, on good grounds, concluded to be a sun, no less spacious and luminous than that which enlightens our day; and has, doubtless, a retinue of planetary globes revolving around it, as the center of light and influence.

Nature and physical constitution of the Sun.—Of the real nature of this luminary we have hitherto acquired but very imperfect conceptions. But since the invention of the telescope, our knowledge of its constitution has been somewhat enlarged. We no longer view the sun as a ball of liquid fire, as had sometimes been supposed, but as a solid body, composed of different materials, in which wonderful processes are going forward on an extensive scale, for preparing and perpetuating that light and heat which are destined to cheer and illuminate surrounding worlds. When the sun is viewed by means of a telescope, spots of various kinds are perceived upon its surface. These spots appear first on its eastern margin, when they appear narrow and somewhat obscure; they move gradually onward to the center of the disc, when they appear largest and most distinct; afterward they proceed toward the western limb, where they again appear narrow and obscure; and after a period of about thirteen days, from their first appearance on the eastern edge, they disappear from the western limb; and, in many cases, they again appear on the eastern limb, after the same period of thirteen days. But they are frequently somewhat changed in their aspect before they reappear; and, in numerous instances, after disappearing from the sun's western boundary, they are never again visible in the same shape; but other spots, at uncertain intervals, are seen diversifying the solar disc; though not unfrequently scarcely a single spot is to be seen over the whole surface of the sun. The spots appearing narrower and less distinct on the eastern and western limbs, is owing to our viewing obliquely these parts of the sun's surface. The conclusions to be deduced from these circumstances are, 1st, that the sun is a globe, and not a flat surface, as it appears to the naked eye, otherwise the spots would appear equally large and distinct on every part of its surface. 2d. That this luminary moves round its axis in the same direction as the rotation of the planets; for its spots do not shift their places on its disc, but are carried along with the whole body of the sun. The time of the apparent revolution of these spots is 27 days, 8 hours; but the real period of the sun's rotation is 25 days, 9 hours, 56 minutes; and therefore, the places about the sun's equator move at the rate of four thousand five hundred and thirty-two miles an hour.*

The solar spots are of all sizes, and of different shapes: their size is from $\frac{1}{600}$th to $\frac{1}{30}$th of the sun's diameter. The smallest of those spots which can be distinctly seen, are nearly a thousand miles in diameter. Spots, the one-fiftieth part of the diameter of the sun—which we have frequently seen—are 17,600 miles in diameter, or more than double the diameter of the earth; and if the spot be considered only as a plane, and somewhat circular, it will contain more than two hundred and forty-three thousand square miles, which is considerably more than the area of the whole terraqueous globe; and yet sometimes a spot of this vast size will disappear in a few weeks, and not unfrequently in a few days. Sometimes not a single spot is to be seen on the solar disc for weeks and even for months together; at other times, we have seen above one hundred spots of all sizes dispersed over the face of the sun at one time. In such cases, there are generally five or six large spots, such as that alluded to above, accompanied with ten, fifteen, or twenty smaller spots; but, after disappearing at the sun's western limb, it is seldom that they come round again in the same order as before. Some appear to have been altogether dissipated, and others to have changed their shape and relation to surrounding spots, in which they formerly appeared. We have seen spots of nearly 2000 miles in diameter vanish in the course of twenty-two hours: and, on the other hand, on a late occasion, we beheld two spots, each of them larger than the earth, and containing at least three hundred millions of square miles, which were formed near the center of the solar disc, where no trace of them was seen forty hours before; which circumstances show the amazing rapidity with which these mighty masses are formed, and again rendered invisible to the sight. The portions of the sun's surface where the spots most frequently appear, are those which lie adjacent to its equatorial regions; no spots being ever seen near its northern or southern poles. In some years, these spots have been very numerous, and seldom a week has passed without a few of them having been seen, while in other years, comparatively few have been visible.

These spots, as to their general appearance, resemble a dark nucleus, surrounded with a penumbra, or belt of a lighter shade. This penumbra is generally of a shape nearly corresponding to that of the dark nucleus, or central spot. This fainter belt is plainly perceptible in the larger spots, and when very high powers are applied to the telescope, the umbræ are also visible in the smaller spots. The following representations will convey a general idea of the phenomena of the solar spots Fig. 6 represents the more common appearance of these spots—a dark central part surrounded by a fainter shade. Figs. 7, 8, 9, represent the appearances of certain spots which exhibit a bright spot, or figure, in the midst of the dark nucleus. Fig. 10 shows a spot, in which various dark spots are surrounded by one common penumbra; figs. 11, 12, spots of different shapes; figs. 13, 14, large spots accompanied or surrounded with dark spots of a much smaller size. This is a very common phenomenon: it is seldom that any large spots are seen without being accompanied with a variety of small spots of different sizes, frequently assuming the appearance of a tail to the large spot. Fig. 15, represents the appearance and progress of a single spot, from the time it appears on the sun's eastern limb until it arrive at the center of the disc. As the sun moves round an axis which is not perpendicular to the ecliptic, but inclined seven and a half degrees from the perpendicular, so the spots move in a line deviating from the ecliptic, and perpendicular to the sun's axis. Thus, in fig. 16, A B represents the ecliptic; D C its axis perpendicular to it; G H the axis of the sun, around which it performs its rotation, deviating seven and a half degrees from D C, the axis of the ecliptic. The spots therefore move in a line E F or K L, which is at right angles with the axis of the sun.

Beside the dark spots whose phenomena we have now described, there are spots which have a bright and mottled appearance, and which it is difficult, in most cases, to distinguish from the general body of the sun. They are chiefly to be seen when they first appear on the eastern margin of the sun, and when they approach near the western limb; but they are seldom or never seen near the middle of the disc. They are most generally seen in connection with clusters of the dark spots, and when they are first seen near the eastern limb, they frequently indicate that dark spots are about to make their appearance. They appear like luminous ridges, and plainly indicate that the sun is not a smooth surface, but is diversified with elevations and depressions, or, in other words, with mountains and vales of a stupendous size, otherwise we could not perceive them at the remote distance at which we are placed. But what these bright ridges, or corrugations, are—whether immense luminous clouds, or solid bodies —or what purpose they serve in the operations which are going forward in this luminary, we are unable to determine.

---

* This is found by dividing the circumference of the sun = 2,764,600 miles, by the number of hours in which the rotation is performed, namely 610 hours, and the quotient is the rate of motion per hour.

The following is a summary of the phenomena of the solar spots. 1. Every spot which has a dark nucleus has also an umbra surrounding it. 2. The boundary between the nucleus and umbra is well-defined. 3. The increase of a spot is gradual, the breadth of the nucleus and umbra dilating at the same time; and its decrease is gradual in the same manner. 4. The nucleus, when on the decrease, in many instances, changes its figure by the umbra encroaching upon it; and thus it sometimes happens that the nucleus is divided into two or more nuclei. 5. The exterior boundary of the umbræ never consists of sharp angles, but is always curvilinear. 6. The nucleus vanishes sooner than the umbra.

The conclusions which have been drawn from the phenomena now described, in reference to the constitution of the sun, are as follows: That the central part of the spots is beneath the level of the sun's surface, or, in other words, that the spots are excavations in the body of this luminary, and that the umbra, or shade, which surrounds it, is the shelving sides of this excavation in the luminous matter. According to this view, the nucleus is nothing else than the dark and solid body of the sun appearing through the openings of a luminous atmosphere which surrounds this mighty globe. According to Sir W. Herschel's estimate, this atmosphere is not less than 1840 miles, and not more than 2760 miles in depth. This he regards as the outermost coating of the sun, or his visible surface; and under this superior stratum, he conceived there is another, more dense and highly reflective which throws back the light of the upper regions, and that this lower atmosphere constitutes the umbra of the spots, and that the dark central parts of the spots, or, the nuclei, are part of the solid matter of which the sun's body is composed. In accordance with such views, the internal part of the sun may be considered as an immense solid ball, not altogether unlike the earth and the other planets; and there is no great improbability in supposing that it is fitted for being the habitation of sensitive and intelligent beings, with constitutions adapted to the situation; and that it may constitute the most glorious habitation connected with the solar system. But whatever may be the real nature and constitution of this luminary, it is evident, from the rapid and extensive changes which are frequently happening both among the bright and dark spots, that there are forces of prodigious power in continual operation, producing the most astonishing effects, in a short space of time, sometimes in a few hours or minutes, on the surface or in the luminous atmosphere of this great central body. And such changes are, doubtless, necessary for preserving the present constitution of the sun—for enabling him to diffuse light and heat—and to act as the soul of surrounding worlds.

This magnificent luminary is the grand source

of light, and heat, and color to this earth, and to all the planetary globes, with their rings and satellites, which belong to our system. By its energy and influence, it cheers, adorns, and animates a retinue of mighty worlds; directing their motions, and preserving them all in the paths prescribed them, so that none shall wander from their course, or interfere with others. It is the central bond which unites the moon to the earth; the satellites of Jupiter, Saturn, and Uranus, to their respective primaries, and all the other planets in one grand and harmonious system. On our globe, the benign effects of the sun are numerous and powerful. He is not only the source of illumination, but of all that beautiful diversity of coloring which adorns every terrestrial landscape.* Both the earth and sea—the lowest depths of the ocean, and the darkest cavern—feel the effects of his powerful agency. All animated beings rejoice in his presence: when his rays dispel the shades of night, millions of the insect tribes awake and sport in his beams, the birds salute him with their melodious concerts, everything that breathes feels the effect of his influence; man watches for the morning and rejoices at his approach; for "truly the light is sweet, and a pleasant thing it is for the eyes to behold the sun." The vegetable tribes likewise feel his energy: he gives circulation to the sap in plants and trees; he causes the blossoms and leaves to shoot; the hills and vales to be covered with verdure, and the fruits of the earth to ripen to a golden harvest, for supplying the wants of man and beast. Without the influence of this luminary, darkness and all its gloomy accompaniments would forever involve this lower creation; all the beauties which now adorn the face of nature would be swept away, the birds would cease their warblings, the flowers would no longer be decked with the gayest colors, nor shed their rich perfumes. Life, activity, and animation would soon cease; and the earth, ere long, would be transformed into a hideous chaos.

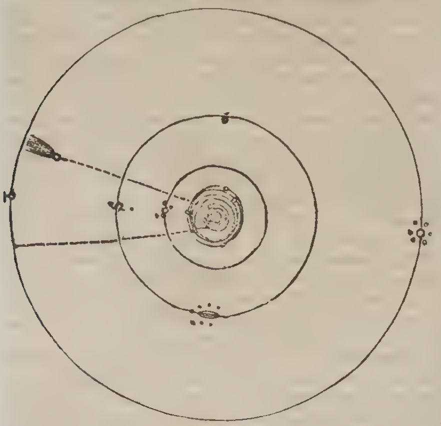
Can we reflect on the grandeur and magnitude of this luminary, and the manifold beneficial effects which it produces on our world, without raising our thoughts to Him who at first launched this vast globe from his almighty arm, and still sustains it in all its energies! In all our surveys of the system of nature, it becomes us to raise our views from the effect to the cause, from the creature to the great Creator, and to give to Him "the glory due to his name." This is not only a duty inculcated in Scripture, but is in full accordance with the dictates of true philosophy; which declare, that every phenomenon, and every effect in the universe should be traced up to a cause adequate for its production. And what cause could produce such a stupendous luminary, but that Being who existed from eternity, whose power is uncontrollable and illimitable, and whose "kingdom ruleth over all?" In the formation of this spacious globe we behold a display of Omnipotence which overwhelms our conceptions, and which shows us that nothing, however amazing and incomprehensible, can be beyond the limits of God's power to accomplish. In the numerous beneficial agencies produced by the sun, we have a display of his beneficence, an evidence that the happiness of his creatures is one of the main objects of his creating power, and that "his tender mercies are over all his works." "The day is thine; the night also is thine; thou hast prepared the light and the sun." He hath placed our world at such a distance from this luminary, as neither to dazzle us with excessive brilliancy, nor scorch us with excessive heat, nor freeze us with insufferable cold; but to produce an illumination and a temperature suited to the inhabitants of every clime. The man who can contemplate this glorious object, and feel all the beneficial effects of its influence, without the least emotion of gratitude, reverence, and adoration, scarcely deserves to enjoy the beneficence of his Creator. Let us, then, "give thanks unto the Lord—to him that made great lights—the sun to rule the day: for his mercy endureth forever." And as the sun enlightens, cheers, and fructifies our globe, and distributes benefits wherever he shines; so let us likewise, according to our power and opportunities, exert all our energies in imparting blessings to our brethren of mankind. As he daily sheds his benign influence around the world; as he rises for the benefit of the ungrateful and the unjust, as well as for the good and the righteous, so let our beneficence be displayed toward men of all characters and nations, that we may prove ourselves to be "the children of the Most High," who, without distinction of persons, distributes blessings without number, among all the ranks of sensitive and intelligent existence.

Notwithstanding the numerous benefits which the sun dispenses to all the inhabitants of our globe, it is a melancholy truth that the greater part of its population is still involved in intellectual darkness and moral debasement, "being alienated from the life of God through the ignorance that is in them." In this respect, it may still be said, as in ancient times, that darkness covers the earth, and gross darkness the majority of the people who inhabit it. While the sun diffuses its splendor around them, their minds are shrouded in a midnight gloom, into which "the light of the knowledge of the glory of God," as it shines "in the face of Jesus Christ," has never penetrated. Before all the effects of light—material and mental—can be fully felt, the Sun of righteousness must arise on the nations "with healing in his beams," to diffuse knowledge, joy, and salvation. His influences are as necessary to our true happiness as those of the material sun to our external comfort and existence. His Spirit irradiates the darkest understandings, purifies the most debased affections, and diffuses gladness and consolation wherever the light of Divine truth shines into the heart. And as the rays of this spiritual Sun are diffused by the truths of revelation, it is our duty to disseminate these truths as extensively as possible among all the kindreds, and families, and tribes, that dwell upon the face of all the earth. Wherever the natural sun shines, the light of Divine truth should be made to shed its influence and its luster, until light shall spring up to those who sit in darkness and the shadow of death; until "the glory of the Lord shall cover the earth—and all flesh see the salvation of God."

SECTION II.

THE PLANET MERCURY.

Having given a general description of the sun—which is the center of the planetary orbs, around which they all perform their revolutions, at different distances and in different periods of time, we shall now proceed to give a brief description of what is most interesting in the phenomena of the different planets, beginning with that which is nearest the center, and proceeding, in order, to those which are most distant. The order in which the orbits of the planets lie from the sun is represented in the following small diagram. The proportional distances of the planets from the center cannot be distinctly represented, unless upon a diagram of very large extent. In this small figure, the middle point represents the position of the sun. The inner circle next the point which represents the sun, is the orbit of Mercury, the nearest planet to the sun; the second circle represents the orbit of Venus; the third that of the Earth; the fourth that of Mars; the next circles, which cross each other, represent the orbits of the lately discovered planets: Vesta, Juno, Ceres, and Pallas. Beyond these, the next circle represents the orbit of Jupiter with his satellites, and next to that the orbit of Saturn. The outermost circle is that of Uranus, sometimes distinguished by the names of Herschel, and the Georgium Sidus.



These orbits appear very small, as delineated in this diagram; but they are in reality so immensely large, that the mind can scarcely form any adequate conception of them. The orbit of Mercury, which is the smallest, is more than two hundred and thirty-two millions of miles in circumference. Were a steam carriage to move round it at the rate of twenty miles an hour, it would require more than one thousand three hundred and twenty-four years before it could complete the circuit; yet the planet itself moves around it in the short space of eighty-eight days. The orbit of Uranus, the most distant planet of the system, is eleven thousand three hundred millions of miles in circumference, and three thousand six hundred millions in diameter. To move round this circumference, at the rate of thirty miles an hour, would require above forty-two thousand nine hundred years, or more than seven times the period which has elapsed since the creation of Adam; while the planet itself moves round it in eighty-four years. So that all the arrangements of the Divine Being are conducted on a scale of magnificence, astonishing to mortals, and corresponding to the infinite majesty and grandeur of Him "who stretched out the heavens by his understanding."

The narrow curve, on the left hand of the figure, crossing the orbits of the planets, represents a portion of the orbit of a comet. The comets move in all directions through the solar system, and their orbits consist of long narrow ellipses, or ovals, some of which extend far beyond the orbits of the most distant planets, where they sometimes remain for a long series of years. These bodies are distinguished by their dim, dusky, and ruddy light, and the long tails, or trains of light with which they frequently make their appearance. Sometimes they are visible to the naked eye, and make a pretty splendid appearance; but numerous bodies of this description pass near the center of our system, which are only visible by means of telescopes, and numbers, doubtless, which are never distinguished even by astronomers, except when by chance they happen to direct their telescopes to those portions of the heavens in which they are moving. From December, 1843, to September, 1844, no less than three comets were discovered, but not one of them was visible to the unassisted eye.

Having made these preliminary remarks respecting the general arrangement of the planets and comets, we proceed to a brief description of—

The planet Mercury. This planet, as already noticed, is the nearest to the sun; at least, no planets, nearer this luminary have yet been discovered, though it is not improbable that one or two may exist within the orbit of Mercury. Its name signifies "the swift messenger," and, in point of fact, it is the swiftest moving planet in the solar system, its rate of motion being, at an average, one hundred and nine thousand eight hundred miles an hour, or one thousand eight hundred and thirty miles in a minute; but its rate of motion is somewhat different in different parts of its course, as it moves in an elliptical orbit. Its distance from the sun is about thirty-seven millions of miles, and it performs its revolution around that luminary in eighty-seven days, twenty-three hours, and twenty-five minutes. As to *magnitude*, this planet ranks among the smaller bodies of the system. Its diameter is three thousand two hundred miles, its circumference ten thousand and fifty-three miles, and its surface contains above thirty-two millions of square miles, which is considerably less than the habitable parts of our globe. Were we to compare its size with that of the sun we should find that it would require nearly twenty-two millions of globes of the size of Mercury to form a globe equal to that of the sun.*

This planet always appears to move in the neighborhood of the sun. It never appears above twenty-nine degrees distant from the sun, and frequently at the period of its greatest elongations it is not above sixteen or seventeen degrees from that luminary. On this account, it is difficult to be distinguished by the naked eye, unless near the periods of its greatest elongations. The time between its greatest elongations from the sun, varies from one hundred and six to one hundred and thirty days. When it is at its greatest elongation east of the sun, it is seen in the evenings, at a low elevation, not far from the point where the sun sets. When it is west of the sun, it is seen in the morning not far from the point of sunrise. The most favorable seasons for observing it are the spring and autumn, as it is in a higher declination at those seasons than in winter, and the twilight is not so strong nor so long continued as in summer. When viewed by the naked eye, it appears to emit a very white light; and those who would wish to get a view of this planet, when it may be seen, should inspect an almanac, or ephemeris, where the times of its elongations are distinctly stated.* When viewed with a telescope it appears, in the course of its revolutions round the sun, to pass through all the phases of the moon, sometimes appearing as a half-moon, sometimes as a crescent, and at other times with a gibbous phase. When it appears of a half-moon or crescent phase, its enlightened side, like that of the moon, is always turned toward the sun, which proves that it is in itself a dark body, and derives all its light from that luminary. On account of its nearness to the sun, few discoveries have been made on its surface by the telescope. It has been observed, however, that when it appears as a crescent, one of its horns is truncated, or cut off at the point, by which the period of its revolutions round its axis has been determined, which is supposed to be accomplished in twenty-four hours and five minutes. This truncature is doubtless the effect of elevations and depressions on its surface; and hence, some astronomers have concluded that mountains of considerable elevation exist on Mercury, one of which is calculated to be eight English miles in perpendicular altitude. It is supposed, likewise, that it is enveloped with an extremely dense atmosphere.

---

* This is estimated in the following manner—the comparative bulks of spheres are to each other as the cubes of their diameters; therefore, divide the cubes of their diameters by each other, and the quotient shows the number of times the one is contained in the other. In the present instance, multiply the sun's diameter, 880,000 miles, twice into itself, and divide the product by the cube of the diameter of Mercury, 3200 miles, and the quotient will give the number of times that the sun is larger than this planet. Thus the cube of 880,000 is 681,472,000,000,000,000, which divided by 32,768,000,000 the cube of Mercury's diameter = 21 millions and five-sixths, nearly.

In consequence of its nearness to the sun—being nearly three times nearer than the earth—the quantity of light is nearly seven times greater than what we receive; and the sun will appear to a spectator in that planet about seven times larger than to us—which circumstances will cause a more brilliant luster to appear on all the objects on the surface of this planet than appears on the scenery of our globe. Such eyes as ours would be unable to sustain so dazzling a brightness, unless their pupils were contracted to the diameter of one-fiftieth of an inch. That the quantity of heat is in the same proportion, or seven times greater than on the earth, is an opinion by no means probable. It is more probable, from many circumstances connected with our own globe, and from a variety of experiments which have been made on the subject of heat, that the sun's rays may be modified in their action by the nature of the atmosphere, and the constituent elements of which the planet is composed. It is probable that sensible heat depends chiefly on the distribution of the substance of caloric, or the principle of heat, on the surfaces and throughout the atmospheres of the planets, in different quantities, according to the different situations they occupy in the solar system; so that it is possible there may be no more sensible heat felt on the surface of Mercury than on the surface of the earth, or even of Saturn, or Uranus.

Mercury revolves in an elliptical orbit, which is more eccentric than the orbits of the other planets except Juno and Pallas. This is the reason why, at some of its greatest elongations, it is only sixteen degrees from the sun; while at others, it is nearly twenty-nine degrees distant. Its eccentricity, or the distance of the sun from the center of its orbit, is above seven millions of miles; which is about the one-tenth part of the diameter of its orbit; and this orbit is inclined to the ecliptic, or the plane of the earth's orbit, in an angle of seven degrees, so that it is sometimes this number of degrees above the level of the ecliptic, and at other times as much below it. The density of this planet is greater than that of any other planet of the system. It has been estimated to be nearly twice the density of the earth, that is about nine times the density of water, or nearly equal to that of lead. Such conclusions are deduced from the laws of gravitation, by which all the planets are directed in their motions.

Transits of Mercury.—At certain periods, this planet is observed to pass across the sun's disc, like a small dark spot. This can happen only at the time of its inferior conjunction with the sun—when it is nearest to the earth—when its enlightened side is turned toward the sun, and its dark hemisphere is turned directly toward the earth; and when the earth, Mercury, and the sun are nearly in one straight line. This passage of Mercury across the solar disc is called its transit, and is considered by astronomers as an interesting phenomenon. If the orbit of this planet were in the same plane with that of the earth, it would transit the sun's disc at every inferior conjunction, or three or four times every year. But as its orbit is inclined to the ecliptic, a transit can happen only when it comes to the inferior conjunction, at the time when it is at or near its nodes, or the points where it crosses the ecliptic, and when the earth is in the same longitude, and this occurs only at intervals of several years. The last visible transit previous to 1845, happened in 1832: another happened in November, 1835, but was invisible in Britain, as the sun was set before its commencement. A visible transit likewise occurred on May 8th, 1845, which began at 19 minutes past 4, P. M., Greenwich time, and the planet arrived near the center of the disc at 35 minutes past 7, P. M.; but before the planet's egress from the sun's western limb, the sun set to the inhabitants of this country. The next visible transits of Mercury will happen at the following periods: 1848, November 9th; 1861, November 12th; 1868, November 5th; 1878, May 6th. The other transits, during the present century, in 1881, 1891, and 1894, will be invisible in Britain and other European countries, but will be seen in several parts of North and South America, and the islands of the Pacific Ocean.

This planet, notwithstanding its comparative smallness, forms a portion of the Divine empire, and is capable of containing a population larger than even that of our globe. Though diminutive in its appearance, and seldom seen by the inhabitants of the earth, we can scarcely doubt that there are to be found on this planet millions of sentient and intelligent beings—perhaps far superior in dignity to man—with constitutions fitted for that sphere in which Providence has placed them, and with mental powers which qualify them to know, to love, and to adore their great Creator. For it may be considered as an axiom, that the material universe was created, and is still preserved in existence, chiefly for the sake of sensitive and intellectual natures, to afford them the means of happiness, and to give them a sensible display of the character and attributes of the Eternal Divinity.

---

* The *Christian Almanac*, published by the "Religious Tract Society," will afford sufficient information on such points, and on various other topics connected with astronomy, and the motions and aspects of the heavenly orbs, especially under the head Phenomena. This almanac is published at the low price of sixpence, contains about 84 closely printed pages, and a vast quantity of useful information on science, religion, philanthropy, domestic economy, acts of Parliament, and a variety of other interesting topics.

SECTION III.

ON THE PLANET VENUS.

NEXT to Mercury, in the order of the system, is the planet Venus. To the naked eye it appears the most beautiful and splendid star in the heavens, and has been distinguished both in ancient and modern times as the morning and evening star, because in one part of its course, it makes its appearance, in the west, in the evening, before any other star is visible; and, in another part of its course, it appears in the east in the morning, ushering in the dawn, and giving notice of the approach of the rising sun. Its distance from the sun is reckoned at sixty-eight millions of miles, being thirty-one millions of miles from the orbit of Mercury, and about twenty-seven millions of miles from the earth at its nearest approach to it. At this distance it is nearer the earth than any other celestial body can approach, the moon only excepted. In respect of *magnitude*, it is found to be 7800 miles in diameter, or very nearly the size of our globe. Its surface contains one hundred and ninety-one millions of square miles, and the quantity of light it receives from the sun is nearly double of that which falls upon the earth, on account of its greater nearness to the sun, so that that luminary will appear from its surface twice as large as it does to us. From a variety of observations which have been made on this planet, it appears that it has a rotation on its axis, which is accomplished in the period of 23 hours, 21 minutes; and as the period of the earth's rotation is 23 hours, 56 minutes, its day is, of course, 35 minutes shorter than ours.

Discoveries made on Venus by the telescope.—The first time the telescope was directed to this planet was in the year 1610, by the celebrated Galileo, who had just a little before constructed one of the first telescopes. The chief discovery he then made was, that this planet, in the course of its revolution round the sun, passed through all the phases of the moon, sometimes appearing as a crescent, or like the moon when three or four days old, sometimes like a half-moon, and at other times with a gibbous phase, or like the moon three or four days before the full. That the planet presents such phases to our eye is a plain proof that it does not move round the earth as its center of motion, as the ancients supposed, but round the sun, in an orbit which lies within the orbit of the earth. For if it moved in an orbit exterior to that of the earth, it could never present to us either a half moon or a crescent phase. At the period to which we allude, the greater part of the learned had adopted the vulgar opinion which so long prevailed, that the earth is at rest in the center of the universe, and that all the planets revolve around it. It was objected to the Copernican system, which supposes the earth to be one of the planets—and which had been recently broached—that if this were the case, the planets Mercury and Venus would appear with all the phases of the moon. This was fully admitted; but it could never be exhibited to the organs of vision before the telescope was invented When Galileo had published this and several other discoveries, the senators of Venice, who were most of them eminent for their love of learning, invited this astronomer to come, and in their presence make a trial of his new instrument. He complied with their request; and, on a fine, clear, and serene evening, mounted his telescope on the tower of St. Mark, and showed them several of the discoveries he had made, and particularly the appearance of Venus, which was then near the point of its greatest elongation from the sun. One senator after another beheld the planet through the telescope, and all were surprised that more than half of its hemisphere was obscured; that it did not appear round, as most of the other heavenly orbs, but inclining to a crescent, with points, or horns, at its opposite sides. Upon this Galileo proceeded to show how this phenomenon furnished a demonstrative proof of the Copernican system of the universe. That night was fatal to the ancient systems maintained in the schools; and from that period, the true system of the world began to be recognized by all intelligent and unprejudiced minds, and, in the midst of every opposition, to be extensively propagated through the world.

After the telescope was improved, and its length and magnifying powers increased, more particular observations began to be made on the surface of Venus. Cassini, an Italian astronomer, with instruments of a large size, on October 14th, 1666, at 5h. 45m., P. M., saw a small bright spot, near the section between the dark and bright side of the planet; at the same time he noticed two dark oblong spots nearer the other side of the disc, as represented in fig. 18. On the 20th of April, 1667, in the morning, a little before sunrise, he perceived, on the disc of the planet, then half enlightened, a bright spot near the section and toward the lower horn; and nearer to the northern horn he saw a darkish oblong spot, as represented in fig. 19; and after sunrise, he perceived that the bright spot was advanced considerably from the southern horn; and from this and several subsequent observations, he had a plain proof of the rotation of the planet, which he afterward determined to be in the space of somewhat more than twenty-three hours. For many years after this period, we have few recorded observations of these spots; and, indeed, they are very difficult to be perceived, on account of the extreme brilliancy which this planet exhibits, and the undulations of the atmosphere, when viewed at a low altitude in the evening. The best time for viewing the surface of this planet is in the day-time, when it is near the meridian, by means of large equatorial telescopes.

M. Schroeter, a late celebrated German astronomer, made a variety of observations on this planet, from which he has deduced several important conclusions. He discovered the twilight of Venus, or the stretching of a faint light beyond the semicircle which ought to be alone directly enlightened, as shown at fig. 20, where the cusps or horns seem to stretch into the dark hemisphere. He deduced from this, and other observations, that Venus has an atmosphere of considerable extent, the densest part of which is above three miles high. A similar conclusion was deduced by a variety of observers in different places, when viewing the transit of this planet in 1761. At the time when the planet entered on the sun's disc, and when it was about to emerge from the eastern limb, a faint penumbra or dusky shade was seen surrounding the planet, which indicated an atmosphere of considerable hight. M. Schroeter likewise detected several mountain ridges, and elevations of great magnitude on the surface of Venus. Such elevations are ascertained from the length of their shadows. He estimated the perpendicular hight of one of these mountains to be ten and a half English miles, and of another no less than nineteen miles. Although these elevations so far surpass the hight of the highest mountains on our globe, yet such estimates are not to be considered on this account as improbable. For, in nature, there is an infinite variety, and every planet differs from another in its arrangements. Such lofty elevations will add to the sublimity of nature on the surface of this planet, and will afford, from their summits, prospects far more extensive and sublime than we can at present conceive.

Apparent motions of Venus.—Were the planets viewed from the sun, the center of the system, their motions would appear nearly uniform, and in one direction, from west to east. But when viewed from the earth, or any other planet, their motions appear very irregular, and in different directions, and sometimes they appear to make a pause in their course. Hence the apparent motions of the planets, as viewed from the earth, are said to be either direct, retrograde, or stationary. This may be illustrated in the apparent motions of Venus, and what is here stated of this planet will equally apply to the motion of Mercury. Thus, in fig. 21, let S represent the sun, E the earth, and *a*, *b*, *c*, *d*, *e*, *f*, *g*, *h*, the planet Venus in different parts of its orbit, as seen from the earth at E. When it is at *a*, it is said to be in its inferior conjunction with the sun, because it is then nearly in a line with the sun; and were it visible, it would be seen nearly in the same part of the heavens as the sun. But at this time its dark hemisphere is turned toward the earth, and therefore is invisible unless it should happen, as it sometimes does, to pass across the disc of the sun. In moving from *a* to *b*, its motion is retrograde, or toward the west. In moving from *b* to *c*, it appears stationary, because the tangent line, or visual ray *b i*, will appear for some time to coincide with the orbit of the planet. At *c* the planet is said to be at its greatest western elongation from the sun, when it appears in its greatest brightness as a morning star. In passing from *c* to *d*, and from *d* to *e*, its motion is direct, or from west to east. At *e* is the point of its superior conjunction, when it is again nearly in a line with the sun, and when its full enlightened hemisphere is turned toward the earth. But at this point it is the whole diameter of its orbit, or one hundred and thirty-six millions of miles farther from the earth than when it was at *a*, and therefore appears smaller near this position than when only the one-fourth of its enlightened side is seen. From *e* to *f*, and from *f* to *g*, the motion is still direct; from *g* to *h*, it is again stationary, and from *h* to *a* retrograde.

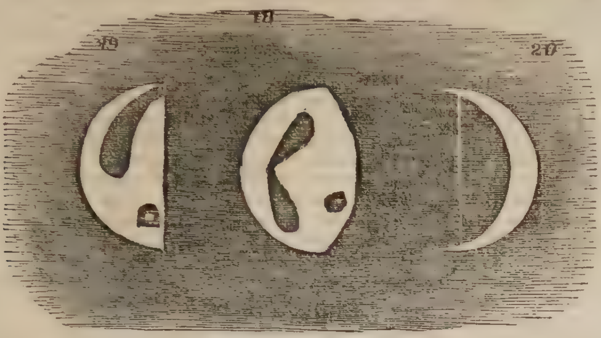


Fig. 21.

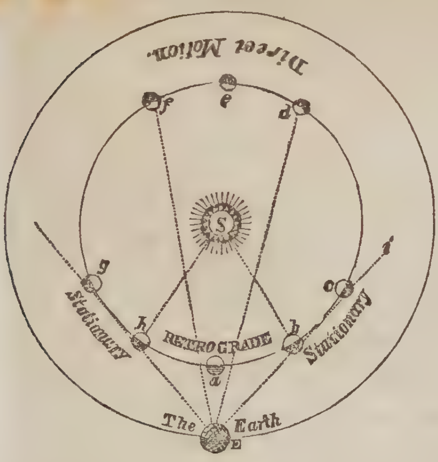

In regard to the *phases* of Venus we may add the following remarks. When the planet is at *e*, at its superior conjunction, if it could then be seen,* it would present a full enlightened hemisphere. As it moves from *e* to *f*, it gradually comes into view as an evening star, and at first appears very low near the point of the horizon where the sun sets. Its motion appears slow on account of its distance from the earth, and it is sometimes two or three months, after passing the point of its conjunction, before it becomes distinctly visible to the naked eye. When it comes to the point *f* it exhibits a gibbous phase, as seen by the telescope. As it moves onward toward *g*, its apparent size increases, and its gibbous phase gradually declines to that of a half-moon. At *g* it appears like a half-moon inclining to a crescent. About this point of its orbit is the period of its greatest brilliancy, and in certain years, when in this position, it may be seen in the day-time by the naked eye. At the point *h*, it appears of a crescent form, and while moving from *h* to *a*, the point of its inferior conjunction, its crescent becomes more slender, but at the same time more expansive, until it appears like the crescent of the moon when she is less than two days old. At *a* the dark side of the planet is turned toward the earth, and consequently invisible. The period employed in passing through these changes, from *e* to *a*, is about nine months and a half. In passing through the other semicircle from *a* to *b*, *c*, *d*, *e*, it becomes a morning star, and, a few days after the conjunction, is seen in the east preceding the rising sun. In proceeding from *a* to *b* and *c*, its apparent motion is rapid, and it presents a crescent phase; at *c* it appears like a half-moon, and in the remaining part of its course to *e* its phase is gibbous, until it arrives at the superior conjunction, when it again presents a full enlightened hemisphere. The time employed in moving from the inferior to the superior conjunction is, as formerly, about nine months and a half.

---

* It has been frequently asserted by astronomical writers that this planet cannot be seen at its superior conjunction. The author of this volume, however, in the course of his observations on the heavenly bodies in the day-time, had an opportunity on the 2d of October 1843, of seeing this planet within a few minutes of the time of its superior conjunction, when it was only 58 minutes, or less than 1 degree from the sun's margin. It was viewed with a three-feet-and-a-half achromatic telescope, magnifying 95 times, and appeared round and perfectly distinct, though partly immersed in the solar rays. This circumstance proves that the surface of Venus reflects the solar rays with peculiar brilliancy, more than that of any other planet. For a more particular account of this observation, see "Edinburgh New Philosophical Journal" for January, 1844.

The following figures represent the phases of this planet, and its gradual increase of apparent size from the period of its superior conjunction to its inferior. Fig. 22 is its phase as a full enlightened hemisphere, and its proportional size when compared with fig. 30, which represents it, when nearest the earth at its inferior conjunction. At this time it is five times nearer, and consequently five times larger in diameter, and twenty-five times larger in surface than it appears at its superior conjunction. Figs. 23, 24, 25, represent different degrees of its gibbous phase; 26, its half-moon phase; 27, 28, 29, its crescent phase; where it will be seen, that as the breadth of the crescent diminishes, its expansion and length increase, as it is then approaching nearer the earth. Fig. 30 represents its dark side turned toward us at the inferior conjunction. In moving from the inferior to the superior conjunction, it passes through all these phases in a reverse order. First it appears as 29, then as 28, and until it arrives at the phase fig. 22.

30

We shall state only the following additional fact respecting this planet. The period of its revolution round the sun is in 224 days 16 hours, during which time it accomplishes a course of 434 millions of miles, at the rate of eighty thousand miles an hour. Its orbit is inclined to the ecliptic in an angle of three degrees twenty-three minutes and a half, and the eccentricity of its orbit is less than half a million of miles, or about the 1-276th of its diameter. On the ground of certain observations, it has been supposed that it is attended with a satellite; but such a body, if it exist, is seldom seen, and therefore its existence is considered as uncertain. In its elongations, it never removes farther from the sun than from forty-five degrees to forty-seven degrees. If its enlightened side were turned toward us when it is nearest the earth, it would present a surface twenty-five times larger than it generally does and shine with the splendor of a small moon; but, at that time, its dark side is turned to the earth. To an inhabitant of Venus, Mercury will appear as a morning and evening star, with more splendor than it does to us; and the earth, when nearest to Venus, will shine forth with a splendor nearly ten times greater than either Jupiter or Venus does to us. This planet, like Mercury, sometimes makes a transit across the disc of the sun. The last transit happened in 1769, and the next will take place on December 9, 1874, at eight minutes past four, A. M., which will be invisible in Britain, and in most European countries; but, as it is a phenomenon of great importance in astronomy, British astronomers will doubtless, be sent to observe it in those countries where it will be visible.

This beautiful planet, distinguished from all the other stars by its superior brilliancy, is occasionally alluded to by the sacred writers, as the "son of the morning"—"the day star," and "the bright and morning star:" emblematical of the Redeemer of mankind, giving light to the world after a long night of superstition and darkness, and of its cheering influence on the minds of sinful men, when the "day star" from on high hath arisen in their hearts. When viewing the bright luminaries of the sky, and especially the morning star, and when we consider the beautiful order and arrangement of these orbs, the placid influences they diffuse, and the harmony with which all their movements are performed, a contemplative mind can scarcely refrain from contrasting such scenes with the darkness and disorder which prevail in the moral world. While the sun diffuses his splendor by day, and the moon and the stars shed their mild radiance by night, it is still necessary to the happiness of our world that intellectual light and sacred joy should be diffused over the minds of its inhabitants—of which the light of these luminaries is designed to serve as an emblem. When the morning star makes its appearance near the eastern horizon, it is a sign that the sun will, ere long, arise, and that the darkness of night will soon be dispelled. When the "day star" arises on the benighted mind, it intimates that gloom and darkness, with all their miserable accompaniments, formerly brooded over it: but now that the light of Divine truth has begun to irradiate the darkness, it is a sign that this light will still increase, and shine "more and more unto the perfect day," until at length it blend itself with the glories of the celestial world, where the "sun shall no more go down," where the Lord God shall be an everlasting light, and where the days of darkness and "mourning shall be ended."

SECTION IV.

THE EARTH: CONSIDERED AS A PLANETARY BODY.

(1.)—*General view of the Earth's surface, atmosphere, magnitude, and method of finding its dimensions.*

It may seem strange to some readers that this world on which we reside should be considered a planetary orb; as, at first view, it appears to bear no resemblance to any of the orbs that appear in our nocturnal sky. The planets, as they are seen in the heavens, by the unassisted eye, appear only as comparatively small points of light; whereas the earth, from whatever point it is viewed, appears the largest body our eyes can anywhere behold, and when we traverse its surface, either by sea or land, there appear no boundaries to its dimensions. From the positions in which we are permitted to view any portion of the earth—even when we ascend several miles above its surface n balloons—it exhibits no luminous aspect such as that which the celestial bodies present; so that, at first view, we might be apt to suppose that no similarity can exist between our sublunary world and the orbs of heaven. Beside, the celestial orbs are apparently in rapid motion from one region to another, while the earth, as a whole, appears to be at rest in the center of the celestial motions. Whether we sit in our apartments, or walk in the fields, we feel no motion in the solid earth which supports us, and are apt to imagine that the portion of the globe on which we dwell remains invariably in the same point of infinite space. We perceive no motions connected with our world but those which are produced by the rivers, the ocean, the atmosphere, and subterranean concussions, and those which are the result of the various processes of the arts—the flux and reflux of the sea—the flowing streams—the roaring cataracts—the stormy winds—the waving forests—the ships moving on the face of the deep—and the steam-carriages, with their hundreds of passengers flying along the railway course. There is not, perhaps, one out of a thousand of the earth's inhabitants that has the least conception that—beside every other movement of which he is susceptible—he is carried along through the regions of infinite space with the rapidity of thousands of miles every hour. Yet this is a fact which is not merely probable, but certain, and can be demonstrated to the conviction of every one who is willing and qualified to enter into such investigations.

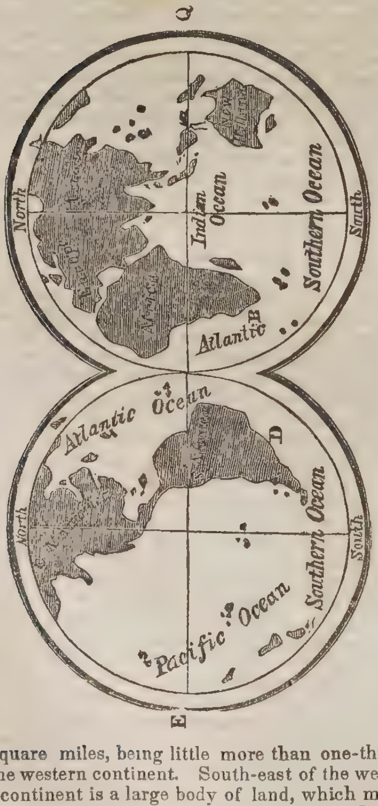
Could we take our station on the surface of the moon, we should behold the earth hanging like a great globe in the firmament, appearing with a surface about thirteen times larger than the moon does to us, and turning round its different sides to our eye—sometimes presenting the view of Ame-ca and the Pacific Ocean, and at other times, Asia, Africa, Europe, and the Atlantic—sometimes appearing like a large crescent, or half moon, and at other times with a full enlightened hemisphere Were we placed on the surface of Venus, we should behold the globe on which we live appearing in the azure sky like a large, bright star, as that planet appears to us when an evening or morning star; and the moon, which appears so large in our firmament, would be seen only like a very small star, very near the earth, and constantly moving around it. At certain times, the earth would appear nearly ten times larger than Venus does to us, and would present the appearance of a small brilliant moon. Were we placed on the planet Mars which, is much farther from the sun than Venus the Earth would appear alternately as a morning and evening star, exhibiting different phases, as Venus does to us, but with a less degree of size and splendor. It might not, perhaps, shine with so much brilliancy as Venus, but it would probably appear with a luster similar to that which Mars presents to us. Nor need it be wondered at that the earth should appear as a luminous body from such distant positions; for we have demonstrative proof that Venus, Mars, and all the other planets, though they appear like shining orbs, are in reality dark bodies like the earth, and have no light of their own but what they receive from the sun; and it is only when the portions of their sides which are enlightened by the sun are turned to us that they are seen in the heavens. On some occasions, the dark side of Venus is completely turned toward the earth, and then she is invisible; and sometimes, when in this position, has been seen, like a dark spot, to pass across the face of the sun. These and other circumstances demonstrate that the planets are in themselves dark bodies, and shine only by reflection; and consequently that the earth, though a dark body, will appear to shine at a distance by reflecting the solar rays which fall upon it, as the moon does to us.

We have already proved, that, as a planet, the earth turns round its axis every twenty-four hours; and, in the sequel, we shall endeavor to show that it also moves round the sun in company with the other planets. In the meantime, we may take a brief view of the surface of our globe, which, in some of its features, may, perhaps, resemble those of some of the other planetary worlds.

When we cast our eyes around us, and take a general survey of the surface of the earth, thousands of objects present themselves to the view which demand attention. One of the most obvious and common arrangements which we behold in almost every country, is the verdant covering of the earth, which is formed by an assemblage of herbs, plants, shrubs, and trees of various shades, which diversify the landscape, and refresh the organs of vision; for there is no color so pleasing, and which refreshes the eye so much as the various shades of green. When we enlarge the circle of our view by traveling through different countries, we behold objects of a more grand and magnificent description; ranges of mountains, hundreds of miles in length, with their summits rising above the clouds, presenting a scene of rugged grandeur and sublimity; rivers, rolling their vast masses of waters, in courses of hundreds or thousands o. miles toward the ocean, in which they are absorbed; the ocean itself, in its numerous windings, spreading its immense sheet of waters over more than half the globe, rising and subsiding at certain intervals, and forming a medium of communication between the most distant regions of the globe. In various regions of the earth, we behold expansive lakes and inland seas diversified with numerous islands, lofty and abrupt precipices, capes and promontories, dashing cataracts, unfathomable caverns, rapid whirlpools, avalanches hurling down the declivities of lofty mountains, the icebergs of the polar regions, the luxuriant scenes of the torrid zone, and numerous volcanoes surrounded with smoke, and pouring forth from their craters, ashes, flames, red-hot stones, and streams of melted lava on the surrounding regions.

When we contemplate our globe in its largest and most general features, we find its surface divided from north to south by two large bands of earth, and two still larger bands of water, which exhibit a somewhat irregular appearance, presenting a number of wavings and indentations, and a great difference of breadth in different places. The first band of earth is the Eastern Continent, comprehending Europe, Asia, and Africa, the greatest length of which is in a line beginning about the northern part of Tartary, and extending to the Cape of Good Hope, or from A to B, fig. 31, which line measures about 10,000 miles from north-east to south-west. This body of land contains thirty-six millions of square miles, forming nearly one-fifth of the surface of the terraqueous globe. The other band of earth is the Western Continent, which comprehends North and South America. Its greatest length is in a line from the mouth of the river Plata, in South America, to the land beyond Hudson's bay, or from C to D. This line measures eight thousand miles; and the whole of this continent contains fourteen millions of square miles, being little more than one-third of the western continent. South-east of the western continent is a large body of land, which may be considered as a third continent; namely, New Holland, which is 2400 miles in length, and 1800 in breadth, and contains nearly three millions of square miles. Beside the bands of earth now specified, there are numerous extensive portions of land dispersed throughout the ocean, such as the islands of Madagascar, Sumatra, Borneo, New Guinea, Great Britain, Ireland, and hundreds of others.

Fig. 31.



Between the two large continents now stated, lie two immense bands of water, which are called the Pacific and the Atlantic oceans. The Pacific is at least 11,000 miles from north to south, and 10,000 miles in breadth from east to west. The Atlantic is about 3000 miles broad from east to west, and more than 10,000 miles in length from north to south. It lies between the western shores of Europe and Africa, and the eastern shores of America. The Pacific occupies the whole range between the western coasts of America and the eastern coasts of Asia, occupying nearly the one-half of the globe. The relative positions of these continents and oceans will be seen by an inspection of fig. 31, where it may be noticed that the projections of the eastern side of the American continent nearly correspond with the indentations of the western side of the eastern continent; so that, if we could conceive the two continents brought together, they would nearly correspond, so as to form one compact continent, with two or three small gulfs between them. The following are nearly the dimensions of the different oceans. The Pacific covers eighty millions of square miles; which is far more than the extent of all the dry land on the face of the earth. The Atlantic covers twenty-five millions; the Indian ocean, thirteen millions; the Southern ocean, twenty-five millions; the Northern ocean, five millions; the Mediterranean, one million; the Black Sea, 170,000 square miles; the Baltic, 175,000; the North Sea, 160,000. And if, as La Place has estimated, the tides demand an average depth of three miles, the whole ocean will contain 450 millions of cubic miles. The whole surface of the ocean, then, contains about 149 millions of square miles, which is more than three times greater than the surface of the land, which contains only forty-nine millions of square miles.

Around this vast body of land and water the Creator has thrown an atmosphere, or body of air, which is as essential to the existence and comfort of the living beings that dwell on its surface, as any other arrangement respecting our world. The denser part of this body of air extends to the hight of about forty-five miles above the surface of the earth, but its density gradually decreases in proportion as we ascend into its higher regions; and at a certain hight it is unfit for respiration and giving play to the animal functions. This atmosphere, though almost impalpable to our senses, is now ascertained to be a compound substance, composed of two very different and almost opposite substances, as to their qualities. One of its ingredients, which forms about four-fifths of the whole atmosphere, is of such a nature that no fire will burn in it, and if man or other animals breathe it, life is almost instantly extinguished. The other ingredient, which forms only one-fifth of the atmosphere, is the principle of combustion, and produces the most rapid and splendid deflagration of all combustible substances, and even a steel wire, made red hot, if plunged into this species of air, will take fire and burn with the utmost brilliancy. Animals might breathe it for some time without much annoyance; but it would soon waste the functions of the animal system It is by an admirable combination of these two opposite principles that the air we breathe is constituted; and in this combination, the wisdom and goodness of our beneficent Creator is clearly manifested; for had these principles been combined in a very different proportion, pain, suffocation, or death might have been produced in all animals that breathed it. It is in this atmosphere that the birds fly, and the clouds are suspended—where rain, hail, and snow are formed—where a portion of the ocean, of the seas, and of the rivers, is continually ascending, to form those clouds which water and fructify the earth—it is the medium in which whirlwinds rage, and lightnings flash, and thunders roll; and were it swept from the earth, or were its constituent principles materially changed, every living being would soon disappear from all the regions of earth, air, and sea. Were the Creator disposed to destroy the human race on account of their transgressions, he has only to extract one of the ingredients which compose the atmosphere which surrounds us, and the awful catastrophe is at once accomplished; so that, in his "hand is the soul of every living thing, and the breath of all mankind." But his forbearance, in this respect, is a palpable evidence that he is "slow to anger," "merciful and gracious," "abundant in goodness," and that "his tender mercies are over all his works."

In regard to the *magnitude* of the earth, it may be stated that its circumference, or a line going quite round it, measures about 24,912 miles; and, of course, its diameter, or a line passing from one side to another through its center, measures 7930 miles,* and the number of square miles on its surface is about 197 millions. It has been ascertained, by various experiments and measurements, that the earth, strictly speaking, is not exactly of the shape of a globe, but of an oblate spheroid, being somewhat flattened at the poles, and having its polar diameter about twenty-six miles shorter than the diameter passing through the equator. But the difference is so small, compared with the whole bulk of the earth, that though a spheroid were constructed of the exact shape of the earth, and fifteen feet in diameter, it could not be distinguished by the eye from a common globe.

To some readers it may appear somewhat strange that we should speak with so much confidence of the bulk and dimensions of the world we live in, which has never yet been completely explored; and they may, perhaps, wish to know how it is possible to determine its magnitude, figure, and other properties and relations. It must be confessed that to measure the earth, and determine its magnitude, and its exact figure, is one of the most wonderful enterprises which has ever been undertaken by man. How shall a creature, only six feet high, whose longest measures are yards, poles, and chains, be able to traverse every region of this great world, and measure its dimensions? His stature and his longest measures are, when compared with the whole earth, but as a grain of sand to a range of mountains. Beside, there are portions of the earth which have never yet been reached either by sea or land; and although he were to carry his measuring lines along with him, and extend them to furlongs, miles, and leagues, yet he could not go round the circumference of the earth to obtain its exact measure. Mountains, rivers, seas, and oceans, and many other obstacles would be continual impediments in his way, and would soon put an entire stop to his progress, and the attainment of his object. But, notwithstanding such difficulties, man, by the exercise of his rational powers, and the knowledge he has acquired of the positions and motions of the heavenly bodies, has been enabled to determine, to a very near approximation, the exact dimensions of his earthly habitation, without putting himself to the trouble of traveling to the most distant regions, or even removing from the land of his nativity.

When the earth was ascertained to be nearly of a globular figure, and when the method was discovered of finding the distance of any place from the equator,* or, in other words, its latitude, a foundation was laid for finding the circumference, and other dimensions of the globe. Every circle, or every circumference of a sphere, whether great or small, is divided into three hundred and sixty equal parts. This number, three hundred and sixty, is arbitrary, and any other number, such as four hundred, six hundred, or one thousand, might have been fixed upon; but mathematicians, in most countries, have fixed upon three hundred and sixty as the number of degrees or divisions in a circle; because, in the first place, it was formerly supposed to be about the number of days in a year, and in the next place, because it is a number that may be divided into halves, quarters, and eighths, without fractions. Now, in order to obtain the dimensions of the earth, it was only necessary that one degree on its surface should be accurately measured in order to obtain the whole circumference. To accomplish this, we must draw a meridian line —that is, a line that runs directly north and south, at any place we make choice of for the first station, and find the latitude or hight of the pole at that particular place. We must then prolong the meridian line, either northward, until we come to a place where the latitude is exactly one degree more—or southward, until it is one degree less than at the first station. We must then measure the distance between these two places, in miles, leagues, yards, or any other known measures; and then we obtain the number of miles, etc., contained in one degree, or the three hundred and sixtieth part of the earth's circumference; and the number of miles, etc., contained in one degree, being multiplied by three hundred and sixty, gives the whole circumference of the earth. And when the circumference is obtained, the diameter may be found by the rule given in the preceding note (p. 35). And when the circumference and diameter are known, the number of square miles on its surface, and the number of cubical miles in its solidity may be obtained by an easy calculation. But although one degree accurately measured would determine the dimensions of the earth, yet more accuracy is obtained by measuring three, five, eight, or ten degrees, as has been done by several European nations.

On the general principle now stated, Mr. Richard Norwood, in the year 1635, attempted to find the circumference of the earth by measuring a meridian line between London and York. He took the sun's altitude when in the summer solstice both at London and York, with a sextant of eight feet radius, and by that means found the difference of latitude between these two cities to be two degrees and twenty-eight minutes. He then measured their distance, in as exact a manner as possible; and having taken into the account all the turnings and windings of the road, with the ascents and descents, he reduced it to an arc of the meridian, and found it to contain 12,849 chains; and this distance being compared with the difference of latitude, gave 5,209 chains, or 367,200 English feet to a degree, which is equal to sixty-nine and a half miles and fourteen poles, and which was considered as a near approximation to the truth, according to which the circumference of the earth would be about 25,035 miles. Since his time, various admeasurements have been made of different parts of the earth's surface, from which its extent has been still more accurately ascertained. The French have measured a meridian line extending from Dunkirk to Formentara, an island in the Mediterranean, an extent of about eight degrees; and a trigonometrical survey, for the same purpose, under the direction of the British Government, has lately been extended over Great Britain. From all the admeasurements hitherto made, it appears that, on an average, a degree of the meridian may be reckoned at sixty-nine and one-fifth English miles; which makes the circumference of the globe 24,912 miles. It may just be noticed further, on this point, that, as the earth is not an exact sphere, but a spheroid, a degree of latitude must measure more in the polar regions than near the equator. From actual measurements, it has been found that a degree of the meridian in Lapland, measures six and a half English furlongs more than a degree at the equator.

---

* As the circumference of a circle or globe is found by mathematicians to bear a certain definite proportion to the diameter—when the one is known the other is easily determined by calculation. The proportion of the circumference of a circle to its diameter is nearly as 22 to 7—more accurately as 3.1416 to 1. Therefore, if we multiply the circumference by 7, and divide the product by 22, we obtain the diameter, nearly. And if we multiply the diameter by 22, and divide by 7, we obtain the circumference. But we obtain the result more accurately by multiplying the diameter by 3.1416, in order to obtain the circumference; and by dividing the circumference by 3.1416, to obtain the diameter.

* The equator is a great circle of the earth, equally distant from the north and south poles, and divides the globe into two equal parts called the northern and southern hemispheres. From this circle the latitudes of places are counted, either northward or southward. It is represented by the line E Q, in fig. 31.

2.—*Proofs of the annual motion of the Earth.*

We have formerly demonstrated the diurnal rotation of the earth, which causes the appearance of the rising and setting of the sun, moon, and stars. We now proceed to state very briefly some of those considerations or arguments by which it is proved that the earth revolves round the sun, as the center of the system, once every year.

In the first place, there are certain general considerations that render it highly probable, if not certain, that the earth must have a motion round the sun. If we admit the annual motion of the earth, then all the phenomena of the heavens, and the apparent irregularities of the planetary motions are completely accounted for, and the whole system presents a scene of unity, harmony, and order, worthy of the perfections and the plans of Him who is "the only wise God,"—who "hath established the world by his wisdom, and hath stretched out the heavens by his understanding." Whereas if the earth be supposed at rest in the center of the system, the order and harmony of the solar system appears completely destroyed, the motions of the planets present an inextricable maze, their phenomena cannot be accounted for on any rational principles, and no evidence of wisdom can be traced in the arrangements of the system to which they belong. Again, the sun is the fountain of light and heat for irradiating and cheering all the planets and other moving bodies of the system, and therefore it is necessary that this luminous orb should be placed in the center, from which position alone its rays can be distributed in proper proportions to all the worlds which revolve around it. Were the earth at rest in the center of the system, and the sun and the planets revolving around it, as was formerly supposed, the planets would be at certain times at very different distances from the sun; and consequently, in one part of their orbits, they would be scorched with superabundant heat, and in another part frozen with insufferable cold. But from the center of the system the emanations of light and heat can be equally distributed to all the planets, whether primary or secondary; and the whole presents to view a system of harmony and order.

The following summary of arguments on this point—did our limits permit us to explain and illustrate them—would appear demonstrative to every one who is acquainted with the subject. 1. The planets Mercury and Venus are observed to have two conjunctions with the sun, but are never in opposition to that luminary, that is, they are never seen in the east, or opposite part of the heavens, when the sun has just set in the west. Now this circumstance could not possibly happen, unless the orbits of these planets lay within the orbit of the earth. If they revolved around the earth as a center, as the ancients supposed, they might frequently be seen in opposition to the sun. 2. The greatest elongation, or distance, of Mercury from the sun is twenty-nine degrees; and the greatest elongation of Venus, or the distance to which it ever recedes from the sun, is forty-eight degrees, which correspond exactly with the distances assigned them in the system; but if they moved round the earth as a center, they would sometimes be seen one hundred and eighty degrees from the sun,—a circumstance which was never observed either in ancient or modern times. 3. The planets, Mars, Jupiter, and Saturn, and all the other superior planets, have each their conjunctions with the sun, and oppositions to him, which could not be unless their orbits were exterior to the orbit of the earth. 4. In the arrangement of the planets—according to the system which places the sun in the center—they will all be sometimes much nearer the earth than at other times; and, consequently, their brightness and apparent diameters will be proportionally greater at one period than at another, which corresponds with every day's observations. But according to the system which places the earth in the center, their apparent magnitudes should always be the same, which is contrary to fact; the planet Mars, for instance, being in one part of its course, five times nearer the earth than in another, and consequently appearing twenty-five times larger in surface. 5. All the planets, in their movements through the heavens, are seen sometimes to move toward the east, sometimes toward the west; and at certain points of their orbits, they appear fixed for some time in the same position; all which diversities of apparent motion are the necessary results of the earth's annual motion, and are completely accounted for, when the sun is considered as the center of the system, and the earth as revolving between the orbits of Mars and Venus. But they are altogether inexplicable, on the supposition that the earth is at rest in the center of the system. 6. When the planets Mercury and Venus are viewed through good telescopes, they are found to assume different phases, in different parts of their orbits, sometimes appearing gibbous, sometimes like a half moon, and at other times like a crescent, or a full enlightened hemisphere—as formerly explained; which could never happen, if they revolved round the earth as their center, and if the earth were not placed in an orbit exterior to that of Venus. But such phases are the necessary result of this position of the earth in the solar system. 7. The law discovered by Kepler, that "the squares of the periodic times of the revolutions of the planets are in proportion to the cubes of their mean distances from the sun," is a law which is established on the most accurate observations, and by which all the planets, both primary and secondary, are regulated. For example, Venus revolves round the sun in 224 days, and the earth in 365, and the mean distance of the earth from the sun is ninety-five millions of miles. Hence, as the square of 365=133,225, is to the square of 224=50,176, so is the cube of 95,000,000=857,375,000,000,000,000,000,000 to a fourth number, which is the cube of the mean distance of Venus from the sun. And if the cube root of this number be found, it will give about sixty-eight millions of miles for her real mean distance. But this law, which applies to all the heavenly bodies without exception, is completely set aside and destroyed, were the sun and planets to be considered as moving round the earth as the center of their motions. In short, were we to suppose the earth at rest in the center of the planetary system, the motions of all the planets would present a scene of inextricable confusion—a scene of such disorder and confusion, as would puzzle not only man, but the most intelligent archangel to account for, and to explain in consistency with the perfections of a Being of infinite wisdom and intelligence.*

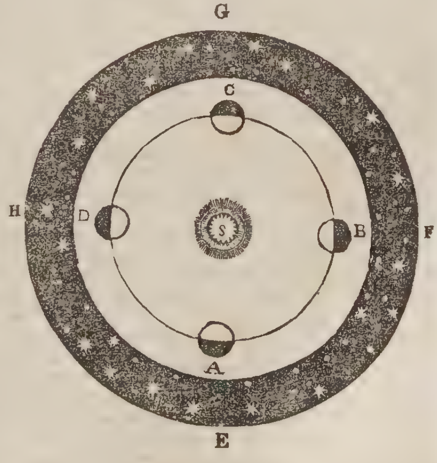
The most complete and sensible demonstration of the annual motion of the earth is furnished by Dr. Bradley's discovery of "the aberration of the light of the fixed stars." In endeavoring to determine the annual parallax of the stars, he discovered that they are not motionless, but that, during the time the earth takes to traverse its orbit, such of them as are in a plane perpendicular to this orbit, appear to describe circles. This is the phenomenon called "the aberration of light," which is found to be the motion of light combined with the progressive motion of the earth in its orbit, which causes the stars to be seen in a different position from what they would be if the eye were at rest. But as the explanation of this phenomenon would require some minute details, and several figures for its illustration, and as it might not be understood by general readers, we will defer in the meantime from entering upon any further statements. We may just remark, that the fact of the aberration of the stars exhibits the motion of the earth to our senses as clearly as if, from a fixed point in the heavens, we actually beheld it pursuing its course through the ethereal regions.

It is of importance that we acquire clear and convincing views on this subject, in order that we may entertain correct and honorable conceptions of the perfections of the Creator, and of the wisdom and intelligence displayed in the arrangements of his works. For, in all cases, we judge of the character and perfections of the designer and workman from the qualities and perfections which appear in their works. If we view the works of the Almighty through a distorted medium, we shall be apt to entertain incorrect and distorted views of the attributes of Him who designed and formed them. If we view the earth as at rest in the center of creation, and the sun, moon, planets, comets, and stars—in other words, the whole universe—revolving around us every day, with motions so rapid as to exceed all calculation and comprehension; or if we suppose the planets moving backward and forward without any order, and presenting in their motions a series of looped curves and mazes without any marks of design, and exhibting a scene of inextricable confusion; we should scarcely be led to entertain high and honorable conceptions of the wisdom of Him who formed such arrangements; for the marks of Divine intelligence, on such suppositions, would nowhere appear. Whereas, in the true system of the universe which science has laid open, the marks of wisdom and intelligence, harmony and design, are everywhere apparent, and present a scene of operation worthy of the perfections of Him who "established the world by his wisdom," and whose "understanding is infinite." Hence the necessity of acquiring correct views of the works of creation and providence, and of the arrangements which exist in reference to our world, and to the universe around us; for upon such views our conceptions of the great object of our adoration will, in a great measure, depend. When, therefore, we obey the Divine command and "lift up our eyes on high, and behold the wonders of Almighty Power," and "stand still and consider the wonderful works of God," we are to contemplate them, not through the mists of ignorance, or vulgar prejudice, nor with the vacant stare of a savage; but with the eye of a Christian philosopher, and through the light which modern science has diffused over the wonders of creation; and the more we contemplate them in this light, the more clear and expansive will our conceptions be of the attributes of the "high and lofty One who inhabiteth eternity," and who presides over all the movements of the universe.

(3.)—*Phenomena arising from the annual motion of the earth.*

In the first place, if the earth revolve around the sun once every year, it is evident that the sun will appear to make a revolution round the heavens in the same period. In fig 32, let S represent the sun at rest in the center, and A B C D the earth in four positions; and let us suppose the earth to move in the order of the letters A B C D;

Fig. 32.



---

* Those who would wish to see a full illustration of the above arguments are referred to "Celestial Scenery, or the Wonders of the Planetary System Displayed;" [Vol. II, Book 2, of this edition,] where these and several other arguments are illustrated in minute detail, and by reference to engravings.

it is evident that when the earth is at A, the sun will appear in that part of the heavens where the stars at G are situate. When the earth has moved to B, the sun will appear to have moved to the stars opposite H; and in like manner, when the earth has moved to C, the sun will appear opposite to E; and when it has moved to D, the sun will appear at F; after which it will again appear at G, when the earth has moved to A. And as the earth revolves around the sun in the orbit A B C D, so the sun will appear to a spectator on the earth to describe the circle in the heavens E F G H. Hence it is that we see the sun gradually proceeding in his course round the concave of the sky from west to east at the rate of nearly one degree every day, through the twelve signs or constellations of the zodiac; and at the end of a year, he returns to the same point from which he set out. Hence also it follows, that if the plane of the earth's orbit be imagined to be extended to the heavens, it would cut the starry firmament in that very circle in which a spectator in the sun would see the earth revolve every year, while an inhabitant of the earth would observe the sun to go through the same circle in the same space of time. This circle is called the Ecliptic, or the apparent path of the sun through the heavens. And, although the path of the sun, and the particular stars he is passing along, cannot be seen in the day-time, yet, from observing the stars that are directly opposite to him at night, we can tell at any time what particular stars the sun is passing along in every part of his course.

The inhabitants of all the other planets will perceive similar motions in the sun as we observed, but performed in different periods of time, according to the times of their annual revolutions. For example, an inhabitant of Jupiter would see the sun apparently revolving around him, describing a circle in the heavens in the space of twelve years. This circle would not be exactly the same as our ecliptic, because the orbit of this planet is somewhat inclined to the orbit of the earth; but it would pass very near it. In the course of one of our years the sun, from Jupiter, would appear to pass through only a twelfth part of the circumference of the heavens. The sun from Saturn will appear to move in another circle in twenty-nine years and a half; and a spectator in Venus will see the sun moving in a circle different from all these, with greater apparent rapidity, in the space of seven and a half months. All these apparent motions of the sun arise from the real motions of the respective planets.

In the next place, the annual revolution of the earth shows the reason why we behold one set of stars in our firmament at one season of the year, and another set of stars at a different season. For example, in our latitude, the stars, and constellations which are seen during the winter months, in the south, are altogether different from those which are seen in summer; and those stars which surround the pole in the north, and which never set, if they are below the pole in winter, they will be seen as far above the pole in summer. At the equator, where all the stars rise and set, the stars which appear in the middle of winter are all completely different from those which are seen at the same hour in the middle of summer. This is easily explained by the preceding diagram (fig. 32), in which the earth, in four situations in its orbit, appears half enlightened and half in the dark, representing day and night. When it is at A, the sun will appear at noon at G, and obscure all the stars in the hemisphere F G H; whereas at midnight the point of the heavens E will be in the meridian, and all the stars in the other hemisphere F E H will be visible. Three months afterward, when the earth comes to the situation B; the sun at noon will be seen at H, and all the heavens G H E will be day, illuminated by the sun; and over all the other half E F G, the stars will shine at night. Consequently, the stars in the quarter F G will now be visible, which in the former position were obscured by the sun, and those in the quarter H E, formerly visible, will become obscured by day-light. In like manner, when the earth is at C, the heavens H E F will be day, and F G H night, where all the stars which were obscured, when the earth was at A, will now be visible. And, lastly, when the earth is at D, the stars and constellations in the hemisphere E F G, will be obscured by the light of the sun, and those on G H E will be visible during the night. Hence, every one who is accustomed to look at the heavens will have observed that the bright constellation Orion, the brilliant star Sirius, which follows it, and the Pleiades, or seven stars, which are visible in the southern part of the firmament during winter and the approach of spring, are never seen during the summer months, because the sun is then illuminating that portion of the heavens where they are situate; but they may be seen in the day-time by means of equatorial telescopes.

(4.)—*On the destination of the earth, or the final cause of its creation.*

In the creation of the material universe, the Creator must have had some grand designs in view, beside the mere formation of immense globes of matter and setting them in motion and arranging them into systems. In so far as we are able to penetrate, it appears demonstrable that matter exists chiefly, if not solely, for the sake of sentient and intellectual beings. This evidently appears to have been the chief design for which our globe was created; and we have the strongest reason to conclude that this was the main end for which all the other planetary globes belonging to the solar system and to other systems, were brought into existence. Hence it is declared in the sacred oracles, when reference is made to the formation of our globe, "God formed the earth and made it;—he created it not in vain; he formed it to be inhabited;" which evidently implies, that to have created it without the design of its being inhabited, would have been an instance of folly inconsistent with the perfections of Him whose wisdom and intelligence are infinite; and the same reasoning will apply to all the other planets, which appear to be furnished with every accommodation adapted to sensitive and intellectual enjoyment.

In peopling the earth and other globes with inhabitants, the Creator evidently intended to give a display of his perfections to beings capable of contemplating it, and to promote their sensitive and mental enjoyment. The happiness of his creatures must have been one grand design which the Creator had in view, when he breathed into them the breath of life, and made them rational and immortal beings. Accordingly, we find that when man was at first placed upon this globe, everything that was beautiful to the eye and the imagination, and pleasant to the taste, was prepared for his accommodation and comfort. The waters were separated from the dry land—the earth was adorned with verdure—rivers and refreshing streams flowed around him to increase his pleasures—trees, and plants, and flowers of every form and hue diversified and embellished the landscape. Light was formed, and celestial luminaries appointed to diffuse its radiance—a canopy was thrown around his habitation adorned with thousands of shining orbs, to elevate his contemplations to other provinces of his Creator's dominions—every plant and tree yielding delicious fruit was provided to gratify his taste, and afford him sustenance; and all the inferior ranks of sensitive existence were placed under his dominion. One chief design of the Almighty, in these arrangements, was to show man his dependence, to make him an adorer, and a being capable of knowing and honoring his Creator and bountiful Benefactor. He gave him a law which implied supreme love to his Maker, and obedience to his will; and as an external sign of his obedience he said to him: "Behold all the trees of the garden in which I have placed thee; of every one of them thou mayest freely eat—only thou shalt forbear eating the fruit of the tree of knowledge." This reserve—which has been so frequently objected to—did in reality constitute the chief glory of man. None of the inferior animals knew their origin or their Benefactor, they could give no testimony of gratitude, nor could they exhibit any shadow of religion. Man alone was elevated to a rank, and endowed with faculties so as to know to whom he is indebted for all his enjoyments—and he alone was taught to express his gratitude to the Giver of all good! This constituted the true glory of man, and his superiority over all the other tribes of sensitive existence. It was a great and honorable prerogative conferred upon him to be able to obey his Benefactor, and to adore the hand which had loaded him with blessings: and therefore it was proper that a visible emblem of his obedience, or the contrary, should be continually before his eyes. The supreme Creator stood in no need either of the fruit of a certain tree, or of the opinions or sentiments of man respecting it. But it was fit that man should make an express profession of his gratitude and veneration: and therefore the sole exception which God made in his first transaction with man, was at once the memorial of his gratitude, and the public expression of his piety and submission to the divine will.

But we know that man did not remain in his primeval state of innocence and happiness, but by his disobedience "brought death into the world, and all our woe." For proof of this position, we have no need to enter into long trains of reasoning, or even to appeal to the records of revelation. The fact of man's fall and disobedience is written on the whole history of our world from the earliest ages to the present time. For what does the history of all nations chiefly record? It presents to our view little else than wars and commotions, contentions, and animosities, and "garments rolled in blood." One nation rising up against another, carrying fire and sword, and all the engines of destruction into a peaceful territory—laying waste provinces, burning cities, turning fruitful fields into a wilderness, and slaughtering, with diabolical fury, thousands and tens of thousands of their fellow-men. This has been one of the chief employments of all the tribes and nations that have ever dwelt on the face of the earth; and this fact, of itself, is a sufficient proof that man is no longer in his primeval condition of paradisaical innocence and rectitude, but is fallen from his high estate, and his glory turned into shame. We trust there is not another instance of creatures endowed with rational faculties, and formed after the Divine image, acting in this way, to be found among all the other worlds of the universe. And were we not accustomed to witness such infernal passions and atrocities, and to behold men glorying in that which is their shame, we should be filled with utter astonishment and wonder that such horrible actions should be perpetrated on each other by brethren of the same family, children of the same Father, and beings destined to an immortal existence.

But the benevolent Father of all did not intend that this moral derangement should be universal and perpetual. As soon as man had fallen from his allegiance to his Maker he displayed his character as a God of mercy, and ready to forgive. He declared that the seed of the woman should bruise the head of the serpent—that an illustrious Messenger, invested with Divine power and authority, should be sent into the world at a proper time, to repair the ruins of the fall; "to finish transgression, and to make an end of sins;"—to bear the sins of many, and make "intercession for the transgressors." Preparatory to the advent of this Divine Messenger, certain families were selected in which the knowledge of the true God might be preserved—a certain nation, before whom astonishing miracles had been displayed, was chosen as the depository of Divine revelations—a ceremonial worship was instituted, prefigurative of the events and blessings of Messiah's reign; prophets were raised up to announce the coming of the great Deliverer, and the glorious results of his administration—the events of Divine Providence toward the nations were overruled and directed in such a manner, as to bring about the advent of the promised Messiah in all the circumstances which prophets foretold, and which God had appointed; and, when the predicted period had arrived, a retinue of celestial messengers was dispatched from heaven to earth to announce the appearance of "the Son of the Highest," of the increase of whose government there should be no end, and to proclaim "glory to God in the highest, and on earth peace, good-will toward men." And when this Deliverer appeared on the public theater of the world, he exhibited the most convincing proofs of his Divine mission by the most astonishing and beneficent miracles, displaying his power over the laws and the elements of nature—the spirits of darkness and the disorders of the human frame—"healing all manner of sickness and disease;" causing the deaf to hear, the blind to see, the lame to walk, and the tongue of the dumb to sing—raising the dead to life, and recalling the departed spirit from the invisible world. And, at length, when the great Sacrifice for the sins of men was about to be offered, a series of the most august and striking supernatural events attended its accomplishment—the sun was clad in black, the heavens were arrayed in sackcloth, darkness for three hours covered the whole land, the vail of the Jewish temple was rent in twain from the top to the bottom, the earth trembled and shook, the rocks rent asunder, the graves were opened, and many bodies of saints that slept in the tombs arose to life. On the third morning after this solemn scene, the "Prince of Peace" arose victorious from the grave, showed himself openly to competent witnesses of his resurrection; and afterward, rising above the confines of this earthly ball, winged his flight on a resplendent cloud, attended by myriads of angels, through distant regions which "eye hath not seen," and entered into heaven itself, there to "appear in the presence of God for us."

In consequence of these astonishing and benevolent arrangements, all men, everywhere, are now commanded to repent, with the full assurance that they shall obtain pardon, peace, and reconciliation, and every blessing requisite for their happiness in the present world and in the life to come. For thus runs the message of the Most High to all the children of men: "God so loved the world, that he gave his only begotten Son, that whosoever believeth in him should not perish, but have everlasting life." "Whom God hath set forth to be a propitiation through faith in his blood, to declare his righteousness for the remission of sins." "This is the record, that God hath given to us eternal life, and this life is in his Son." These announcements are made to all the inhabitants of this world, however vile, and however atrocious the deeds they may have committed—to the ferocious warrior that has slaughtered thousands, and to those who have long wallowed in the mire of depravity and licentiousness, as well as to those who have manifested some external decency of conduct. For He who is exalted as a Prince and a Saviour "is able also to save them to the uttermost that come unto God by him." And if we believe the record of God, and rest upon it as the declaration of a faithful Creator, we shall endeavor "to abound in all the fruits of righteousness"—to cultivate love toward God and toward man—"to add to our faith virtue, knowledge, temperance, patience, brotherly kindness, and charity," and every other Christian disposition and virtue which will tend to prepare us for the intercourses and employments of that higher sphere of existence where all is peace, and harmony, and love.

One reason why the benevolent arrangements which have been made for the happiness of man have been so long kept hid from the greater part of the world, and moral evil has been permitted to abound, doubtless is, that an extensive and impressive display might be given of the dismal and miserable consequences which necessarily flow from refusing allegiance to the Most High, and from a violation of his laws—to serve as a warning not only to the inhabitants of our globe, but to the inhabitants of other worlds of the necessity of submitting to the will of the Supreme, and of the inevitable disastrous effects which flow from the prevalence of moral evil. For if the fundamental laws of heaven—love to God and to man—were to be reversed, or universally violated, misery would pervade the whole moral universe, although it consisted of millions of worlds; and happiness could never be enjoyed by any rank of intelligent existence. But, however dismal a scene may have been presented to view, in the ages that are past, we are assured that a period is approaching—foretold by inspired prophets—when the world shall be regenerated, when "wars shall cease even to the end of the earth;" when violence and oppression and all unrighteousness shall be undermined and destroyed; when "the kingdoms of this world shall become the kingdoms of our Lord, and of his Christ;" when "every one shall sit under his vine and fig-tree," without the least fear of annoyance; when "the earth shall be full of the knowledge of the Lord, as the waters cover the sea," and "the Lord God will cause righteousness and praise to spring forth before all the nations." Then the antipathies of nations shall be destroyed; "the earth shall yield her increase;" its desolate wastes shall be cultivated, and its ruins restored, and all people "shall dwell in a peaceable habitation and in sure dwellings, and in quiet resting-places." And when the purposes of Divine Providence shall have been fulfilled in regard to the present state of our globe, its constitution shall be changed, its elementary parts dissolved; and "new heavens and a new earth" shall arise wherein righteousness shall forever dwell. Such is the destination of our world, and such are the arrangements which its Creator has made in reference to its inhabitants.

Some readers may, perhaps, be disposed to say, "What has all this theological dissertation to do with astronomy? we do not see that it has any connection with a description of the solar system." On this point we beg leave to differ from such objectors. What is the material universe, when separated from its reference to the Creator, and its relation to intelligent beings? A mere machine, which displays nothing but uncontrollable power acting at random, without the least trace of wisdom, benevolence, or rectitude. To view the planetary system, or other systems, as consisting merely of a number of large globes, wheeling round their axes, and round their suns, in certain periods of time, is to overlook some of the grandest and most interesting objects of astronomy. To suppose all the orbs of heaven to be self-existent and self-moving is absurdity and atheism: and to suppose the Creator to have formed them merely as so many august and splendid pieces of machinery, without any relation to intellectual natures, is inconsistent with every idea we ought to form of the attributes of the Divinity. The relation of the material system to intellectual beings ought, therefore, to be connected with astronomical investigations. We know not, indeed, the physical and moral characteristics of the inhabitants of Venus, Jupiter, or other planets; but we know, for certain, that if they be in a state of primeval innocence and happiness, they obey the two grand principles of the law prescribed to the inhabitants of our world—"Love to their Creator, and love to one another," without the observance of which precepts, true happiness cannot be enjoyed in any world in the universe, and the whole material creation would be nothing else than a boundless Pandemonium. We know that these precepts have been generally violated in our world; and hence the wars, devastations, insurrections, systems of oppression and iniquity, and other evils, which have produced so much misery and wretchedness among the population of our globe. And shall it be considered as improper and unphilosophical, that, in describing the material fabric of the world, those arrangements which the Almighty has formed for the regeneration of society, and the happiness of the human race, should be occasionally adverted to and detailed? We must demur to such a sentiment. Philosophy has been too long dissevered from its connection with religion—to which it ought ever to be allied; and it is now high time that every department of human knowledge should be studied in connection with the moral arrangements of the Almighty, the renovation of the world, and the eternal destiny of man. The sciences, when disjoined from such connections, lose the greater part of their value, and can be considered as useful only in reference to the concerns of this world, and the transitory duration of the life of man. Whereas, when studied with right views, and in all their legitimate connections and relations, they bear an intimate relation to the Divinity, to the progress and expansion of the human mind to other worlds, and to the scenes and employments of an immortal existence.

In reference to the earth, we shall now only state the following circumstances: The number of inhabitants which people the earth at one time is estimated at eight hundred millions—of these, five hundred millions are reckoned to Asia; fifty-eight millions to Africa; forty-two millions to America; and two hundred millions to Europe. Of these assemblages of human beings, twenty-five millions die every year, sixty-eight thousand every day, two thousand eight hundred and fifty every hour, and forty-seven every minute; so that at almost every pulse that beats within us, an immortal being is passing from time into eternity, from this visible and material world to another scene of existence—a solemn and important consideration to every one of us who must shortly follow, in our turn, the generations that have gone before us. If we reckon thirty-two years as the average period for a generation, as has been generally done—at the end of which period the whole human race is renewed, with a few exceptions; it will follow, that one hundred and forty-six thousand two hundred millions of human beings have existed on our globe, since its present arrangement commenced, reckoning 5849 years from the formation of Adam to the present time. But if we make our estimate according to the Samaritan and the Septuagint chronology, 7256 years are to be reckoned from Adam to the present time; and consequently, if mankind had never died, there would have been, at present, on the surface of the globe, 182,800,000,000: that is, one hundred and eighty-two thousand eight hundred millions of human beings. Whether the earth would have furnished subsistence for such a population is left to Malthusians and political economists to determine. But it appears, in point of fact, that the Creator never intended that such a number of the human species should remain on the earth at one time, in its present state; though it might easily be shown, that were all the habitable parts of the globe properly cultivated, it would support at least sixteen thousand millions of human beings, or twenty times the number that now exist on its surface, while each family would have an estate of twelve acres of land for its support. But the inferior tribes of animals are far more numerous than the amount of all the human inhabitants that have ever dwelt on the earth, from Adam to the last new-born child. At a rude calculation, the inferior tribes connected with the air, the waters, and the dry land, at one time, cannot amount to less than thirty billions of living beings; which is 164 times the number of all the human beings that have ever appeared on the earth. As one instance out of many of the immense numbers of certain species of animals, we may mention what Mr. Wilson states, in his "American Ornithology," that a single flock of the migratory pigeon of the United States was found to be about a mile in breadth and 240 miles in length—having occupied four hours in passing across the country; which flock, by a moderate calculation, was estimated to contain two thousand two hundred and thirty millions, which is nearly three times the human population of the globe.

We may just farther make the following statements in reference to the earth. In its course round the sun, it moves in an elliptical orbit, the longer diameter of which is 3,236,000 miles greater than the shorter, and consequently it is nearer the sun at one season of the year than at another. The time of its annual revolution is 365 days, 5 hours, 48 minutes, 49 seconds, which is called the tropical year; but the time it takes in moving from a fixed star until it returns to it again is 365 days, 6 hours, 9 minutes 12 seconds,—which is called its sidereal year. With regard to the density of the earth, it is found to be about five times denser than water; so that could we suppose five globes as large as the earth composed of water, suspended at one end of an immense balance, and the earth at the other, they would nearly counterpoise each other.

SECTION V.

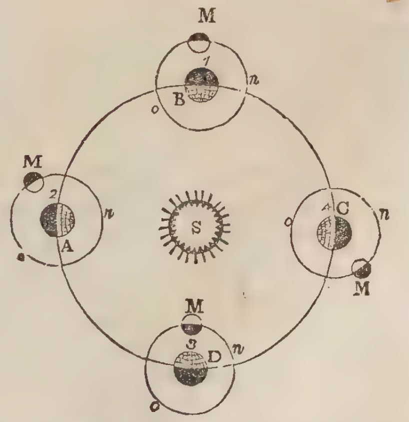
On the moon.

The moon is the nearest of all the celestial bodies to the earth, and is its constant attendant during its revolution round the sun. It belongs to that class of bodies called secondary planets, or satellites. A primary planet is one which revolves around the sun as its center: a secondary planet is a body which revolves around a primary planet as its center of motion, and is at the same time carried along with its primary around the sun.

Motions of the Moon.—The moon has an apparent motion round our globe every day, somewhat similar to that of the sun. She rises in an easterly direction, and, after a certain number of hours, sets in the western quarter of the heavens; this motion is not real, but only apparent, and is caused by the diurnal motion of our globe from west to east. The real motions of the moon are as follows:—In the course of 27 days, 7 hours, and 43 minutes, the moon makes a progress through the ecliptic, or round the whole heavens, from west to east, and returns to the same stars from which she set out. This is called her tropical revolution. The period from one new moon to another, or from one conjunction with the sun to another—which is 29 days, 12 hours, 44 minutes, and 2 seconds, is called her synodic revolution. The reason why these periods are different is this: at new moon, the sun and moon are in the same part of the heavens: but by the time the moon has returned to that point—namely, 27 days, 7 hours, 43 minutes—the sun has proceeded, in his apparent course through the heavens, twenty-seven degrees farther to the east, and is still going on, and the moon has to overtake him before she can be again in that position which is called new moon.

Fig. 33 exhibits some of the motions of the moon in relation to the earth and the sun. The small circle in the center, S, represents the sun; the circle A B C D. the earth's orbit and the earth

Fig. 33.

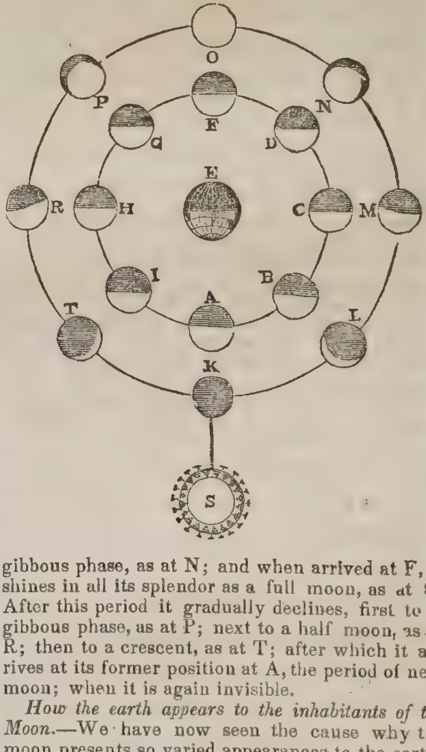


in four different positions. The smaller circle M *n o*, represents the orbit of the moon in its course round the earth. Around this orbit she moves, in a period somewhat less than a month, at the rate of 2300 miles an hour. But while she is thus carried, monthly, around the earth, she is also carried forward along with the earth, in its revolution round the sun. For example, while the earth has moved from B to A, the moon has made more than three revolutions round the earth, and at the same time has moved, along with the earth, nearly one hundred and fifty millions of miles, or the fourth part of the earth's annual circuit; so that the moon's motion through space is much more rapid than that stated above, and cannot be estimated at less than 70,000 miles an hour. When the earth is at B, in the position marked 1, and the moon at M, the enlightened side of the moon is turned to the dark side of the earth, and the moon is in the position we call full moon, the whole of its enlightened surface being then turned toward the earth. When the earth is at D, and the moon in the position marked 3, the dark side of the moon is turned toward the earth, and she is consequently invisible. This is the position of new moon. In the manner now described, does the moon revolve round the earth, and is carried along with the earth round the sun, from one year and one century to another; and has done so ever since she was appointed to give light to the earth, and "to rule the night." And since she is acted upon by two forces—the attraction of the earth and the attraction of the sun, which sometimes act in opposite directions—her motions are very irregular; which renders it somewhat difficult and tedious to calculate her precise position in the heavens at any particular moment of time.

Phases and general appearances of the Moon.—The sun always enlightens one half of the moon; and sometimes the whole of this enlightened side is turned toward the earth, when she appears a round luminous orb: but this happens only in one point of her orbit. At all other parts of her course, only a portion of her enlightened hemisphere is seen from the earth; and in one particular position in her orbit, her enlightened side is altogether invisible. When she is at the change, or the period of new moon, she is invisible; both because she is in the same part of the heavens as the sun, and because the whole of her dark hemisphere is then turned to the earth. After this it is generally two days, or more, before any part of her enlightened surface is visible. About the third day after the change, she is seen in the western sky, at no great distance from the point at which the sun set, and then appears under the form of a slender crescent, with its horns pointing toward the east. Next evening, about the same hour, she will have moved about thirteen degrees farther to the east, and her crescent will appear to have increased somewhat in breadth. Every succeeding night she will appear to have moved still farther to the east, while her crescent is still increasing in breadth and luminosity, until about the eighth day from the change, when she appears in the form of a half moon. She is then about ninety degrees from the sun. After this period, still proceeding eastward, she assumes a gibbous phase, until she arrives at the period of full moon, when her whole enlightened hemisphere is turned toward us; which happens on the fifteenth day after the time of the new moon, when she is in opposition to the sun, or one hundred and eighty degrees distant, and rises about the time when the sun sets. On a cloudless night, she then displays to every beholder a delightful and magnificent spectacle, calculated to arrest the attention of every eye, and to inspire the soul with emotions of sublimity. But she does not remain long in her full orbed luster; she gradually loses a portion of her brightness, by presenting to us a part of her dark hemisphere. She again appears for a few days in a gibbous phase; afterward she assumes the appearance of a half moon, and then that of a crescent whose horns are now turned toward the west. In this position she is seen only in the mornings before sunrise; and in a few days afterward, she is in conjunction with the sun, when her dark side is again turned toward the earth. All these changes are accomplished in twenty-nine days and a half.

These phases are more particularly represented in fig. 34, where S represents the sun, E the earth, and A B C D F G H I the moon in different parts of its circuit round the earth, with its hemisphere turned toward the sun fully enlightened. When the moon is at A, its enlightened side being turned to the sun, its dark side is turned toward the earth, and were it then visible, it would appear as at K, in the outer circle; but it is never visible in this position, except at the time of an eclipse of the sun, when its body, either in whole, or in part, interposes between us and the sun. This is at the period of new moon. When the moon has moved from A to B, a portion of its enlightened surface is then turned to the earth, and it appears as a crescent, as represented at L; when arrived at C, the one-half of its enlightened hemisphere is turned to the earth, and it appears in the form of a half moon, as at M; when arrived at D, it presents a gibbous phase, as at N; and when arrived at F, it shines in all its splendor as a full moon, as at O. After this period it gradually declines, first to a gibbous phase, as at P; next to a half moon, as at R; then to a crescent, as at T; after which it arrives at its former position at A, the period of new moon; when it is again invisible.

Fig. 34.



How the earth appears to the inhabitants of the Moon.—We have now seen the cause why the moon presents so varied appearances to the earth; let us now consider how the earth itself will appear as viewed from the surface of the moon. Could we take a view of the earth from one of the mountains, or plains, of the moon, we should find that it exhibits the same changes or phases, that the moon does to us, but in a reverse order. For when, at new moon, the dark side of the moon is turned toward us, the whole of the enlightened hemisphere of the earth is then turned toward the moon. And as the hemisphere of our globe is thirteen times larger than that of the moon, it will present in the lunar firmament a shining orb as large as thirteen of our full moons, and will therefore, diffuse a considerable degree of luster in the absence of the sun. That the earth shines with a full enlightened face upon the moon at the period now stated, will appear from the preceding diagram, fig. 34. At A, the moon is in conjunction with the sun, as seen from the earth, and its dark side is turned toward us; but it will be perceived that, at that time, the enlightened side of the earth, E, is completely turned toward the moon, so that while she is invisible to us, our globe appears in its full orbed majesty and brightness to the lunar inhabitants. On the other hand, when the moon is at F, when it is full moon to us, the dark side of the earth, E, is turned toward the moon, and is consequently invisible to the inhabitants of the moon, being then nearly in the same part of the firmament as the sun. When the moon is increasing to us, the earth is diminishing in its illuminated surface to the moon. When the moon is at B in its increase, the earth appears as at P; when she appears as a half moon as at M, the earth apears a half moon in the decrease, as at R; and when she increases to a gibbous phase as at N, the earth has decreased to a crescent, as at T; so that the phases of the earth, as seen from the moon, are exactly opposite to those of the moon as seen from the earth.

That the earth actually shines upon the moon, and illuminates its surface as the moon does that of the earth, is proved from the following circumstance. On the second or third day after new moon, when she appears as a slender crescent, we perceive a faint light on the dark part of the moon which is not enlightened by the sun, so that the whole hemisphere of the moon is visible—one part faint, and the other bright. This is perceptible even by the naked eye, but it appears pretty vivid through the telescope when a small power is applied, so that many of the principal spots of the moon may be distinctly perceived. This may be termed the "moonlight of the moon," as the earth is then shining upon its surface with nearly a full enlightened hemisphere. This light on the dark side of the moon gradually decreases, as the enlightened part of the moon increases, because the enlightened portion of the earth is at the same time diminishing, so that its effect is not much perceived after the period of half moon. It has been sometimes observed that a brighter reflection proceeds from the moon when the continental parts of the earth are opposite to her than when the Atlantic or Pacific ocean is in the same position. There is less light reflected from the sea than from the land upon the moon, and therefore it is natural to suppose that when the hemisphere of the earth which contains Europe, Asia, Africa, and New Holland, is shining upon the moon, a considerably greater quantity of light will be reflected on her surface than when the Pacific ocean, which covers nearly half our globe, is directly opposite to her. In the course of the diurnal rotation of the earth every part of its surface in succession will be presented to the moon; and therefore it will appear to a lunar inhabitant with different degrees of brilliancy, at different times, arising from the circumstances now stated. (See fig. 31, p. 34.)

The moon always presents the same side to the earth, so that we never see its opposite hemisphere. This circumstance proves that she turns round her axis in the same time she takes to move round the heavens. If the moon had no motion round her axis, we should see both her hemispheres in the course of every revolution she makes round the earth. Whether the other side of the moon be less adapted for reflecting light than that which is next us, or whether it be equally diversified with mountains, caverns, and plains, we have no opportunity of determining; though, reasoning from analogy, we may conclude that the arrangements of nature in that hemisphere are not essentially different from those we perceive in the hemisphere presented to our view.

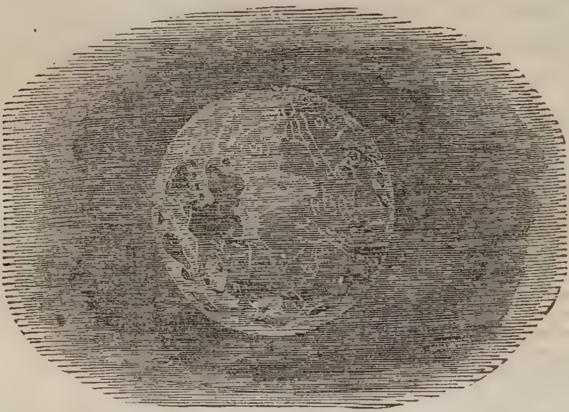
There is a peculiar appearance which may be noticed, that the earth will present to an inhabitant of the moon, and it is this—that from any particular spot on the lunar surface, the earth will appear in a fixed position in the heavens, without any apparent motion. To those who live in the middle of the hemisphere next the earth, the earth will appear as a large globe in the zenith, or point directly above their heads, sometimes appearing as a half moon, a crescent, or a full enlightened hemisphere, and sometimes invisible, but always in the same position. The only motion they will occasionally perceive is the earth's rotation, which they will observe as the different continents, islands, and oceans of our globe present themselves in succession. Those who live near the margin of the moon's hemisphere next the earth, will see the earth near the horizon, and it will never appear from such places in a more elevated position in the heavens. Those who live in intermediate positions will behold the earth at higher or lower elevations, according to their distance from the center of the hemisphere. All these appearances necessarily result from the circumstance that the moon always presents the same side to the earth, and to account for such phenomena will be apt to puzzle the lunar astronomers. Hence, it necessarily follows that those who live on the opposite hemisphere of the moon will never see the earth nor enjoy its light. From the central parts of that hemisphere, an astronomer—who had heard of the remarkable celestial phenomenon to be seen in the other hemisphere—would have to travel more than 1700 miles before he could see the earth emerging from the horizon; and in order to behold it in its full luster, shining directly from the zenith, he would have to travel 1700 miles farther, or 3400 miles in all. We presume that there are few terrestrial astronomers who would grudge to undertake such a journey were they to behold a resplendent moon hanging in the vault of heaven in another hemisphere, which is altogether invisible in his native country. Sir J. Herschel, in order to explore the starry regions in the southern hemisphere, undertook a voyage to the Cape of Good Hope, where he remained for years, and brought home some interesting pieces of intelligence from the starry regions.

Distance and magnitude of the Moon.—The moon, though the nearest celestial body to the earth, is still at a considerable distance. This distance is reckoned to be, at a medium, about 237,000 miles, or about thirty times the diameter of our globe, which is determined from its horizontal parallax, or the angle formed by a line drawn from the center, and another line drawn from the surface of the earth. As the moon, however, moves in an elliptical orbit, she is sometimes more than 240,-

000 miles distant, and sometimes considerably less than 237,000. Small as this distance is, compared with that of the other planets, it would require nearly 500 days, or about sixteen months, for a steam-carriage to move over the interval which separates us from the lunar orb, although it were moving day and night at the rate of twenty miles every hour. Although the apparent size of the moon is equal to that of the sun, yet the difference of their real bulk is very great; for it would require more than sixty-three millions of globes of the size of the moon to form a globe equal in magnitude to that of the sun. The reason why the sun appears so small, when he is in reality so large a globe, is this—that he is removed ninety five millions of miles from the earth, which is nearly four hundred times farther than the moon. The diameter of the moon is 2180 miles, which is little more than the fourth part of the diameter of our globe, and consequently, in point of solidity, it is only the forty-ninth part of the bulk of the earth. Its surface, however, contains fifteen millions of square miles, or about one-third of the habitable regions of our globe, and were it peopled as densely as England, it would contain a population amounting to four thousand two hundred millions, which is more than five times the population of the earth. The circumference of the moon is 6848 miles, and, therefore, if a railroad were formed around it, its inhabitants could travel completely round their world in the course of fourteen of our days, at the rate of twenty miles an hour; and the journey could be so arranged that they might enjoy uninterrupted moonlight from the earth in one part of it, and uninterrupted sunlight during the other—an advantage which we can never enjoy in our terrestrial region.

Telescopic appearance of the Moon.—When the moon is viewed with a good telescope, the lunar surface presents a very interesting and diversified appearance. Mountains and plains, caverns and insulated rocks, hills and plains of almost every shape, diversify every portion of the surface of the moon. It is evident almost at first sight, that the moon is diversified with inequalities of surface, and has lofty eminences and deep vales, when we view her surface with a powerful telescope, when she appears in the form of a crescent or of a half moon; for then we perceive the boundary between the dark and enlightened side—not a straight line or a regular curve, as it would be if the moon were a smooth surface—but jagged and uneven, somewhat like the edge of a coarse saw. Within the dark portion of the moon, adjacent to this boundary bright points appear, somewhat like stars, which are evidently the higher tops of the lunar mountains, enlightened by the sun before his rays can reach the valleys, just as we find that in our globe, when the sun is rising, his beams gild the mountain tops, while the plains and valleys are still in the shade. Shadows of different dimensions, too, are to be seen in various parts of the enlightened portion of the moon, indicating both elevations and depressions.

Fig. 35.



The mountainous regions of the moon are arranged in a very different form from those of the earth. There are, indeed, some mountain ranges on the lunar orb somewhat resembling our Alps, and Apennines, and Andes; but one of the distinguishing features of the moon consists in hundreds of circular ranges of mountains surrounding plains of the same shape. The following are a few of the characteristic features of the lunar surface 1. Plains of various extent and peculiarities Some of these plains are more than one hundred miles in diameter, or in length and breadth. They present a darker and more somber appearance to the eye than the other parts of the lunar surface, and in many instances, they contain, here and there, deep cavities. They were formerly considered as seas, or large collections of water, but there appears no evidence that seas, or any large collection of waters, exist on the surface of the moon. Beside these large plains, there are numerous circular plains of a lesser size, of all dimensions, from two or three miles to thirty miles in diameter, surrounded with a circular ridge of mountains, as with a wall or rampart. These are to be found in most regions of the moon, and they form a peculiar feature of her surface altogether different from what obtains on our globe. 2. The moon displays a great variety of mountain scenery. In the first place, there are chains of mountains, which run in a right-lined direction, not altogether unlike those which exist on our globe. The most remarkable range of this kind is that called the Apennines, which traverses a portion of the lunar disc from north-east to south-west, which may be seen to advantage about the time of half moon, and a day or two afterward. It rises with a precipitous and craggy front, from a large plain called the *mare imbrium*, extends to a great length, and, in some places, rises to the perpendicular hight of four miles. This is most precipitous on the side of the plain, and gradually slopes off with its hundreds of peaks to the opposite declivity, resem bling in some degree our Andes and Himalayas. In the next place, there are insulated mountains, or peaks, or mountains in the shape of a sugar loaf, which rise directly from the plains, and are altogether unconnected with any ridge or group whatever. Some of these are several miles in perpendicular altitude, and their shadows thrown opposite to the sun are as distinctly seen through the telescope as the shadow of a gnomon on a sun-dial. They bear a certain resemblance to the Peak of Teneriffe, and Adam's Peak in the island of Ceylon. But in the third place, the chief features of the mountain scenery of the moon consist in those circular ranges of mountains which occupy nearly one-half of the lunar surface, and are dispersed in all directions. In some cases, they appear like a wall of sixty, one hundred, or one hundred and fifty miles in circumference, surrounding circular plains of corresponding extent. In other cases they are from five to ten or twelve miles in diameter; and in many instances there is a central mountain of a considerable elevation, which rises from the center of the circular plain. There is nothing similar to these arrangements in any part of our terrestrial system. The lunar mountains, according to Schroeter's measurements, are of all sizes, from three hundred feet to five miles in perpendicular hight. 3. Another singular feature of the moon's surface consists in those numerous depressions or cavities, which appear on almost every part of her disc. These cavities are circular, and bear a certain resemblance, in shape, to an egg-cup. A high annular ridge, marked with lofty peaks and small cavities, generally encircles them, an insulated mountain frequently rises in the center, and sometimes they contain smaller cavities of the same nature as themselves. These hollows are most numerous in the southwest parts of the moon, and from this cause it is owing that that portion of the lunar surface is more brilliant than any other portion of the moon; these cavities, along with the mountainous ridges which encircle them, reflecting a greater quantity of light than any other part of the lunar regions. As to their dimensions, they are of all sizes, from three miles to fifty miles in diameter at their orifices, but they generally decrease in breadth toward the bottom. Their depth varies from about one-third of a mile to three miles and three quarters below the summits of the mountains which surround them; but in all cases the internal depth of the cavity is much lower than the general surface of the moon. Of this feature of the lunar surface we have no examples in any part of our globe; but we have reason to believe, from the variety which exists in nature, that not one world in the universe exactly resembles another in its particular arrangements.

The following figures will perhaps convey a rude idea of some of the objects on the lunar surface now described. Fig. 36 is a view of the brilliant spot called Aristarchus, which is situate in the north-east quadrant of the moon's surface, where the shadows of some of the circular cavities and also the shadows of the mountains may be perceived. Fig. 37 is the spot called Hevelius, which contains an annular cavity, and a broken elevation somewhat resembling an egg. Fig. 38 represents a cavity surrounded by a circular range of mountains, with two central mountains in the middle of the plain, in which the shadows of one side of the circular range and of the central mountains may be seen. Fig. 39 shows another magnified portion of the moon's disc, exhibiting several circular plains, cavities, and other varieties of the lunar surface.

From what we have now briefly stated, it is evident that an immense variety of picturesque and sublime scenery is presented to view on the surface of the moon, and could we conceive ourselves standing on some of her lofty peaks, her circular mountain ridges, or on the summit of her central mountain, we should behold a much greater extent of prospect, and an assemblage of more grand and sublime objects than is presented to our view in any of our terrestrial landscapes. The best time for viewing all the varieties of scenery on the moon's surface, with a telescope, is about the period of half moon, or two or three days before or after it, at which times the shadows of the lunar mountains and cavities are longest and most distinct. At the time of full moon, many of the objects described above cannot be

Fig. 36.

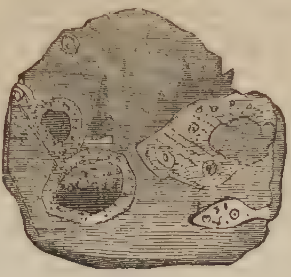


Fig. 37.

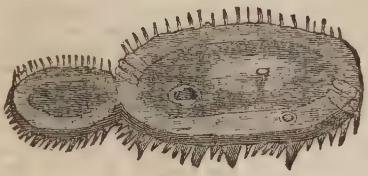

Fig. 38.

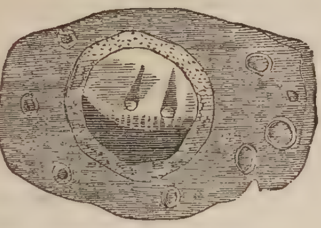

Fig. 39.

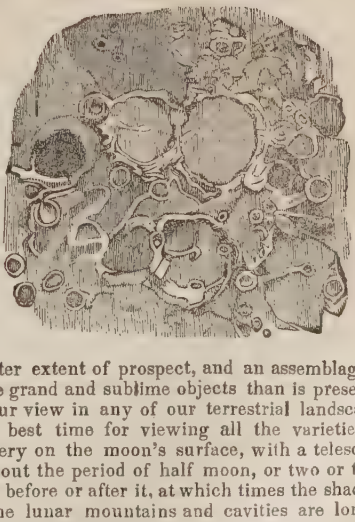


perceived, as the sun then shines perpendicularly upon the moon's surface, so that the shadows of the different objects cannot be distinguished. The following additional particulars respecting the moon may be stated.

1. The length of a lunar day is equal to nearly fifteen of our days, and the length of the night the same, so that a day and night in the moon is equal to twenty-nine days and a half, or one lunar month. On the hemisphere next the earth, there is moonlight nearly all the time the sun is absent; but in the other hemisphere, in the absence of the sun, there is no light but what proceeds from the stars and planets. Were a lunarian to travel, at the rate of ten miles an hour, in a direction at right angles to the moon's axis, he might keep pace with the moon's rotation, and be enabled to live in perpetual sunshine. 2. The light of the moon has been computed to be 300,000 times less intense than that of the sun, when shining in an unclouded sky; yet its utility is considerable, and when the full moon shines in its splendor, it throws a cheerful, though mild light, over the surrounding landscape. 3. The nearer the moon is to the periods of new and full moon, the greater is her velocity in her orbit; and the nearer she is to the quadratures, the slower she moves. When the earth is in its perihelion, or nearest the sun, which happens in the winter, the periodical time of the moon is greatest; and when the earth is in its aphelion, which happens in summer, the periodical time of the moon is the least. 4. The mean inclination of the moon's orbit to that of the earth is five degrees, nine minutes. 5. The eccentricity of her orbit is 12,960 miles. 6. The moon in all probability is surrounded with an atmosphere, but it is evidently a very small one, and of extreme tenuity; and no clouds or vapors appear to exist in it. It is stated as having been distinctly perceived during the annular eclipse of May, 1836, when just before the rims of the two bodies met, the light of the sun was seen to shoot through the moon's atmosphere, mollified into twilight. Schroeter calculates its hight at 5742 feet.

There can be little doubt that the moon, like the earth on which we dwell, is a world replenished with inhabitants. Matter appears to have been created chiefly in subserviency to mind; and it is highly improbable that the Creator would leave a globe containing a surface of fifteen millions of square miles altogether destitute of sensitive and intellectual beings, especially when we behold its surface diversified and adorned with such a vast assemblage of picturesque and sublime scenery, and when we consider that every department connected with our globe is peopled with sentient beings of every description. Although seas and rivers and a dense atmosphere are not to be found connected with the lunar orb, and although some of its arrangements are different from those of the earth, yet these circumstances form no valid objection to the moon being inhabited, for the Creator can in all cases adapt the inhabitant to the nature of the habitation provided for him, as he has adapted the birds for winging their flight through the air, the fishes for gliding in the waters, and man and quadrupeds for traversing the dry land.

It has frequently been a subject of inquiry, Whether the inhabitants of the moon may ever be discovered by the inhabitants of our globe? Notwithstanding the improvements that have been made on telescopes in modern times, we have no expectations that such a discovery will ever be made. Even the large telescope lately constructed by the Earl of Rosse, however distinct and beautiful a view it may exhibit of the mountains and vales, rocks and caverns, on the lunar surface, will never be able to show us its inhabitants, although they had bodies five hundred times larger than those of the inhabitants of the earth. That telescope has seldom been used with powers exceeding eight hundred times; but although a power of two thousand times could be put upon it with distinctness, it would make the moon appear no nearer to us than one hundred and twenty miles, at which distance a living being, although a hundred feet high, could not be beheld. For, with such a power, a space on the moon's surface one hundred and eighty-three feet in diameter could only be perceived as the smallest visible point. Beside, we ought to consider that when we view objects on the surface of the moon, we do not view them in perspective, as we view objects on the surface of the earth, but only obtain a bird's eye view, as we do of objects on the surface of our globe, when viewed from a balloon suspended in the atmosphere, in which case, when we look down upon a group of human beings, we perceive only the length and breadth of their heads and shoulders.

There is a possibility, however, of tracing the operations of sensitive, or intelligent beings, in the lunar orb, although we can never expect to trace the forms or motions of its inhabitants. Were a vast number of persons in different parts of the world to devote themselves to a particular survey of the moon—were different portions of its surface allotted to different individuals as the object of their particular research—were accurate observations made, and frequently repeated, on every mountain, hill, cavity, cliff, and plain, and every change and modification in the particular spots and their localities carefully marked and represented in a series of delineations, it might lead to some certain conclusion both as to the physical constitution of the moon, and as to whether any of the observed changes proceeded from the operations of living agents. If an observer in the moon, with such a telescope as Sir William Herschel's, or that of the Earl of Rosse, had observed the city of Babylon, when in its splendor, and afterward when reduced to a desert, as it now is, he must have observed a change in the locality where that famous city once stood, indicative of the operations of intelligent, or at least, of sensitive, or living agents. And had he viewed the dense forests of America before civilized nations took possession of that country, and were he now to take a view of the eastern states of North America, in their present state of cultivation, and since the great cities of New York, Boston, and Philadelphia were reared, a striking difference between the present and the former state of that country would doubtless be perceptible. For, if an extent of only one hundred and eighty-three feet, or sixty-one yards, would be perceptible by a telescope magnifying two thousand times, much more would the extent of a large city, such as New York, be distinctly visible, as a prominent and well-defined object. Now, if changes similar, or analogous to these, could be traced on the surface of the moon, it would lead us to form some certain conclusions in relation to the operations of intelligent agents, and consequently, that such beings actually exist on the lunar surface. But such observations as those to which we allude would require not only to be specific and minute, but also to be continued for a length of years—perhaps a century or more—before any striking changes could be expected to occur.

Dr. Olbers was fully of opinion, from the observations he had made, "that the moon is inhabited by rational creatures, and that its surface is more or less covered with a vegetation not very dissimilar to that of our earth." It has formed a subject of speculation with some, whether it might be possible to correspond with the lunar inhabitants by symbolical representations. If they be mathematicians, it has been conceived that the erection of geometrical figures on some extensive plains on our globe, on a scale of vast extent, might be recognized by the inhabitants of the moon, as a signal of correspondence, and that they might erect similar figures in return. But it is highly questionable whether the design of such figures would be appreciated, or whether they would be visible to the eyes of the inhabitants. Many a look, we may conceive, will be directed to our globe by the lunar inhabitants, and much wonder will doubtless be expressed at such a large globe hanging over their heads, apparently immovable, excepting a rotation round its axis; and much speculation, will, without question, take place among them as to whether such a globe as ours be inhabited. But it does not appear to be the design of the Creator, in the meantime, that the inhabitants of our globe and those of the moon should become acquainted, or that any direct correspondence should take place between different worlds. And therefore, we must wait with patience until the scenes of a future life shall unravel the mysteries, and dispel the darkness which now hangs over the history, the population, and the transactions of other worlds. Whatever may be the peculiar circumstances of the beings that people other globes, we know that they are all under the care and superintendence of Him who is infinite in wisdom, power and intelligence; whose "kingdom ruleth over all," and whose "tender mercies are over all his works."

But, whatever opinions we may entertain respecting the inhabitants of the moon, certain it is that she forms a beautiful and noble appendage to our globe, and her light and motions are of high utility to its inhabitants. How cheerless and uncomfortable, in many cases, would be our nights, were it not for the mild radiance which the lunar orb dispenses in such regular and agreeable vicissitude! To the mariner, while plowing his course through the stormy deep; to the plowman, "plodding his weary way;" to the peasant, pursuing his course through moors and morasses after nightfall; to the shepherd, tending his fleecy charge by night; to travelers in foreign lands; and to the missionary in pagan countries, when returning at midnight from his sacred labors; the moon, in her various stages, is always a most cheerful and welcome visitant. She throws a mild and silvery luster over the forests, the mountains and the vales, and we behold a new picture of terrestrial objects, which is more delicately shaded, and disposed into softer lights than that which is displayed under the blaze of the meridian sun—a scene which leads the pensive mind to pleasing reflections, and to solemn contemplation. By her attractive influence, she sways the ocean, and perpetuates the regular returns of ebb and flow, by which the liquid element is preserved from putrefaction, and the inhabitants of the islands and continents from infection and disease. And, although her brightness is not the same at all seasons, and though she is sometimes absent from our nocturnal hemisphere, yet, in her absence, we enjoy, on a clear evening, a more extensive prospect of the starry regions, and of those remote spaces of creation where suns unnumbered shine, and planets and comets run their solemn rounds. Let us then be grateful to our beneficent Creator, who, in this as well as in all his other works, has displayed his infinite wisdom, and his unbounded goodness; and let us in unison with the inspired writers, praise the name of the Lord, who hath appointed "the moon to rule by night," as an evidence of his fatherly care, and of his mercy, which "endureth forever."

CHAPTER IV.

DESCRIPTION OF THE SUPERIOR PLANETS OF THE SOLAR SYSTEM.

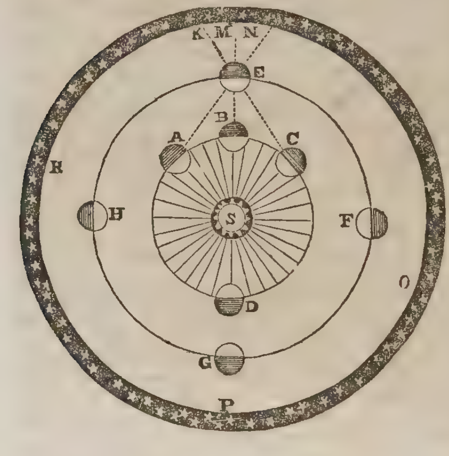
SECTION I.

On the motions and aspects of the superior planets.

The planets Mercury and Venus, whose motions and phases we formerly described, are called inferior planets, because they revolve round the central luminary in orbits which are included within the orbit of the earth, and consequently nearer the sun than the earth is. The superior planets are those whose orbits are without that of the earth, and, of course, at a greater distance from the sun. The superior planets are Mars, Vesta, Juno, Ceres, Pallas, Astræa, Jupiter, Saturn, and Uranus. They are distinguished from the inferior planets in the following respects:—1. They come to our meridian at midnight, which the inferior planets never do. 2. They are sometimes seen rising in the east, when the sun is setting in the west; a circumstance which never happens to Mercury or Venus. 3. While the inferior planets always appear to move in the neighborhood of the sun, never removing beyond forty-eight degrees of that luminary, the superior planets may be seen at all distances from the sun, and even in the opposite quarter of the heavens. 4. The superior planets never can appear to transit the sun's disc, as Mercury and Venus have been seen to do at different periods. 5. The superior planets never appear in the form of a crescent, or of a half moon, as the two inferior planets are found to do in certain parts of their orbits. They always appear with a round face, when viewed with a telescope, except Mars, which sometimes appears with a slight gibbous phase. 6. A superior planet can only be in conjunction with the sun, when the sun is between the earth and the planet; whereas an inferior planet may be in conjunction with the sun, when it is between the sun and the earth. 7. There are also certain peculiarities in reference to the direct and retrograde motions of the superior planets, and the points in which they appear stationary, different from those of the inferior planets. All these circumstances clearly show that the path of the earth round the sun is included within the orbits of the superior planets; that we occupy a station that is never very far removed from the center of their orbits, and that we see these planets in a direction which is nearly that in which the sun's rays enlighten them.

Apparent motions of the superior Planets as seen from the Earth.—The superior planets are retrograde when seen in opposition to the sun, that is, they appear to move from east to west, or contrary to the order of the signs of the zodiac; and their motion appears direct, or from west to east, when in conjunction with the sun. The following diagram, fig. 39,* will illustrate some of the motions and aspects of these planets. Let the central circle S represent the sun, A B C D the orbit of the earth; E F G H the orbit of a superior planet, suppose that of Mars, and K M N O P R a portion of the starry heavens. When the earth is at D, and Mars at E, the planet, as seen from the earth at D, will appear in the same part of the heavens as the sun, or in conjunction with him. When the earth is at B and the planet at E, it is then said to be in opposition to the sun; for the sun is then seen in the direction S P, while the planet is seen in the direction B M. In this case, the planet is nearest to the earth, and in the case of Mars, it is only fifty millions of miles distant from us. But when the earth is at B and Mars at G, the planet is the whole diameter of the earth's orbit, or one hundred and ninety millions of miles farther distant, and consequently, at that time, two hundred and forty millions of miles from the earth. Hence it happens that this planet appears about twenty-five times larger in the one case than in the other. When farthest distant from the earth, it appears like a small star; but when nearest us, it appears nearly as large as Jupiter or Venus, but with a more ruddy aspect. These circumstances clearly prove that Mars does not move round the earth as its center of motion, as the ancients supposed, but round the sun, and that, too, in an orbit which includes the earth's orbit within it.

Fig. 39.*



The cause of the direct and retrograde motions of the superior planets will likewise appear from fig. 39 Suppose the earth at A, and Mars at E, while the earth is moving through the part of its orbit A D C, the planet will appear to move from N to K among the stars, which is its direct motion through the heavens, or from west to east; so that when the earth is at D, the planet will appear at M, and when the earth is at C, it will appear at K. But while the earth moves through C B A to A, it will appear to return to N, having a retrograde motion from east to west; so that when the earth is at B, it will appear to be at M, and when the earth is at A, it will appear to have returned back to N. When the earth is either at A or C, the planet will appear stationary for a few days. The direct motion is very slow from N to K, because the earth has to move, during its continuance, through the large part of its orbit A D C; but the retrograde motion, from K to N, is performed in much less time, because the earth, while it continues, has to move only from C to A.

We have supposed the planet at rest, in order to avoid complexity in the illustration; but the appearances will be the same, whether we conceive the planet at rest or in motion; only the time in which the direct and retrograde motions are performed will be different when we view the planet as in motion. Jupiter, Saturn, and all the other superior planets have similar direct and retrograde motions and stationary positions. They all retrograde when in opposition, and for some time before and after it; but they differ greatly as to the time of its duration. It is more rapid and extensive in the case of Mars than of the other planets which are farther distant from the sun. It may just be further stated, that the times of the conjunctions, oppositions, direct and retrograde motions, and also of the stations of the superior planets depend upon the combinations of their motions in their orbits with the motion of the earth in its orbit; and this combination causes all the apparent irregularities which appear in the motions both of the superior and inferior planets. But all the planets, if viewed from the sun, the center of their motions, will appear to move without interruption in the same direction; only moving somewhat more slowly in their Aphelion, and more swiftly in their Perihelion.*

SECTION II.

ON THE PLANET MARS.

THIS is the first of the superior planets next to the earth. Its name, which was given by the ancients, signifies "the god of war," which appears to have been given on account of its ruddy or fiery appearance, and because the astrologers imagined it to be a promoter of war and bloodshed. It is rather unfortunate that the names of the planets, as well as of the celestial constellations, should all be derived from heathen mythology, and from the superstitious and idolatrous views of the ancients. It ill comports with the peaceable study of astronomy that a god of war should be supposed riding in his fiery chariot through the heavens, and brandishing his sword over the nations to excite them to diabolical contests. It presents a melancholy and degrading picture of human nature, that in all ages war has produced its horrid massacres and devastations among every kindred, and in every clime, and that men should have imagined that a celestial deity was appointed to preside over its infernal operations, and to "urge the foes to battle." It will be to the eternal dishonor of the human character, that ever such malignant exploits were engaged in, in our terrestrial sphere. In modern times, it is an indelible disgrace to nations, who designate themselves as civilized and enlightened, that such a mode of settling disputes between states and empires should be resorted to as that of warfare. It is glaringly unchristian; it is inhuman and atrocious; it is a violation of the fundamental laws which unite the moral universe; it is accompanied with almost all the evils which can afflict humanity; it is subversive of the wealth and prosperity of nations; and it must be highly offensive to the Creator, who has so curiously constructed the human frame, and formed man "after his own image," that such an exquisite structure should be cut and slashed and destroyed by those who are partakers of the same nature. In short, it conveys an absurdity in the very idea of it; for it never can decide on which side of a disputed question justice and right are to be found; and it degrades man, who is endowed with high intellectual powers, to a level with the inferior animals—with the bear, the lion, and the hyena, that have no other mode of settling their disputes but by physical force. Scarcely anything can be more degrading and monstrous, in beings furnished with moral faculties, and endowed with reason and intelligence. But it is needless to say that the planet Mars, though somewhat more ruddy than the other planets, has no influence whatever over such barbarous and malignant exploits. It sweeps along in its course through the heavens, in unison with the other bodies which compose the solar system, in obedience to a universal law, and displays, in its motions, its Creator's power and wisdom.

---

* The Aphelion is that point of the orbit of the earth, or of any other planet, which is farthest from the sun; and the Perihelion is that point in the orbit of a planet which is nearest to the sun. As the planets move in elliptical orbits, they must, of course, be at different distances from the sun in different parts of their orbits.—See Appendix, No. III.

The distance of this planet from the sun is one hundred and forty-five millions of miles, and the circumference of its orbit about nine hundred millions of miles. The distance of its orbit from that of the earth is fifty millions of miles; and, at the time of its opposition to the sun, it is about this distance from the earth—which is the nearest approach to the earth which any primary planet can make, the planet Venus only excepted. It accomplishes its revolution round the sun in six hundred and eighty-seven days, or about one year and ten months, which is at the rate of fifty-four thousand miles an hour—a rapidity of motion which affords a striking idea of the omnipotent energies of the Creator. But before it can return to the same relative position in regard to the sun, or, in other words, from one conjunction or opposition to another, it occupies a period of seven hundred and eighty days—that is, two years and fifty days. It is only at the period of its opposition, when it is nearest the earth, and a short time before and after it, that this planet makes its most splendid appearance, almost rivaling Jupiter in its luster; and therefore, before we can again see it with the same degree of luster, a period of two years and fifty days, at an average, must elapse. It was in this position in June, 1843; again in August, 1845; and again in October, 1847. This is the most eligible period for observing the surface of Mars through telescopes, and, likewise, for observing its direct and retrograde motions. From spots which have been observed on the surface of Mars by the telescope, it was determined that it makes a revolution round its axis in twenty-four hours and nearly forty minutes—which is only forty-four minutes longer than the diurnal rotation of the earth, and is performed in the same direction, namely, from west to east. Its axis is inclined to the plane of the ecliptic at an angle of nearly sixty degrees, or about thirty degrees from the perpendicular. Of course there must be different lengths of days and nights in different regions of this planet; and, likewise, a diversity of seasons, somewhat similar to what we experience on our globe.

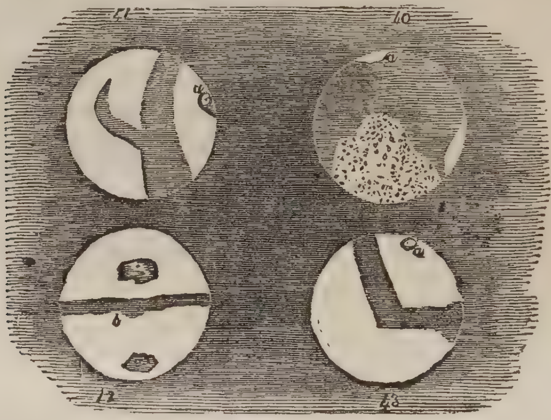
This planet, as to size, ranks among the smaller bodies of the solar system. Its dimensions are as follows:—Its diameter is found to be about four thousand two hundred miles—which is little more than half the diameter of our globe. Its surface contains above fifty-five millions of square miles, which is several millions more than the number of square miles on the habitable parts of the earth. Were its whole surface composed of land, and were it peopled in the same proportion as Belgium—three hundred inhabitants to a square mile—it could contain a population of sixteen thousand five hundred millions, or more than twenty times the present population of our globe; so that this planet, though comparatively a small one, may rank higher than even our world in respect to the number of sensitive and intellectual beings it may contain. This planet, like the earth and several other planets, is of a spheroidal figure, its polar diameter being about two hundred and sixty miles shorter than its equatorial.

When viewed with good telescopes, spots of various forms have been discovered on the disc of Mars. It was, however, more than fifty years after the invention of the telescope, before any discoveries were made on the surface of this planet, or any spots could be seen to determine its rotation. Cassini, an Italian astronomer, about the year 1666, was among the first who perceived several dark spots on the surface of Mars; and Dr. Hooke, in England, and Campani, at Rome, about the same time, made similar observations. It was found that all the features which the planet exhibits at any moment, gradually disappeared in twelve hours and twenty minutes, at the expiration of which time it exhibits an entirely different appearance; and, by continuing to observe its disc, the former features were seen to come successively into view—and thus was its revolution round its axis ascertained, and the period of it accurately determined. Some observers have remarked that these spots do not always appear well-defined, and that they frequently change their form; but that some of them continue always the same. It appears probable that clouds exist in the atmosphere of Mars, and that these, being occasionally interposed between the eye of the observer and the surface of the planet, may cause the changes of appearance which have been observed. It is admitted by all astronomers that an atmosphere, or body of air, of considerable density and extent, surrounds this planet; for it is found that small stars, as they approach the edge of its disc, suffer a gradual diminution in brightness, before they disappear, by the interposition of its body; and this obscurity of a star, when seen in such circumstances, must arise from its being viewed through a dense medium connected with the planet. The circumstance, therefore, of an atmosphere around Mars, combined with the fact that it has a revolution round its axis, to produce the alternate succession of day and night, forms a strong presumptive proof that this planet is an inhabited world, and destined to afford existence and happiness to numerous orders of beings.

There is an intensely white spot which has been long observed around the pole of Mars, when, emerging from darkness, it first receives the sun's light; and this gradually diminishes in magnitude and brightness until the pole again withdraws itself from the sun; and as regularly and certainly re-appearing, when the same pole emerges from the cold and darkness of its winter. For as the axis of Mars is inclined to its ecliptic, or the plane of its orbit, one of its poles is deprived of the solar light during eleven months, or one-half of its year, in the same manner as the north pole of our globe is in darkness from the end of September to the 21st of March. Now, it has been supposed that, during this long winter of eleven months in the polar regions of Mars, these regions are covered with snow, which is the cause of the white appearance about the poles, when these poles emerge from darkness; and, after long exposure to the sun's rays, during the other eleven months, when the sun is shining upon them without interruption, these polar snows are gradually dissolved, so as to leave the naked soil of that region exposed to view.

The following are the results of Sir John Herschel's observations on this planet, made with a twenty feet reflecting telescope. He says that, on account of the clearness of its atmosphere, he has been enabled to observe, with perfect distinctness, the outlines of continents and oceans; that the land on its surface is distinguished by a red hue, which imparts to the planet the ruddy appearance it has when viewed by ordinary telescopes, and which its light exhibits to the naked eye. This redness he ascribes to a quality in the prevailing soil, like that which our red sandstone districts would exhibit to an observer contemplating the earth from the surface of Mars. The seas of this planet, he observes, have a greenish hue, altogether resembling the color of our own. These spots, however, are not always to be seen equally distinct, because of the varying transparency of the atmosphere; but when they are distinctly seen, they always present the same appearance. The following are some of the telescopic views which have been taken of this planet. Fig. 40 is one of the views taken by Sir J. Herschel with his twenty feet reflector. The dark portions are considered to be water, and the white spaces land—at *a* is the white polar spot described above. Fig. 41 is one of the views given by Sir W. Herschel, which presents the appearance of a portion of a sea, with a gulf running up into the land. Fig. 42 is a view of Jupiter given by Maraldi, which he observed in 1704, and, by means of the prominence marked *b*, he determined the period of rotation. Fig. 43 is a view of Mars, which we have several times observed about the time of its opposition to the sun.

Figs. 40–43.



From the whole of what has been now stated respecting this planet, the following conclusions may, with a high degree of probability, be deduced—that it is environed with an atmosphere of considerable extent, in which clouds probably exist; that the dark spots are water, or seas, which reflect a much less proportion of the solar light than land, and probably cover about one-third of its surface; that a variety of seasons, somewhat similar to ours, must be experienced in this planet, but of a much longer duration; and that it bears a more striking resemblance to the world in which we dwell than any other planet of the solar system. It was owing to observations made on this planet by the famous astronomer, Tycho Brahe, and to the records of his observations having fallen into the hands of Kepler, that the three great laws of planetary motion, generally termed "Kepler's Laws," were discovered. These laws, which we may afterward notice, lie at the foundation of modern astronomical science, and give precision to its principles.

SECTION III.

On the new planets.

Within the limits of the present century, four new planetary bodies have been discovered, none of which was known to former astronomers. They are named Vesta, Juno, Ceres, and Pallas. They are all situate beyond the orbit of Mars, and within that of Jupiter, and present a variety of singular anomalies; but, as they are all invisible to the unassisted eye, and can never be noticed by common observers, we shall give only a brief sketch of their history, and their magnitudes and motions, so far as they are known. From the interval of nearly three hundred and fifty millions of miles which lies between the orbits of Mars and Jupiter, it was long conjectured, as highly probable, that some undiscovered planet either exists, or had existed, in some part of this vast region, so as to present something like proportion in the arrangements of the system, when compared with the distances which intervene between the orbits of Mercury, Venus, the Earth, and

Mars. This conjecture may be considered as having been in some degree realized by the discovery of four small bodies, situate in orbits at no great distance from each other, at an average of about a hundred millions of miles beyond the orbit of Mars.

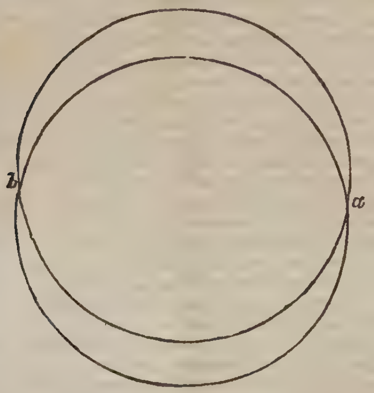
History of their Discovery.—The first of these bodies which was discovered, was the planet Ceres. It was discovered at Palermo, by Piazzi, a Sicilian astronomer, in the constellation Taurus, on the 1st of January, 1801—being the first day of the present century—and within the limits of the next seven years, all the other three bodies were discovered. After being lost for some time, it was re-discovered by Dr. Olbers, of Bremen, after a series of unwearied observations—when its motions and position in the system were determined—since which time, its place in the heavens can always be ascertained. Only fifteen months elapsed, after the discovery of Ceres, when Dr. Olbers, on the 28th of March, 1802, discovered the planet Pallas. The planet Juno was discovered on the first of September, 1804, at the observatory of Lilienthal, near Bremen, by Mr. Harding, while he was endeavoring to form an atlas of all the stars near the orbits of Ceres and Pallas, with the view of making further discoveries. The planet Vesta was discovered on the 29th of March, 1807, by Dr. Olbers, who had previously discovered Pallas. He had previously conjectured that the three small celestial bodies, lately discovered, were merely the fragments of a larger planet, which had been burst asunder by some internal convulsion, and that several more might yet be discovered between the orbits of Mars and Jupiter. On this hypothesis he concluded that, as these fragments must all have diverged from the same point, they ought to have two common points of reunion, or two nodes in opposite regions of the heavens, through which all the planetary fragments must sooner or later pass. One of these nodes he found to be in the sign Virgo, and the other in the constellation of the Whale—and it was actually in the Whale that Mr. Harding discovered the planet Juno. Therefore, with the intention of discovering other fragments of the supposed planet, if any should exist, Dr. Olbers examined three times every year, all the small stars in the opposite constellations of Virgo and the Whale—and his labors were crowned with success, by the discovery of a new planet, in Virgo, to which he gave the name of Vesta.

The magnitudes of these bodies, on account of their comparatively small size, and the difficulty of measuring their apparent diameters, have not yet been accurately determined. The following is a brief summary of what has been ascertained respecting their distances, motions and magnitudes. The planet Vesta, which was last discovered, is considered as the nearest to the sun. Its distance from that luminary is reckoned to be about 225 millions of miles, and it revolves about the sun in 1325 days, or in three years, seven months and a half, moving at the rate of 44,000 miles an hour. Some have estimated its diameter at 276 miles, and if so, it will contain 229,000 square miles on its surface. But it is probable, from a variety of circumstances, that it is considerably larger in size than what is here stated. The distance of Juno from the sun is 254 millions of miles, and it accomplishes its revolution in four years and one hundred and twenty-eight days, at the rate of 41,850 miles an hour. Its diameter is estimated by certain German astronomers, at 1425 English miles. It is of a reddish color, and is free from any nebulosity, and is supposed to be environed with a dense atmosphere. The planet Ceres is 263 millions of miles from the sun, and finishes its revolution in four years, seven months, and ten days. Its real diameter is estimated at 1624 miles, so that its surface will contain more than eight millions of square miles; but its atmosphere is reckoned at about 675 miles in hight. It is of a slight ruddy color, and appears like a star of the eighth magnitude. The planet Pallas is distant from the sun about 263 millions of miles, or about the same distance as Ceres, and completes its revolution in four years, seven months, and one-third of a month, which is within a day of the time of the revolution of Ceres. Schroeter, a German astronomer, considered this planet as the largest of the four, and he estimated its diameter to be 2099 miles, and consequently nearly the size of our moon. It presents a ruddy aspect, and is surrounded with a nebulosity, somewhat like Ceres, but not so extensive. It is distinguished from all the other planets by the very great inclination of its orbit to the plane of the ecliptic, which is no less than thirty-four degrees thirty-seven minutes.

These four planets present to our view certain singularities and anomalies, which, at first view, appear incompatible with the harmony and proportions which we might suppose originally to have characterized the arrangements of the planetary system. 1. Their orbits are in general more eccentric than those of the other planets; in other words, they move in longer and narrower ellipses. The eccentricities of the orbits of Juno and Pallas amount nearly to one-eighth part of the transverse axes of their orbits; whereas the eccentricities of the orbits of Jupiter and Uranus are only the one forty-third part, and that of the earth, one hundred and nineteenth. Hence it follows, that Pallas and Juno will sometimes be 129 millions of miles farther from the sun at one period than at another. 2. Their orbits have a much greater degree of inclination to the ecliptic than those of the other planets; that of Pallas being no less than thirty-four degrees and a half, which is twenty-seven times greater than that of Jupiter. 3. They revolve nearly at the same mean distance from the sun. The mean distance of Juno is 254,000,000; of Ceres, 262,903,000, and of Pallas, 262,901,000 of miles; while in the case of all the other planets, many millions of miles, sometimes amounting to hundreds, intervene between their orbits. 4. They perform their revolutions in nearly the same periods. The period of Juno is four years, four months and a half; of Ceres, four years, seven months and a half; and of Pallas, four years, seven months and a half; whereas the periods of the old planets differ very considerably from each other: that of Mars being less than two years; that of Jupiter, twelve years; of Saturn, nearly thirty years; and of Uranus, eighty-four years. 5. The orbits of some of these planets cross each other. This is a very singular and unaccountable circumstance in regard to planetary orbits, and cannot possibly happen in the case of the other planets, or any of their satellites. This is represented in the following diagram, fig. 44. The orbit of Vesta crosses the orbits of the other three, and therefore it is a possible circumstance that a collision might take place between Vesta and these three planets at the points of intersection *a* and *b;* and were it ever to happen, the consequences would be dreadful to both planets.

Within a very short period, a new planet has been discovered by Mr. Hencke, of Dreisen, in Prussia. It appeared like a star of the ninth magnitude, in a place where, before, there was none. This discovery was made on the 8th of December, 1845. Its place on December the 14th, as found by Professor Encke, of Berlin, at six hours twenty-eight minutes, was, right ascension, 64 deg 4 min. 53 sec. At thirteen hours, 34 min. 55 sec., its right ascension in time was 4 hours, 16 min., 2 sec. Declination north, 12 deg. 39 min. 53 sec. At fourteen hours, 33 min. 27 sec. Right ascension in time, 4 hours 16 min. Declination north, 12 deg. 39 min. 52 sec. Its motion was retrograde, and its daily amount, as determined from the observations, 8 hours apart, was, in right ascension, 14 min. 21 sec. In declination, its motion was quite insignificant. This moving body was afterward observed in England by Messrs. South, Airy, and others; and from their observations and those of foreign astronomers, it has now been determined to be a planet belonging to the solar system, to which the name Astræa has been given.

Fig. 44.



From the notes of Astræa's position given by Encke and Schumacher, M. Faye, a French astronomer, has calculated the elements of its orbit. They are as follows:—

	Deg.	Min.
Epoch, 1845, Dec. 14,.......	71	13.6
Longitude of ascending node,	135	14.6
Inclination,................	6	1.2
Semidiameter of orbit,........26,024		
Movement,...............direct.		
Period of sidereal revolution, 4 years 2 months.		

It appears, therefore, that Astræa has a certain relation to the four minor planets, revolving between Mars and Jupiter, which were discovered about the beginning of the present century. This relation will appear at once when their elements are compared, as in the following statement:—

	Mean dist. from the sun.	Mean period in days.	Inclination of orbit.		
Vesta,....	2.3678	1325	7°	8′	9″
Juno,....	2.6690	1592	13	4	9
Ceres,....	2.7672	1681	10	37	26
Pallas,....	2.7728	1686	34	34	55
Astræa,...	2.6024	1521	6	1	2

In the element of distance, that of the earth from the sun is taken as a unit. The distance of Astræa from the sun is to that of the earth as 2.6024 to 1.000, or in round numbers as 26 to 10. It follows that Astræa revolves round the central luminary at the distance of 247,000,000 miles. In its distance and period of revolution, Astræa agrees most nearly with Juno, in inclination with Vesta.

The discovery of this planet affords a strong corroboration of the hypothesis which supposes that the four new planets formerly discovered, originated from the disruption of a large planet which formerly moved between Mars and Jupiter Such a catastrophe is involved in a great mystery; and yet, without supposing it to have taken place, we can scarcely account for the peculiarities of these planets, which form anomalies in the solar system. It is not improbable that other bodies, originating from the same source, may yet be discovered.

Such anomalies and singularities, in the case of these lately discovered bodies—so very different from the arrangement of the other planets—have opened a field for speculation and inquiry. It has been supposed, on somewhat plausible grounds, that these planets are only the fragments of a larger planet which had been burst asunder by some immense eruptive force proceeding from its interior parts. This hypothesis accounts in a great measure for the anomalies and apparent irregularities to which we have alluded, particularly for the intersection of their orbits, and for the fact, that the planets are not round, as is indicated by the instantaneous diminution of their light, when they present their angular faces. It has also been supposed that the smaller fragments that may have escaped at the time of the disruption, may account for some of the meteoric stones which at different times have fallen from the higher regions upon our globe.

Whether we consider the present peculiarities, positions and motions of these planets, as accordant with the state in which they were originally created, or whether we view them as the effects of some tremendous shock or disruption, there appears to be something sublimely mysterious and worthy of attention in the physical—not to say moral—arrangements of the Almighty, in the state in which these bodies are now found. If they were originally arranged in the position and order in which they now appear, they present an anomaly, a want of proportion and harmony, to whatever appears elsewhere throughout the whole range of the system. And, if their present phenomena be the effects of some dreadful concussion, the fate of the beings that inhabited the original planet must have been involved in the awful catastrophe We need not be much surprised, although such an event should have taken place, nor should we consider it as inconsistent with what we know of the physical and moral government of the Almighty. For an event somewhat analogous happened to our own globe, at that period when "the cataracts of heaven were opened, and the fountains of the great deep were broken up," when a flood of waters ensued which covered the tops of the loftiest mountains, transformed the earth into a boundless ocean, and buried the myriads of its population in a watery grave. And we profess to believe that a period is approaching when the great globe we inhabit shall undergo a tremendous change, and its elementary parts be dissolved, when the aërial "heavens shall pass away with a great noise, and the elements shall melt with fervent heat, the earth also, and the works that are therein shall be burned up."

All the parts of the material system are liable to change; and we have no reason to conclude, that, throughout the future periods of duration the earth is the only globe in the universe whose present constitution and aspect shall undergo an important change. As it is probable that the work of creation is incessantly going forward throughout different regions of immensity, so it is highly probable that numerous changes and renovations are taking place in those departments of creation which have long existed, in order to present new scenes and new manifestations of the perfections of the Creator to the view of the intelligent universe. For the whole system of creation appears to be in incessant motion; there is not an orb in the firmament, among all the millions it contains—whether great or small—but is in rapid and perpetual motion through the vast spaces of infinitude, and, in the course of ages, these movements, conducted by certain laws, under the direction and superintendency of the Supreme, may produce changes and revolutions which will add to the grandeur of the material universe, and excite the admiration of the intelligent system. He only is immutable who existed from eternity past, who gave birth to all created beings, whose presence fills the immensity of space, and of whose years there shall be no end. And throughout all the regions of space, so far as the material creation extends, his moral government is exercised, in a thousand different modes, corresponding to the rectitude, the wisdom and the benevolence of his character, and the condition of the intellectual beings he has formed. For wherever power, wisdom, and intelligence are displayed, there also must all the other perfections of the Almighty be in incessant operation; and hence we are informed, that "he doth according to his will in the army of heaven" as well as among 'the inhabitants of the earth."

SECTION IV.

On the planet Jupiter.

This planet is the largest body connected with the planetary system, the sun only excepted. It is situate about 232 millions of miles beyond the orbit of Pallas, 350 millions beyond the orbit of Mars, and 495 millions from the sun. When nearest the earth, it is 400 millions of miles distant from us, and when in the remotest part of its orbit from the earth, it is 590 millions of miles distant. Notwithstanding this immense distance, owing to its great magnitude, it appears the most brilliant star in the heavens next to the planet Venus. Its revolution round the sun is accomplished in four thousand three hundred and thirty-two days and a half, or about 11 years, 10 months, and 17 days, during which it performs a circuit of more than three thousand millions of miles, at the rate of more than twenty-nine thousand miles an hour. Its diameter is no less than eighty-nine thousand miles; its circumference two hundred and seventy-nine thousand miles, and its surface twenty-four thousand eight hundred and eighty millions of square miles, which is more than one hundred and twenty-six times the area of our globe. But as globes are to each other as the cubes of their diameters, and the cube of Jupiter's diameter is 704,969,000,000,000 miles, and the cube of the earth's diameter is 498,677,257,000; divide the cube of Jupiter's diameter by that of the earth, and the quotient will be 1413; showing that Jupiter, as a solid globe, is one thousand four hundred and thirteen times larger than the earth. This huge planet moves round its axis in the space of nine hours and nearly fifty-six minutes; which is a more rapid rotation than that of any of the other planets. Its equatorial parts will move with a velocity of twenty-eight thousand miles an hour, which is twenty-seven times more rapid than the earth's rotation, by which the inhabitants at the equator are carried along at the rate of 1037 miles an hour. The rotation of this planet was first determined about the year 1665, by Cassini, by observing the gradual motion and revolution of a spot which appeared to move from one side to another of its disc, and returned again to the same point in nine hours and fifty-six minutes, and as the spot was evidently connected with the body of the planet, the conclusion was evident, that the planet itself turned round its axis. Hence we learn, that there is an alternate succession of day and night on Jupiter, analogous to that which we experience on the earth; but the days and nights are much shorter than ours, and the sun and the moons which belong to this planet, together with the whole frame of the heavens, will appear to move around it with a much greater rapidity than what appears from our terrestrial habitation.

The axis of this planet being nearly perpendicular to the plane of its orbit, it cannot have the same variety of seasons as the earth and Mars. Its inclination, however, is three degrees, five minutes, which will produce a slight change of seasons both in the polar and equatorial regions. Had the axis been as much inclined to the orbit as in the case of the earth, the polar regions would have been deprived of the light of the sun for nearly six years without interruption. And although the light and heat of these regions cannot be so great as in other parts of the planet, yet there are many ways unknown to us, by which the All-wise and Beneficent Creator may render every region of this globe a comfortable habitation for both sensitive and intelligent beings.

The apparent motion of this planet, like that of Mars, formerly explained, is sometimes direct, sometimes retrograde, and sometimes stationary. Its retrograde motion commences or finishes when it is at a distance from the sun, which varies from 113½ to 116½ degrees. The arc which it describes in this case varies from 9 degrees, 59 minutes, to 9 degrees, 51 minutes, and its period of duration from 116 days, 18 hours, to 122 days, 12 hours. Its apparent motion through the signs of the zodiac is, at an average, at the rate of a little more than thirty degrees in a year. It is at present (April, 1846), near the beginning of the sign Gemini, and will be in opposition to the sun on the 3d of December, about which period it rises near the time of sunset, in a direction nearly north-east, and will be seen shining in all its splendor, in a clear evening, until five or six o'clock the next morning. During the following years, it will be somewhat more than a month later, every year, before it arrive at its opposition: but it will be a conspicuous object in the heavens, during the winter evenings, for several successive years; and as it is the most brilliant planet in the heavens—with the exception of Venus—it is easily distinguishable from all the surrounding stars by its superior luster.

This planet, when viewed through a good telescope, presents a very splendid and interesting appearance, especially when its moons are arranged, two on each side, at nearly equal distances from the planet and from each other. When a magnifying power of above a hundred times is used, its surface appears much larger than the full moon does to the naked eye.* The most striking appearance on the surface of this planet is a series of darkish stripes, which run across its disc parallel to its equator, which are generally denominated its belts. They were first discovered by Fontana, and two other Neapolitans, about twenty-five years after the invention of the telescope. They were afterward more particularly described by Cassini, who was enabled to view them with more powerful telescopes. Their number is variable—sometimes eight have been seen at one time, and sometimes only one or two have been distinctly visible. Their general appearance for several years past, as viewed with telescopes magnifying from one hundred to one hundred and eighty times, is as follows:—two dark belts, one on each side of the planet's equator, and two fainter ones, one at each pole, somewhat broader than the equatorial belts. Sir James South states, that when he was making observations with his twenty-feet achromatic telescopes, with powers of 252 and 346, he perceived Jupiter "literally covered with belts." These belts, though generally parallel to each other, are not always so—for a portion of a belt has been seen in an oblique position to the rest. At certain times the belts have continued without sensible variation for six or eight months, and, according to some observers a new belt has been formed in the course of a few hours.

---

* Those who are not accustomed to view the heavenly bodies through telescopes, are apt to imagine that they are not nearly so much magnified by the instrument as they real-

It has been a subject of much speculation and conjecture among astronomers, as to the views we should entertain respecting the nature of these belts, and the causes which operate in producing the changes which occasionally take place among them. Whatever opinion we may form on this point, it is pretty evident that the dark stripes or belts are the real body of the planet, and the bright spaces between them are either clouds in its atmosphere, or circular zones, liable to variations, which surround the planet at a certain distance from its body. Some have insinuated that the changes among these belts are owing to great physical convulsions occasionally taking place on the surface of Jupiter—an opinion altogether improbable. Others suppose that the bright streaks are the external surface of masses of clouds disposed in rows, and that such a disposition of clouds might be produced by prevailing winds blowing in a direction parallel to the equator of the planet. They have been compared to our trade-winds, which are considered as the necessary effect of the earth's diurnal rotation, combined with the influences of the solar heat upon the tropical belt of the earth; and that the rapid diurnal motion of Jupiter will cause the trade-winds in that planet to have a permanence, force and range, which would produce a distribution and arrangement of the clouds floating in its atmosphere, such as we observe in the appearance of its belts.

This is an opinion which very generally prevails among astronomers; but we do not think that it will fully account for the phenomena of the belts, or that it is consistent with the idea of a habitable world. For if the trade-winds in Jupiter were increased, in velocity and force, twenty-seven times greater than our trade-winds—which is admitted by those who hold this opinion—then their violence would be such as to drive everything before them along the surface of the planet, and there would be no possibility of living beings moving in opposition to such rapid currents. It is reckoned that, in a high gale, the wind moves at the rate of about thirty-eight miles an hour—multiply this number by twenty-seven, and the product, 1026, will give the velocity of a gale in Jupiter, in the same time. Now, it has been found, that a West India hurricane, blowing at the rate of a hundred miles an hour, has blown heavy cannon out of a battery, torn up trees by the roots, and carried huts, sheds, and human beings to a considerable distance through the air. What, then, would be the force of a gale moving at the rate of a thousand miles an hour? And, much more, what would be the force of a hurricane in Jupiter, moving at the rate of two thousand seven hundred miles an hour? On such a globe as ours, it would overturn and demolish everything upon its surface, so that our strongest and most stately buildings could not possibly resist its force. Such a state of things appears altogether inconsistent with the idea of a comfortable habitation either for sensitive or intellectual beings. It is much more consistent with the imperfection of our knowledge, at once to acknowledge our ignorance, and to wait for future discoveries on this subject, than to broach opinions which lead to such consequences.

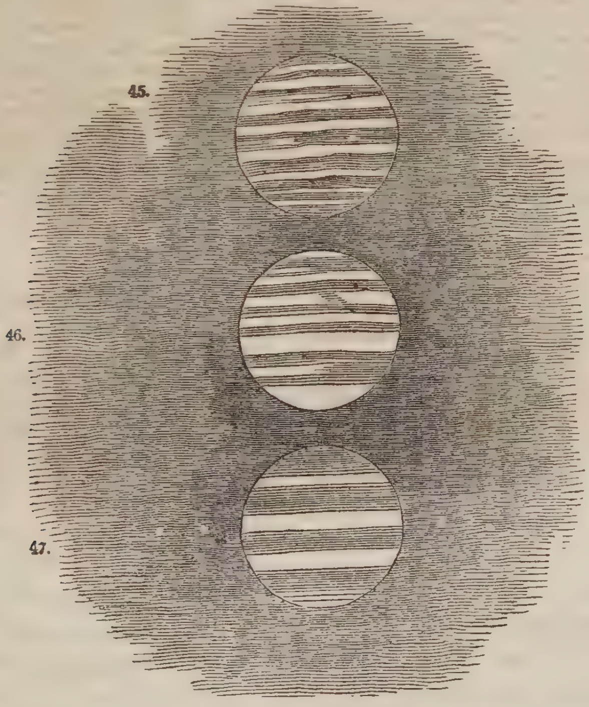
The following figures represent different views of the belts of Jupiter. Fig. 45 represents one of the views taken by Cassini, in which about eight or nine belts appear, some of them somewhat broken and irregular. Fig. 46 represents another view, in which there appears an oblique belt forming a connection with two adjacent belts, as if it were a fluid running from the one into the other. Some have attempted to trace a resemblance in the changes of the belts and spots to what would appear upon the disc of the earth, viewed at such a distance as would bring it to the size of Jupiter. It is supposed that the great ocean, which environs our globe, would resemble the principal belt of Jupiter; the Mediterranean, one of the broken belts; the Caspian Sea, a large spot; some of our largest islands, the bright spots seen in the belts, as in fig. 45; and the clouds stretched round the equator of the earth, the changeable belts. But such views are more fanciful than accordant with the observed phenomena of this planet, and we must wait for further discoveries before we come to any decisive conclusions on this subject. Perhaps the Earl of Rosse's great telescope, which is now in use for celestial observations, may be the means of throwing some further light on this subject, and enable us to form more correct views of the belts, spots, and other phenomena of this planet. It has already resolved certain nebulæ into stars, which were formerly supposed to be unresolvable. Fig. 47 represents a telescopic view of Jupiter and his four satellites, when two of them happen to be on each side of his disc. The belts, as represented in this figure, are nearly similar to what they have appeared for several years past.

---

ly are. With a power of one hundred times, most persons would imagine that Jupiter appeared much less than the moon to the naked eye; and yet it may be proved that such a power presents this planet to the eye with a diameter of about twice that of the apparent size of the moon. The mean apparent diameter of Jupiter is thirty-eight seconds, which, being multiplied by one hundred, the magnifying power, produces three thousand eight hundred seconds, which is equal to sixty-three and one-third minutes. Now, the mean apparent diameter of the moon is thirty-one minutes, twenty-six seconds, the double of which is sixty-two minutes, fifty-two seconds, which is less than the apparent size of Jupiter when magnified one hundred times. But, when in opposition, Jupiter's apparent diameter is forty-seven and a half seconds, and consequently, at such a period, this planet will appear still larger. In order to produce full conviction of the accuracy of the above statements, an observer should view Jupiter, when in the immediate vicinity of the moon, and, looking with one eye through the telescope, and with the other at the moon, endeavor to make the image of Jupiter in the telescope to coincide with the moon, and he will then clearly perceive the proportion of their apparent magnitudes. From what has been now stated, it appears that a magnifying power of fifty times will make the disc of Jupiter appear as large as the moon to the naked eye.

We may just mention the following additional particulars respecting this planet:—Notwithstanding the brilliancy with which it appears in our nocturnal sky, its light, derived from the sun, is 27 times less than what falls upon the earth; and the diameter of the sun, as seen from Jupiter, is only 6 minutes, 9 seconds, or about one-fifth of the diameter the sun appears to us. The figure of this planet is that of an oblate spheroid—the equatorial being more than six thousand miles larger than the polar diameter. Its density, compared with that of water, is as $1\frac{1}{24}$ to 1—in other words, it is somewhat denser than water. Although it is one thousand four hundred times larger than the earth in bulk, yet it would weigh only three hundred and twelve globes of the same size and density as our globe. Its mass, as compared with that of the sun, is as 1 to 160,709. A body weighing one pound at the equatorial surface of the earth, would, if removed to the surface of Jupiter, weigh 2 pounds, 4 ounces, 8 drams. The eccentricity of its orbit, in miles, is 23,810,000, and the inclination of its orbit to the ecliptic is 1 degree 19 minutes. In the firmament of Jupiter, no planets will be visible to such eyes as ours, excepting Saturn and Uranus. An observer, placed on this planet, would have no suspicion that such a globe as our earth had an existence in the universe—all its fancied splendors and its proud inhabitants are as much unnoticed and unknown as the smallest animalculæ in a drop of water to the unassisted eye. To his satellites, Jupiter will appear as a large and resplendent moon in their firmament, filling a considerable portion of the sky; from the surface of the first satellite it will appear above a thousand times larger than the moon does to us, and will, in succession, present to it all the diversified phases of the moon—a crescent, a gibbous phase, a half-moon, and a full enlightened hemisphere.

Figs. 45, 46, 47.



SECTION V.

On the satellites of Jupiter.

This planet is accompanied by four satellites, or moons, which revolve around it in different periods of time. The discovery of these revolving bodies was among the first enterprises accomplished after the invention of the telescope; they were first discovered by Galileo, an Italian astronomer, in the beginning of the year 1610. In his book, entitled "Sidereus Nuncius," he gives us a particular account of their discovery, and the numerous observations he made on their motions and relative positions, accompanied with sixty-four figures of their various aspects at different times. On the 7th of January, 1610, in the evening, while observing the stars with his newly-invented telescope, he perceived Jupiter making his appearance, and, applying his instrument to that planet, he perceived three small bright stars very near it, two on the east side and one on the west. These he took to be fixed stars at that time; but, happening the next night to view them again, he saw them all three on the west side of Jupiter; which made him greatly wonder how this could be, for it was an event quite inconsistent with the theory of the planets and fixed stars. On the tenth night he saw but two, and both on the east of Jupiter; on the eleventh also he saw but two, and both on the same side; but one of these was twice as large as the other—and, hence, he was sure they were not the same he saw the night before. On the thirteenth night, viewing them again, he saw four of these small stars, three on the west side of Jupiter, and one on the east side, all nearly in a straight line. On the fifteenth, he beheld all the four on the west side of the planet, nearly in a straight line, and at equal intervals from Jupiter and from each other. These were all he could ever discover; and, by constantly observing their situation and changes, found that they were not fixed stars, but moons, or secondary planets, revolving about Jupiter in the same manner as the primary planets revolve about the sun. The telescope with which these observations were made magnified about thirty-three times.

These satellites form a system of revolving bodies, somewhat similar to the great system of the sun and primary planets. As the sun is the center of the primary planets, so Jupiter is the immediate central body around which the satellites revolve; but while these revolutions are going forward, the satellites are at the same time carried along with Jupiter in his course round the sun. The satellites are governed by the same laws as the primary planets; they describe equal areas in equal times; and have the squares of their periodical times proportioned to the cubes of their mean distances from the planet. They revolve from west to east, in the same direction as the moon and the primary planets—and in planes very nearly, though not exactly, coincident with the equator of the planet, or parallel to its belts. Accordingly, we see their orbits projected very nearly into straight lines, in which they appear to oscillate to and fro, sometimes passing before Jupiter, and casting shadows on his disc, and sometimes disappearing behind his body, or being eclipsed by his shadow at a distance from it. It has been established, from observation, that 247 revolutions of the first satellite, 123 revolutions of the second satellite, and 61 of the third satellite, are performed exactly in the same number of days. It has been found, by La Place, that "the epoch (or mean longitude) of the first satellite, minus three times that of the second, plus two times that of the third, is exactly equal to a semicircle, or 180 degrees." From this it follows, that the first three satellites of Jupiter can never be eclipsed at the same time; for, if this were possible, the longitude of three satellites would be equal at the time of their eclipse, which is impossible.

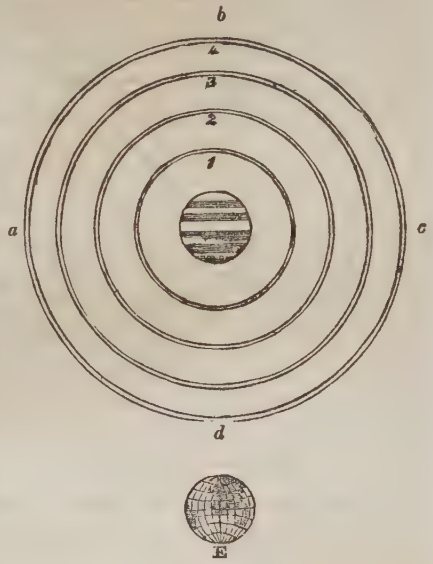
These satellites suffer numerous eclipses in their revolutions round Jupiter. The first three suffer an eclipse every time they are in opposition to the sun. The first is in opposition every forty-two and a half hours, and consequently suffers about eighteen eclipses every month. The second and third likewise suffer a variety of eclipses every month; but the fourth satellite frequently passes its opposition without being involved in the shadow of Jupiter, as its orbit has a greater degree of inclination to the orbit of Jupiter, than those of the other satellites. During the year 1845, there happened 174 visible eclipses of the first satellite, 88 of the second, and 45 of the third—beside those which are invisible on account of Jupiter's nearness to the sun. Whereas the fourth satellite did not suffer a single eclipse during the year 1846. These satellites may be seen with a telescope magnifying about twenty-five or thirty times; but, in order to see their eclipses to advantage, the telescope should be furnished with powers of 100 or 200 times. The circumstances to be chiefly observed, in reference to the satellites, are, their eclipses—that is, their entering into the shadow of Jupiter, when they suddenly disappear, or their emersion from it; their occultations or disappearance behind the body of the planet; their transits or passage across its disc; and the transits of their shadows across the face of Jupiter, which appear like dark spots on a bright ground—all which phenomena may be perceived by means of powerful telescopes. When they pass across the disc of Jupiter, and project a shadow on its surface, this produces a solar eclipse to all those places over which the shadow passes.

It has been concluded, from observations made by Sir W. Herschel and others, that the satellites of Jupiter always turn the same face to the planet, and make one rotation on their axis during one revolution round the planet—which corresponds with what we find in the case of our moon, which, as formerly noticed, always turns the same hemisphere to the earth. The following table shows the magnitudes of these bodies, their times of revolution, their distances from Jupiter in miles, and the duration of their eclipses:—

	Diameter in Miles.	Dist. from Jupiter.	Times of Revolution.	Duration of Eclipse.
1st satellite,	2,508	260,000	1d. 18h. 28m.	2 hours.
2d	2,068	420,000	3 13 14½	3
3d	3,377	670,000	7 3 43	3½
4th	2,890	1,180,000	16 16 32	5

The fourth satellite is about three times the bulk of our moon, and all the satellites taken together are equal to nearly thirteen of our moons. The number of square miles on the surfaces of all the satellites is above ninety-five millions. Fig. 48 shows the orbits of the four satellites, though not in the exact proportion of their distances from Jupiter—the fourth satellite being nearly double the distance of the third. When a satellite moves through the part of its orbit *a b c*, which is farthest distant from the earth—which is supposed to be placed in the direction E—it appears to move from west to east; but when it moves through the other portion of its orbit, *c d a*, it appears to move from east to west. But, as our eye is nearly on a level with the plane of the orbits of these satellites, their motions appear to be performed nearly in straight lines. Though their enlightened sides are almost constantly turned toward the earth, yet they present all the varied phases of

Fig. 48.



the moon to Jupiter himself—sometimes appearing as crescents, sometimes as half moons, and sometimes shining with full enlightened hemispheres.

The eclipses of these satellites have been found of great utility in determining the longitude of places on the surface of our globe, in a manner much more accurate and easy than was known prior to their discovery. They also led to the discovery of a sublime and unexpected fact, namely, the motion of light, and the rate at which it is propagated through the regions of space. It was found that a difference of sixteen and a half minutes existed between the times when the eclipses were seen when Jupiter was nearest the earth, and when he was farthest distant, and it was concluded that light requires this space of time to fly across the earth's orbit, which is one hundred and ninety millions of miles in diameter, and, consequently, that light moves with a velocity of about one hundred and ninety-two thousand miles every second. This conclusion has been fully confirmed by Dr. Bradley's discovery of the aberration of the light of the fixed stars.

The four moons, which accompany this planet, must exhibit many curious and sublime phenomena to its inhabitants, as they perform their nocturnal courses through their firmament. Sometimes they will be seen eclipsing the sun, and, at other times, the stars, and sometimes eclipsing each other. Sometimes two, three, and even all the four will be seen shining in the heavens in one bright assemblage—one, perhaps, in the form of a crescent; one with a gibbous phase; one like a half moon; and the other with a full enlightened hemisphere; one moving comparatively slow, and another rushing rapidly through the sky, and leaving all the others behind it; one under a total eclipse, another entering into it, and a third emerging from it. These, and many other celestial phenomena, must be highly interesting and gratifying to the astronomers and all others in that far distant world. The celestial scenes exhibited from the satellites themselves will be no less interesting and sublime. From the surface of the first satellite, the globe of Jupiter will appear like an immense body in the firmament, above a thousand times the size that the moon appears to us, and filling a large portion of the sky; and it will exhibit, in the course of twenty-one hours, a crescent, a half moon, a gibbous phase, and a full enlightened hemisphere, with all the variations of the belts which diversify its surface. Beside, the appearances of the other three moons in its firmament will be highly interesting. At certain times, one of these moons will come so near the first satellite as to appear three times larger than the moon does to us, and, at other times, it will appear sixteen times smaller than in its former position; and a variety of other phenomena will be presented, which it would be too tedious to describe—all which will present to view objects of overpowering grandeur, far superior to what we behold in our nocturnal sky.

On the whole, the planet Jupiter, as accompanied with his satellites, presents to our view an object of surpassing grandeur and sublimity, when we contemplate the vast magnitude of this magnificent globe, and the velocity with which it flies through the regions of space. Let us conceive, if we are able, a globe, fourteen hundred times the size of our world, with a surface capable of containing a number of inhabitants, eight thousand times greater than the present population of our globe; let us conceive such a globe revolving round its axis at the rate of four hundred and sixty miles in a minute, and flying through the regions of the heavens at the rate of nearly thirty thousand miles every hour, carrying along with it four revolving worlds in its swift career, and continuing this rapid course, without intermission; from one century to another, for thousands of years—and we behold a scene, calculated to fill every reflecting mind with admiration and astonishment. While contemplating such a scene, can we forbear raising our thoughts to that Almighty Being, who at first formed this mighty globe, and launched it from his powerful arm, and whose incessant energy sustains it in its swift career from age to age? Here we behold a demonstrative proof that "power belongeth unto God;" that "his greatness is unsearchable;" that "all nations before him are as nothing;" that there is none like unto Jehovah, nor any works like unto his works; that He "doth great things, and unsearchable," and "marvelous things without number." And here we have palpable evidence to confirm our belief that there can be nothing beyond the power of Jehovah to accomplish, and that we may rest secure that all the promises and predictions of his word shall, in due time, be fully accomplished, to the eternal happiness of all those who put their trust in Him: "For the Lord God omnipotent reigneth, his kingdom ruleth over all;" and his faithfulness is established "in the very heavens."

SECTION VI.

On the planet saturn.

This planet is situate at nearly double the distance from the sun as the planet Jupiter—an immense interval of 410 millions of miles intervening between the orbits of these planets, although next to each other in the order of the system. Its distance from the sun has been estimated at 906 millions of miles; when nearest to the earth, it is 811 millions of miles distant from us; and, when most remote, it is distant above a thousand millions of miles. It takes nearly thirty years to perform its revolution round the sun—during which period it moves round a circumference of nearly five thousand seven hundred millions of miles, at the rate of twenty two thousand miles every hour. Its period of rotation was for a long time, unknown; but Sir W. Herschel, from observing the motion of some spots on its surface, at length ascertained that it turned round its axis in the space of ten hours, sixteen minutes, and nineteen seconds.

When viewed by the naked eye, this planet presents the appearance of a nebulous star, of a dull leaden color, which would lead one, at first sight, to imagine that it could present no very interesting appearance, even through a telescope; and, as its motion is slow, it is hardly distinguishable from a fixed star. Its motion being slow compared with that of most of the other planets—if it be once recognized in the heavens, by any observer, near any large star, it will be found, from year to year, making only a slow progress to the eastward from that point. Its apparent motion in that direction, in the course of a year, is little more than twelve degrees, or less than the moon moves in twenty-four hours. Hence, if we perceive this planet in any particular point of the heavens this year, about the same time next year it will appear only about twelve degrees farther to the east. In the year 1846, Saturn might be seen rising on the 5th of July, about 10 o'clock in the evening, in north latitude 52 degrees, near the south-eastern part of the sky; and in 1847, about twelve days later, or about the 17th of July, he might be seen rising at the same hour, nearly in the same point of the horizon: thus the time of his appearance in the evening, from year to year, may be readily traced by any common observer.

Notwithstanding the dull appearance of this planet to the naked eye, when viewed through a powerful telescope, it presents a more singular and magnificent appearance than any other body connected with the solar system; and were it as near us as Mars, or even as Jupiter, it would present a splendid aspect even to the naked eye. The ancients, who first traced the motion of this planet, could form no idea of the grandeur of Saturn, and of the system with which it is connected; and their astrologers, on account of his pale, leaden hue, accounted him as a cheerless, unfortunate planet, and as shedding a malign influence upon the inhabitants of the earth. But after ages of darkness and superstition had rolled away, the telescope, which has unfolded to us the wonders of the heavens, was invented, and, by the help of this noble instrument, a system of revolving bodies was discovered around this planet, and a piece of celestial mechanism disclosed to view, more wonderful and magnificent than any other object within the limits of our system—the existence of which we could never previously have anticipated.

In magnitude, this planet nearly approximates to the size of Jupiter. Its diameter is estimated at seventy-nine thousand miles ; its surface contains nineteen thousand six hundred millions of square miles; and its solid contents amount to two hundred and sixty-one billions, three hundred thousand millions of cubical miles. It is, consequently, nearly a thousand times larger than our globe. With powerful telescopes, four or five belts have been discovered on its surface, which are broader and less strongly marked than those of Jupiter, and are not subject to the variations which appear in Jupiter's belts—and therefore it is probable that they form permanent portions of the globe of Saturn, indicating that there is a diversity of surface on this planet; but whether land and water, or any other substance, is to us unknown. Its figure, like that of Jupiter, is a spheroid—the proportion of the polar and equatorial diameters being nearly as eleven to twelve; consequently the equatorial diameter is 6700 miles longer than the polar. The quantity of light it receives from the sun is only the one-ninetieth part of what we receive; but this portion of light is equal in effect to the light which would be reflected from a thousand full moons of the size of that which is connected with our world The density of this planet is less than that of any other planet in the system. It has been calculated, on physical principles, that a ball of cork equal in size to Saturn would nearly counterpoise it, that is, would be nearly of the same weight; so that its specific gravity is less than half the weight of water. Notwithstanding, it is possible that the density of the materials on its surface may be as great as those substances which form the upper crust of our globe; and its density, instead of increasing toward the center, as is the case with the earth, may gradually decrease from its surface to its central parts, so that the materials near the center may be as light as air.

The satellites of Saturn.—This planet is accompanied with a more numerous train of attendants than any of the other planets. No fewer than seven large moons have been discovered moving around this mighty orb to diffuse light over its surface in the absence of the sun, and to diversify the scenery of its firmament. It was nearly half a century after the invention of the telescope, before any of these satellites were discovered. The first of these bodies which was discovered was that which is the sixth in the order of distances from Saturn. It was discovered on the 25th of March, 1655, by Huygens, a celebrated Dutch astronomer. In his work, entitled "Systema Saturnium," published in 1659, he gives us an account of sixty observations—each accompanied with a figure—which he made on the various positions of this satellite in respect to Saturn; in order to determine that it was a revolving body which performed a circuit around Saturn as a center. These observations were made with a common refracting telescope, twelve feet long, which magnified about sixty-eight times, but had not power nor light sufficient to show the rest of the satellites. It was not until the year 1671, that any other satellite was discovered: in that year Cassini, a French astronomer, discovered the seventh satellite, or the most distant from Saturn, which is next in brightness to the sixth; and in 1672, the same observer discovered the fifth satellite. Fourteen years afterward, namely in 1686, he discovered the third and fourth; and in making these observations he used telescopes of more than a hundred feet in length: though he tells us that afterward he could see all the five satellites with a telescope only thirty-four feet long, which could bear a magnifying power of only about one hundred and twenty times.* No other satellites were discovered until more than a century afterward; when Sir W. Herschel erected at Slough, near Windsor, his large forty feet reflecting telescope. On the first day this telescope was fit for observation, namely on the 28th of August, 1789, the second satellite was discovered; and soon after, the same unwearied observer discovered the first, by means of the same instrument. These satellites cannot all be seen but by means of powerful instruments. The sixth and seventh, or the two outermost, may be perceived by telescopes magnifying from eighty to one hundred times; but the two innermost, discovered by Herschel, are the most difficult objects to be perceived throughout the whole range of the solar system, and have seldom or never been seen with a less instrument than a twenty feet reflector, and eighteen inches aperture. It has been remarked, that the seventh satellite, or the most distant from Saturn, is sometimes not visible in the eastern part of its orbit, and that it appears to grow dimmer and dimmer as it recedes from its primary. This has been accounted for by supposing that it is sometimes covered with spots, and at other times free of them, or, if the spots be permanent, that it has a rotation round its own axis. The following are the periods of the sidereal revolutions of these satellites, and their distance from Saturn in miles. The first satellite, or that nearest to Saturn, performs its revolution in twenty-two hours and a half, at the distance of 120,000 miles from the center of the planet, and only 18,000 miles from the edge of the ring. Of course, this satellite will move round the visible hemisphere of Saturn's firmament in little more than eleven hours. The second satellite revolves round the planet in one day and about nine hours, at the distance of 150,000 miles. The third satellite performs its revolution in one day twenty-one hours and a quarter, at the distance of 190,000 miles. These three satellites are all much nearer to Saturn than our moon is to the earth; and as they are undoubtedly larger than our moon, they must present a large and splendid appearance to the inhabitants of Saturn. The fourth satellite completes its circuit in two days, seventeen hours and three quarters, at the distance of 243,000 miles,or a little more than the distance between the earth and moon. The fifth satellite finishes its periodical revolution in four days, twelve hours, fifty-five minutes, at the distance of 340,000 miles. The sixth requires a period of fifteen days, and twenty-two hours and three quarters, and revolves at the distance of 788,000 miles. The seventh, or outermost satellite, requires seventy-nine days and about eight hours to complete its revolution, and its orbit is 2,297,000 miles from the center of Saturn, or more than nine times the distance between the earth and the moon. The orbits of the six interior satellites are nearly circular, and very nearly in the plane of the ring. The orbit of the seventh approaches nearer in coincidence with the ecliptic.

---

* The long telescopes here alluded to—which were very difficult to manage, and required great dexterity and address in using them—are now entirely superseded by the invention of achromatic and reflecting telescopes, which will bear a high power, with a comparatively short length of tube; an achromatic telescope, 5 feet long, may carry a magnifying power superior to that of a common refracting telescope a hundred feet in length.

These satellites, like those of Jupiter, undergo frequent eclipses; but on account of their great distance from the earth, these eclipses are not frequently observed. It is evident that such a numerous assemblage of moons revolving around this planet at different distances and in different periods of time, will present a most beautiful, variegated, and sublime appearance in the heavens of Saturn; especially when all the seven satellites happen to appear at the same time above the horizon. Then one will appear as a full moon, another as a crescent, and another with a half moon, or a gibbous phase—one entering into an eclipse, and another emerging from it—the two inner satellites, on account of their nearness to the planet, presenting the largest discs, and the most splendid appearance, and moving with great velocity in their orbits, rapidly passing the other satellites, at different rates of motion, and leaving them behind in their courses. On the surface of Saturn itself, a curious effect will be produced, and a diversified scene presented. The shadows of all objects will be projected in different directions by the different satellites, according to their relative positions in the heavens. One satellite will project the shadow of an elevated object toward the east, another will project it toward the west; a third will make it fall toward the north; and in a variety of other directions, according to the number of satellites above the horizon, and the positions they occupy in the firmament; and the swift motion of the first two satellites will cause the direction of these shadows rapidly to change. In addition to all this variety of celestial scenery there is the grand spectacle produced by the magnificent rings with which the planet is encircled—which we will now endeavor to describe.

SECTION VII.

ON THE RINGS OF SATURN.

THESE rings form one of the most wonderful objects connected with the solar system. Galileo, soon after he had presented his newly invented telescope to the heavens, was the first of mortals who caught a glimpse of this singular appendage to the globe of Saturn: but on account of the want of sufficient power in his telescope, he did not recognize the nature of the object he was contemplating. From what he could discern, he imagined that Saturn consisted of three globes—a larger globe in the middle, and two small globes, one on each side, and all the three nearly touching each other. After viewing this phenomenon for the space of two years, he was amazed, at the end of this period, to find the middle globe left quite alone, and the two smaller globes to have disappeared; but after a period of about a year he again caught a glimpse of them, when they continued visible for about fourteen years in succession. Nearly half a century elapsed before the true nature and form of this extraordinary phenomenon were discovered. During this period many were the strange conjectures which were formed respecting it. Some astronomers thought that the two small globes stuck to the middle globe, others that they were separated from it. Some thought that the phenomenon consisted of one longish body, or ellipsoid, and that it was perforated with a very large hole, or opening on each side. Some imagined that two bodies, each of the form of a crescent, were connected with the body of Saturn, and one placed on each side; and some that the phenomenon consisted of an elliptical ring, but that this ring was attached to the globe of Saturn, above and below. Huygens, in his "Systema Saturnium," presents us with fourteen engravings of the various forms which different astronomers had conceived respecting this appendage to the globe of Saturn, some of which are very curious, and almost ridiculous, yet, in some cases, indicating considerable ingenuity of conception. It was not until about the years 1655 and 1656—forty-six years after the invention of the telescope—that the real nature and figure of this singular phenomenon were discovered by Huygens. This ingenious mathematician and astronomer, in order to settle the disputes on this subject, resolved in the first place, to improve the art of grinding object-glasses, so as to increase the magnifying power of telescopes; and in this he succeeded so far as to make some that magnified two or three times more than those which had been previously in use. With a telescope twelve feet long, and another, twenty-three feet in length—which would magnify nearly a hundred times—and, after a long series of observations, he demonstrated the true cause of those surprising phenomena, which had puzzled all preceding astronomers, and showed to a certainty that Saturn is surrounded with an immense ring, which is entirely separated from its body by an interval of many thousand miles, and that the diameter of the ring, in proportion to the diameter of the planet, was as 9 to 4.

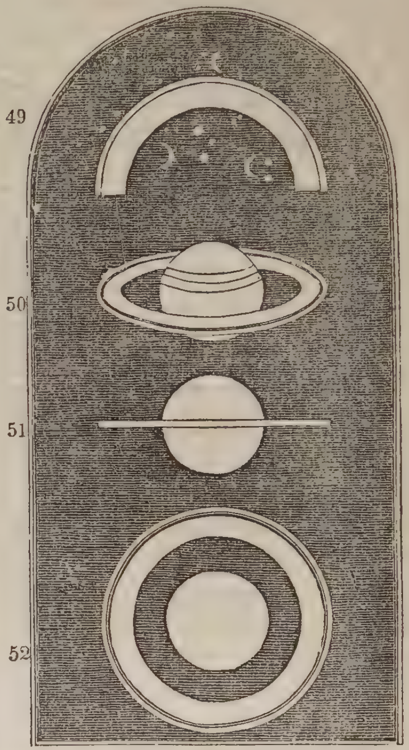
Since the time of Huygens, it has been discovered that this circular arch, which surrounds Saturn, is composed of two concentric rings, separated by an interval of nearly two thousand miles. The following are the dimensions of these rings, as calculated by Sir J. Herschel, from the measurements of Professor Strüve, made at Dorpat—by means of the superb micrometer attached to his great telescope:—Exterior diameter of the exterior ring, 176,418 miles; interior diameter of ditto, 155,272. Exterior diameter of the interior ring, 151,690; interior diameter of ditto, 117,339. Equatorial diameter of the body of Saturn, 79,160. Interval between the planet and the interior ring, 19,090. Interval between the two rings, 1791. Thickness of the rings, 100 miles. These dimensions are considered by some as rather too small. Sir W. Herschel, and all the astronomers who preceded him, estimated the exterior diameter of the exterior ring as above two hundred thousand miles; and Sir John Herschel himself admits, that "the interval of the rings above stated is possibly too small." Still the dimensions here stated convey to us a most astonishing idea of the magnitude and grandeur of those magnificent rings which encompass the globe of Saturn. Sir W. Herschel, by means of several protuberant points connected with the ring, discovered that it has a swift rotation around the globe of Saturn, which it accomplishes in about ten hours and a half—which, reckoning its circumference, according to the lowest dimensions, at 554,234 miles, is a velocity of about nine hundred miles every minute.

This double ring is evidently a solid body, as appears by its throwing a well-defined shadow upon the body of the planet, on the side nearest the sun, and on the other side receiving the shadow of the planet itself,—which is seen, at certain times, by means of powerful telescopes. It is everywhere at least twenty thousand miles distant from the surface of the planet, and yet it is carried along with it in its annual revolution round the sun; and, therefore, if it were not a solid body, it would either fly off from Saturn, or its centrifugal force, caused by its rapid rotation, would dissipate all its parts, and disperse them around the body of the planet. These rings contain, on all their surfaces taken together, an area of more than twenty thousand millions of square miles, which is more than a hundred times the area of our globe. They, therefore, contain ample space for the accommodation of thousands of millions of inhabitants.

In consequence of the immense size of these rings, and the large space they will occupy in the heavens, they will present a magnificent spectacle from those regions of the planet which lie under their enlightened sides, particularly those places which are situated not far from the planet's equator. They will appear as vast arches, spanning the firmament from one part of the horizon to the opposite, and holding an invariable situation among the stars. They will not be visible at the poles of the planet, on account of the convexity of the globe of Saturn interposing between them and the observer; but, near the polar regions, a segment of the rings will appear, presenting a brilliant appearance in the horizon. Advancing from these regions toward the equator, they will appear to span the heavens, like brilliant arches of different degrees of magnitude, until, approaching near the equator, they will appear in the form of complete semicircles. Fig. 49 presents a rude sketch of the rings, as they will appear from such a position, together with a partial view of the nocturnal firmament of Saturn. But no pictorial representation, however ample the scale, can convey even an approximate idea of the august and splendid objects which must diversify and adorn the nocturnal sky of Saturn. For, beside the rings, which will form the most striking and magnificent spectacle, there are seven moons, three or four of which generally diversify the celestial hemisphere, appearing in different positions, and with different phases; and, sometimes, the whole seven satellites may be beheld in one bright assemblage, pursuing their different courses among the stars, and rapidly shifting their positions and aspects.

The views of Saturn and the rings, obtained by powerful telescopes, are highly interesting and beautiful; but the appearance of the rings is not the same at all times. When seen to the greatest advantage, they appear as represented in fig. 50, where they assume the appearance of ellipses, or ovals, with the planet in the center, and on each side of the planet the dark space or interval between the interior ring and Saturn. The division between the rings is indicated by a dark line which seems to go round the ring, which is the empty space by which they are separated. It is only once in fifteen years, however, that the rings appear so open as here represented; and sometimes they are altogether invisible as seen from the earth. This happened in October, 1832; and after being visible for some time, from December, 1832, to April, 1833, the ring again disappeared for two or three months. During this time the only indication which was given of its existence was the shadow of the ring, which appeared like a dark belt across the body of the planet. At present (1846), the rings appear much narrower than what is represented in the figure, though the dark space between the planet and the ring is distinctly visible. In 1847, the ring will appear still narrower—in the beginning of that year, it will appear nearly as in fig. 51, like a line of light on each side of the planet, but without any apparent opening of the ring; in the beginning of 1848, it will entirely disappear, and, in this case, the thin edge of the ring is turned toward the earth, and the planet appears as if it were entirely divested of its magnificent appendage, and to move solitary among the stars. About July or August, of the same year, the ring will again appear, through good telescopes, as a fine thread, or line of light, on each side of

Figs. 49, 50, 51, 52.



the planet; and, in 1849, the opening of the ring and the dark space between it and the planet, will be distinctly visible. During the years 1850 and 1851, the ring will appear still more expanded, until toward the end of 1854, when it will appear fully expanded, as in fig 50; and, during the other seven years and a half, it will gradually contract until about the end of 1861, or the middle of 1862, when it will again become invisible.

The phenomenon of the disappearance of the ring takes place at intervals of 14 years and 9 months, and happens when the planet is in 170 degrees, and 350 degrees of longitude, or in the 20th degree of Virgo, and the 20th degree of Pisces. The sun shines on the one side of this ring during a period of nearly 15 years, and the regions of the planet, that lie under the dark side, suffer a solar eclipse, under its shadow, during the same period. But there is no doubt that this apparent defect is compensated, not only by the light of the satellites, but by other arrangements, with which we are unacquainted. This planet, with its rings, would exhibit a more splendid and interesting apearance through our telescopes, could we view the rings, not obliquely, but as standing at right angles to our line of vision, as represented in fig. 52. This represents the real position of the rings in respect to the planet; but our eye is never so much elevated above the plane of the rings as to view them in this manner; it is never elevated more than 30 degrees above the planes of the rings, so that we never see the rings more fully expanded than what is represented in fig. 50.

Had our limits permitted, we might have inquired into the ends for which these rings were formed by the Almighty Architect, and the designs they are intended to accomplish in the system of Saturn. But, in consequence of the great distance at which we are placed from this planet, and of our ignorance of many of the plans of the great Creator in his arrangements of the universe, we are unable fully to appreciate all the designs he intended to accomplish, either in this, or in other parts of his operations. There is one object, however, that these rings were evidently intended to accomplish; namely, to throw a light on the regions of the planet in the absence of the sun—to serve the purpose of a thousand moons—to produce a diversified and sublime scenery in the nocturnal sky of Saturn, and to display the glory and magnificence of the Creator. They evidently manifest his power in the amplitude and greatness of their dimensions, in the vast quantity of matter they contain, and in the amazing rapidity with which they revolve around the planet—and his wisdom in nicely balancing and proportionating every minute circumstance in their construction and arrangement, by certain laws, so as to prevent them either from flying off from the planet in its swift career, or from falling down upon its surface, and producing a complete derangement of the whole fabric of this mighty globe—and likewise in preserving them in their exact position, and proper motions, without variation from age to age. They may likewise be intended to teach us in what a variety of modes, inscrutable to us, the Creator may bring into existence numerous worlds, encompassed with celestial machinery and arrangements altogether different from anything we have hitherto contemplated—which may lead us to conclude that, in other systems, and around other suns, worlds may exist diversified with celestial scenery, of which we find no traces throughout the whole range of our planetary system.

But, beside these general designs, we conceive, there is another important end these rings are intended to subserve; namely, to form a habitation for numerous orders of intellectual beings. Wherever matter exists in our world, we find it peopled with different orders of animated existence; and therefore it would be absurd to suppose that the celestial bodies—formed by the same All-wise and Almighty Being—should be altogether destitute of inhabitants. The quantity of surface on the rings is more than twenty-thousand millions of square miles, being more than a hundred times the area of the whole terraqueous globe, and consequently contains ample space for the accommodation of myriads of inhabitants; and it is highly improbable from what we know of the plans of infinite wisdom, that such a space should remain forever as a barren desert, without contributing either to sensitive or intellectual enjoyment. The scenery of the heavens as beheld from the rings, would even be more grand and diversified than that which is beheld from the surface of Saturn, and would afford to intelligent natures a striking display of the perfections of their Creator.

We may just farther state, in relation to this planet, that several late astronomers are of opinion that the outer ring of Saturn is divided into several smaller rings. Captain Kater states, in a paper sent to the "Astronomical Society," that on December 17th, 1825, with a reflecting telescope of six feet six inches focus, "he saw the outer ring of Saturn, separated by numerous divisions, extremely close, one stronger than the rest, dividing the ring about equally. Professor Quetelet, at Paris, likewise states, that, with the achromatic telescope of ten inches aperture, "he saw the outer ring divided;" and Decuppis, at Rome, is also said to have observed the same phenomenon. Mr. Lawson, an ingenious astronomer, at Bath, who has lately erected a splendid achromatic telescope, twelve feet long, states, that with some of its higher powers, he has several times observed several divisions on the ring of Saturn If this magnificent arch is not merely double, but even treble, or quadruple, it presents a still more wonderful idea to the mind, especially if each of the rings have a distinct and separate rotation round the planet. But as the divisions alluded to have not been perceived by other observers in the most favorable circumstances, we must suspend our opinion on this point, until more minute and extensive observations be made, either to disprove or to confirm those which we have now stated.

In concluding our reflections on this planet, it is almost needless to remark, that the planet itself, with all the celestial scenes connected with it, presents to the mind an object of surpassing grandeur and sublimity: Let us suppose ourselves stationed within a few thousand miles of this planet—a station which some superior intelligences may occasionally occupy—from such a position, the globe of Saturn, the rings, and the satellites, would appear to fill the greater portion of the visible heavens. Let us then conceive this planet—a thousand times larger than the earth—flying before us at the rate of twenty-two thousand miles an hour, carrying along with it stupendous rings, five hundred thousand miles in circumference, and these rings revolving round the planet with a velocity of nine hundred miles every minute, and seven other spacious globes, larger than our moon, wheeling their rapid courses, at different distances around the planet and its rings—let us endeavor to stretch our imagination to the utmost, to represent such a scene as nearly as possible to the reality, and suppose ourselves as spectators—how grand and overwhelming, and almost terrific, would be the amazing spectacle! Amidst the emotions it would excite, we could only exclaim, "GREAT AND MARVELOUS ARE THY WORKS, LORD GOD ALMIGHTY!"—"Thy right hand, O Lord, is become glorious in power!"—"Who can utter the mighty acts of the Lord!"—"The Lord God Omnipotent reigneth!" Is it possible to separate such scenes and operations from the idea of an eternal and Almighty intelligence, who formed, and arranged, and set in motion, such stupendous machinery? Could chance, or the fortuitous concourse of atoms, have ever produced such a portion of celestial mechanism, and preserved it unimpaired in all its relations and movements, from age to age? Such an idea is fraught with the grossest absurdity that ever entered the human imagination. If a Divine superintendent over creation did not exist, the whole frame of universal nature would long ere now have been unhinged, and the universe, with all its splendid orbs and mighty movements have been transformed into a chaos, and scattered throughout the regions of infinitude. And, "since a God there is, that God how great!" His power is irresistible, his wisdom is unsearchable, and his agency pervades the immensity of space. To refuse to submit to his laws and his moral government must, therefore, expose us to the most dismal consequences. For thousands of means are within the range of his wisdom and intelligence by which the rebels against his authority may be arrested and punished; and his power to execute his purposes no created beings can control. "The mountains quake at him, and the hills melt, and the earth is burned at his presence. Who can stand before his indignation?" "The pillars of heaven tremble and are astonished at his reproof." Happy they who have this Almighty Being as their father and their friend, "who do his commandments, hearkening unto the voice of his word." For all the glories of creation, and all the resources of the universe are at his disposal to contribute to their knowledge and felicity, while ages numerous as the drops of ocean are rolling on.

SECTION VIII.

ON THE PLANET URANUS.

UNTIL near the close of the last century, Saturn was considered as the remotest planet from the sun, and his orbit as forming the outermost boundary of the planetary system. But, since the discovery of Uranus, the diameter of the system is doubled, and the area of the space it comprehends is four times the dimensions formerly supposed. Instead of an area of twenty-five thousand millions of square miles—its former supposed dimensions—it now comprehends at least one hundred thousand millions of square miles; throughout every portion of which the influence of the great central luminary extends, and likewise as far beyond as the erratic comet pursues its distant course. It is somewhat strange that, from the time of Huygens and Cassini, when telescopes were brought to a certain degree of perfection, until near the close of the eighteenth century (a period of more than a hundred years), no new discoveries were made in the heavens, when the number of those who cultivated the science of astronomy was increased, and the science itself had received many improvements. But the mind of man has a propensity to indolence when not stimulated by worldly gain, and certain difficulties to be encountered tend to discourage and impede its progress. The long and unwieldy telescopes used by the astronomers of the seventeenth century were very difficult to manage, and required long exposure to the cold air of the evening, and their attention was chiefly directed to observations on the planetary bodies which were then known. Few observations, comparatively, were made on the fixed stars, so as to ascertain the varieties which exist among them, the changes to which they are subject, or the moving bodies that may be found in the stellar regions; and hence, in part, the reason that so few discoveries were made during that period.

The appearance of the late Sir William Herschel, as an observer of the heavens, formed a new era in the history of astronomy. This illustrious astronomer having viewed the heavens with a two-feet Gregorian telescope, which he had borrowed, was so much interested with the instrument, that he commissioned a friend in London to purchase for him one of a larger size. The price, however, being more than he anticipated, and more than he could afford, he resolved to attempt the construction of one with his own hands; and in this he succeeded. A five-feet Newtonian reflector, which he completed in 1774, was the commencement of that brilliant series of discoveries and improvements which he afterward effected. While residing in Bath he had been engaged for a year and a half in making a regular survey of the heavens, when on the evening of the 13th of March, 1781, he discovered, among other stars one of unusually steady radiance; continuing to watch it, he found, after several observations, a perceptible change in its position, although its motion with relation to the other stars was very slow. Having sent an account of this observation to Dr. Maskelyne, the astronomer royal, it was at first supposed to be a comet, but soon afterward it was ascertained beyond a doubt that it was a new planet which had, in all former ages, eluded the observation of astronomers. For this discovery the Royal Society conferred upon Herschel the honorary recompense of Sir Godfrey Copley's medal; and he named the planet Georgium Sidus, in honor of his majesty king George the Third: but the continental astronomers distinguished it by the name of Herschel, in honor of the discoverer; and it is now more generally known by the name of Uranus. Soon after this discovery, Herschel was taken under the patronage of his majesty, and rewarded with a pension of £300 per annum. He removed to Slough, near Windsor, where, in 1789, he erected his large forty-feet telescope, by which he was enabled to make further discoveries.

The planet Uranus is not visible to the naked eye, and requires a certain degree of magnifying power to render it visible as a very small star. We have seen it in this way with a power of twenty times, but it requires a power of at least two hundred times to make it appear like a well-defined visible disc. Its real magnitude, however, is considerable,—being no less than thirty-five thousand miles in diameter, or more than eighty times the size of our globe. Its surface contains three thousand eight hundred and forty-eight millions of square miles,—which is seventy-eight times the area of all the habitable portions of the earth; so that this apparently small body, which had remained unnoticed for thousands of years, adds considerably to the quantity of matter formerly supposed to belong to the solar system. For it contains a mass of matter, as to bulk, more than twenty times larger than what is contained in Mercury, Venus, the Earth, the Moon, Mars, Vesta, Juno, Ceres, and Pallas. Its distance from the sun is about double that of Saturn,—being no less than eighteen hundred millions of miles. To reach the nearest point of its orbit, a cannon ball, flying from the earth in that direction, at the rate of five hundred miles an hour, would require a period of three hundred and ninety years. It moves round the sun in the space of eighty-four years, in an orbit eleven thousand millions of miles in circumference; at the rate of fifteen thousand miles an hour. The inclination of its orbit to the plane of the ecliptic, is 46 minutes, 28 seconds.

From the immense distance at which this planet is placed from the sun, we might be apt to imagine that there will be a great deficiency of light and heat on its surface. The quantity of light it receives from the sun is about three hundred and sixty time less than what the earth receives; for the quantity of illumination enjoyed in any planet is in an inverse proportion to the square of the distance of the luminous body that enlightens it. The quantity of light on Uranus—notwithstanding its great distance from the sun—will be equal to what we should have, were three hundred and forty-eight full moons continually shining on our globe at one time. But the pupils of the eyes of the inhabitants of this planet may be so constructed as to take in ten or twenty times the quantity of light which our eyes would receive, were we placed in that distant region. And as to sensible heat, it does not appear that this depends on the distance of a planetary body from the sun; but on the nature of its atmosphere, and the substances on its surface on which the rays of light and heat fall. Every part of our globe may be considered as at an equal distance from the sun, and yet there are all the varieties of temperature experienced from twenty degrees below zero in the frozen regions of Greenland, to a hundred degrees above it, in the scorching climes of the torrid zone. On the top of the Andes, in South America, there is the most intense cold, and perpetual snows; while in the plains below excessive heat is felt under the rays of a tropical sun, while only a few miles intervene between the respective localities. At any rate, we may rest assured that, throughout all the regions of the universe, the Creator has displayed his wisdom and goodness in adapting the structure and constitution of the inhabitants to the nature of the habitation he has provided for them.

In consequence of the great distance of this planet, no discoveries have been made on its surface; no spots have been seen to indicate a rotation, and therefore the period of its revolution round its axis is unknown. But the same illustrious astronomer who first detected it, soon after discovered no less than six satellites which revolve around it. The following table contains a list of these satellites, with their distances from Uranus, and their periods of revolution.

	Period.			Distance.
1st, or nearest to Uranus,	5d.	21h.	25m.	230,000 miles.
2d,	8	17	1	298,000
3d,	10	23	3	348,000
4th,	13	10	56	399,000
5th,	38	1	48	777,000
6th,	107	16	40	1,597,708

It is somewhat remarkable, that these satellites, instead of moving from west to east, or in the direction of all the other planets and satellites, have their orbits nearly at right angles to the ecliptic, and move in a direction from east to west. These are exceptions to the general laws of the planetary system which it is difficult to explain. But they occur at the farthest limits of the solar system, perhaps to teach us, that in other systems arrangements may exist very different from those we experience in the system to which we belong.

SECTION IX.

General remarks on the solar system.

Such is a brief description of the principal phenomena connected with the planetary bodies which compose the solar system. We have no reason, however, to conclude that all the planets belonging to our system have yet been discovered. Were a planet of double the magnitude of the Earth revolving between the orbits of Jupiter and Saturn, it would be altogether invisible to the naked eye, and might revolve for thousands of years without being observed by the inhabitants of our globe, unless astronomers were to make a minute survey, with powerful telescopes, of the whole range of the zodiac, in which most of the planets are found to move, along with portions of the celestial regions on either side of it. If the inhabitants of Jupiter and Saturn have no better eyes than ours, and no artificial helps to vision, they must be altogether ignorant that such a globe as the earth exists in the universe, nor will they ever obtain a glimpse of either Mars, Mercury, or Venus. Considering the distance that intervenes between Jupiter and Saturn, it is not at all improbable that one or more planets may exist in the interval; and since no less than 900 millions of miles intervene between the orbits of Saturn and Uranus, several planets, much larger than the earth, may revolve in those regions, which the keen eyes of astronomers have never yet detected. Even within the orbit of Mercury a planet may exist, which we may never be able to discover, on account of its nearness to the sun, being at all times immersed in the effulgence of the solar rays. Our views of the universe and its arrangements are only beginning to open and expand; but in the ages to come, if art and science still advance, objects of which we have no conception at present may be disclosed to view, even within the bounds of the planetary system.

Throughout the whole of this system we perceive *order* and *harmony* prevailing without interruption. While the planets are prosecuting their courses with amazing velocity, and moving onward in their respective spheres without a moment's pause—while their attractive forces on each other sometimes produce slight perturbations—while one sometimes interposes between the sun and another, and casts a transient shade over its surface; yet no disorder or confusion ever occurs throughout the system: every orb finishes its respective circle of revolution in exactly the period of time in which it has been performed for thousands of years; no one ever interrupts the course of another; no satellite ever forsakes its primary, in the course of its rapid movement; but the laws of motion originally impressed upon all the bodies of the system continue to operate as they have done from the beginning. These circumstances evidently demonstrate the existence of a presiding Intelligence, who at first formed and arranged this magnificent system, and who every moment sustains it in all its movements. It would be easy to show—if this were the proper place for it—that unless an Immaterial Power continually re-excited motion in the material universe, all motion would stop in a very short time—perhaps in less than an hour—except that the planets would run out in right-lined directions;

and then nothing would ensue but confusion, darkness, silence, and chaos. For matter of itself can pursue no end, obey no law, nor change the direction of its motion. If, then, a presiding Divinity is continually exerting his attributes, impressing every part of that universe to which he gave existence, we cannot deny his title to supreme dominion; and, if so, we must acknowledge that all praise, adoration, submission, and obedience are due to Him who hath created all things, and for whose "pleasure they are and were created."

It may likewise be remarked, that amidst all the varieties which characterize the planetary system, there are evident marks of unity and mutual relationship. The distances of the planets from the sun, vary from thirty-seven millions to one thousand eight hundred millions of miles. The quantity of light that falls on the surface of Mercury is two thousand four hundred times more intense than that which falls on Uranus. In point of magnitude some of the planets are several thousand times larger than others; and as to the times of their revolutions, their periods vary from eighty-eight days to eighty-four years. Some have one accompanying moon, some have four, some have seven, and others are destitute of such appendages. Yet a family likeness pervades the whole. The figure of all the planets is nearly the same; they are all either globes or spheroids; they all move round their axes, and round the same central luminary, producing an alternate succession of day and night, and, in most instances, a variety of seasons. Most of them, if not the whole, are environed with atmospheres; and on their surfaces, mountains and plains, hills and vales, have been descried, and the law of gravitation pervades and governs the whole. One sun enlightens every member of this system, whether primary or secondary; and although this luminary appears to one planet seven times larger than to us, and to another a hundred times smaller, yet it serves all the purposes of a sun to diffuse that degree of light and splendor and benign influence which is requisite for the comfort of each respective planet. These and other circumstances plainly indicate that ONE Supreme Mind contrived this system of moving bodies, and superintends, directs, and governs the whole. For two or more supreme beings—whose plans and purposes might clash—could never be the parents of that harmony and unity of design which we perceive throughout the system of nature. Such considerations, likewise, lead us to conclude that all the planets of this system are destined to subserve in their respective spheres the same grand purposes, namely, to serve as comfortable habitations for numerous orders of sentient and intellectual beings, capable of knowing and adoring the perfections of their great Creator. For the material world could never be shown to manifest the wisdom and intelligence of its Author and Contriver, if this position were denied. For it would then exhibit only a stupendous system of means without an end, corresponding to the magnificence of the operations employed; and, in this case, there would be no extensive display of the riches of Divine beneficence.

Illustrations of the distances and magnitudes of the Planets.—Sir J. Herschel proposes the following illustration, to convey to the minds of general readers an impression of the relative distances and magnitudes of the parts of the solar system:—"Choose any well-leveled field or bowling-green; on it place a globe two feet in diameter—this will represent the sun; Mercury will be represented by a grain of mustard seed, on the circumference of a circle one hundred and sixty-four feet in diameter for its orbit; Venus, a pea, on a circle of two hundred and eighty-four feet in diameter; the earth, also a pea, on a circle of four hundred and thirty feet; Mars, a rather large pin's head, on a circle of six hundred and fifty-four feet; Juno, Ceres, Vesta, and Pallas, grains of sand, on orbits of from a thousand to a thousand and two hundred feet; Jupiter, a moderate-sized orange, on a circle nearly half a mile across; Saturn, a small orange, on a circle of four-fifths of a mile; and Uranus, a full-sized cherry or small plum, upon the circumference of a circle more than a mile and a half in diameter."

From this illustration it appears, that an orrery to represent both the proportional distances and the proportional magnitudes of the sun and planets would require to be more than a mile and a half in diameter, and nearly five miles in circumference; and, in this case, scarcely any of the planets would be visible from the center. Our common orreries and planetariums can exhibit only the relative motions of the planets, and the order in which they are placed from each other in the system; but they can present no accurate or comprehensive idea of their proportional distances or magnitudes; and the balls which represent the sun and planets being so small, and placed so near each other, have a tendency to produce erroneous conceptions. The comparative distances and the comparative magnitudes can only be separately exhibited on a small scale. The following is a simple method by which we have frequently exhibited the proportional distances of the planets. Provide a small square rod about eight feet long, at one end of which place a ball or other object to represent the sun. At two inches from the sun's ball, place a ball to represent Mercury; at three inches and a half, Venus; at five inches, the earth; at seven inches and a half, Mars; at thirteen inches, Ceres, Pallas, Juno, Vesta, almost close to each other; at twenty-five inches, Jupiter; at forty-seven inches, or about four feet, Saturn; and at eight feet, Uranus. These proportions will convey an approximate idea of the relative distances of the planets from each other and from the sun; and if wax tapers were placed instead of the balls, and lighted, these comparative distances might be exhibited to a large audience. The proportional magnitudes might likewise be exhibited as follows:—Suppose a globe of eighteen inches diameter to represent the sun, Jupiter will be represented by a ball one inch and four-fifths diameter; Saturn, one inch and two-thirds; Uranus, three-quarters of an inch; the Earth, one-sixth of an inch; Venus, one-sixth of an inch; Mars, one-eleventh of an inch; Mercury, one-fifteenth of an inch; Moon, one-twenty-fourth of an inch; Ceres, Pallas, Juno, Vesta, by small pin heads The following numbers may assist the memory in recollecting the proportional mean distances on the planets. Suppose the distance of the Earth from the Sun to be divided into 10 parts—Mercury may then be estimated at 4 of such parts from the Sun; Venus at 7; the earth at 10; Mars at 15; the new planets, Ceres, Vesta, etc. at 26; Jupiter at 52; Saturn at 95; and Uranus at 190 such parts.

Method of acquiring an approximate idea of a million units.—In the preceding description of the solar system, the distances of the sun and planets, and the extent of the planetary orbits, have been expressed by millions of miles. But however accurately such distances and dimensions may be considered as stated, the mind is unable to form a

SUMMARY VIEW OF THE SOLAR SYSTEM.

The following Table exhibits, at one view, the distances, diameters, periods of revolution, etc., of the Planets, and other permanent elements of the Solar System.

Names of the Planets	Distances from the Sun, in Miles.	Diameters, in Miles.	Periods of Revolution round the Sun.	Rotation on Axes	Mean angular Diameter, in Seconds, etc.	Velocity in Orbit per Minute in Miles.	Inclination of Orbits to the Ecliptic.	Inclination of Planet's Equator to the Ecliptic.	Density, that of Water being 1.	Mass, that of the Earth being 1.	Diameter of the Sun, seen from the Planets.
Sun,		880,000		25d. 10h.	32' 3"			7° 20'	1 2-15	354936.	
Mercury,	37,000,000	3,200	88 days	24h. 6m.	8".5	1830	7°		9 1-6	0.16	80'
Venus,	68,000,000	7,800	224 —	23h. 20m.	35"	1333	3° 23'		5 11-13	0.94	46'
Earth,	95,000,000	7,930	365¼ —	23h. 56m.		1133		23° 28'	4 ½	1.	32'
Moon,	95,000,000	2,180		27d. 8h.	31' 8"		5° 8' 47"			0.013	32'
Mars,	145,000,000	4,200	686 —	24h. 40m.	11"	833	1° 51'	29° 30'	3 2-7	0.13	21'
Vesta,	225,000,000	276	1335 —		0".5	733	7° 8'				13'
Juno,	254,000,000	1,425	1592 —		3"	697	13° 5'				12'

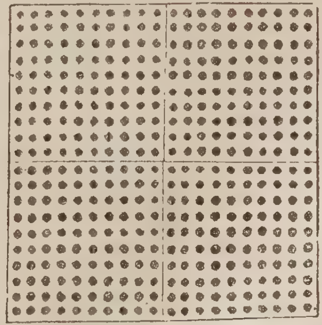
Uranus,	1820,000,000	35,000	84 years		4"	250	0° 46'		0 99-100	17	1'

distinct and comprehensive idea of such vast distances and dimensions, and even at its utmost stretch, and with all its efforts, must be contented with a very vague and indefinite conception of the immense spaces of the heavens. This is partly owing to our want of a clear and comprehensive idea of the number of units contained in a single million. We can form a clear idea of a hundred units, and even of a thousand; our ideas of ten thousand, fifty thousand, and a hundred thousand are less clear and definite; and it is but a vague idea we generally have of ten hundred thousand, or one million, when we attempt to grasp it at one conception. We may assist our conceptions a little by such illustrations as the following:—A million of pounds would be sufficient for the formation of 5000 miles of road, at the rate of £200 for each mile—which would be sufficient to reach from the Land's End of England to the northernmost point of Scotland, to go quite round the island of Great Britain, and to cross it in different directions. The same sum would be sufficient to rear more than 666 churches, at £1500 each. It would be adequate to the building and furnishing of 2500 schools, at £400 each. Were a man to count a million sovereigns, one by one, and allow only a single second for each sovereign, and continue, without intermission, 12 hours every day, it would require more than 23 days before such a sum could be counted; and, consequently, to count in the same manner 800 millions of sovereigns, the amount of our national debt, would require more than fifty years! Were a million of men to be arranged in a straight line, similar to a line of soldiers when on parade, and three feet allowed for the breadth of every man, that line would extend over a space of more than 568 miles in length—in other words, it would extend over the whole length of the island of Great Britain, from the Straits of Dover to the Orkney Isles. Such illustrations may help to assist the mind a little in forming its conceptions of the number of units contained in a single million; to which we may add the following—that a line a million miles in length would go forty times round the circumference of the earth; and that, since the creation of the world, little more than two million of days have elapsed.

Mr. Henry Martin, teacher, Chatham, has lately contrived a plan by which a million of units may be represented to the eye, and which produces a more striking effect than any plan hitherto adopted. It consists in the arrangement of spots of the size of those in the annexed figure. They are arranged in squares, in the manner here represented—every square containing one hundred spots. There are a hundred squares on a sheet of foolscap, which, of course, contains ten thousand spots or units; and there are one hundred of these sheets pasted on a piece of calico, which doubles up like a long map, a small space being left between each sheet, that the calico may form a hinge for doubling. The number of spots on these hundred sheets amounts to 10,000×100, or exactly a million. This representation of a million of units, were it to be exhibited in the most striking manner, should be stretched along the side of a large room, 8 feet high and 14 feet

Fig. 53.



long, which it would completely fill; or on any surface about 10½ feet square, and containing an area of about 108 square feet. The annexed figure contains 400 spots, which are only the 1-2500th part of a million, so that it requires two thousand five hundred times the space and the number of spots contained in this figure to represent the units in a million. On beholding such a number of units or spots, as close to each other as those in the figure, and covering such a large space, the mind is struck with wonder at the number of units which a single million contains; and Mr. Martin informs me that "all persons, who have seen it, have expressed themselves much astonished at the vastness of it." Were each square, containing 100 spots, exactly of the same size as in the figure, placed along side each other, in a straight line, that line would extend above a thousand feet in length.

When beholding such a number of units compressed together, and yet filling so great a space, we might be apt, at first view, to consider it as a faint picture, or emblem, of immensity and eternity. But what is one million compared with hundreds and thousands of millions? That sun, which enlightens our day, is ninety-five millions of miles distant from us. The planet Uranus is one thousand eight hundred millions of miles distant from the sun, and yet is within the reach of his illuminating and attractive influence. Such immense distances are comprised even within the limits of the planetary system. How overwhelming, then, to consider the distance of the nearest stars! That distance is not less than twenty billions of miles; and let it be remembered that each billion contains no less than ten hundred thousand millions. And as to magnitudes, we are almost equally overpowered at the idea of their immensity. The sun contains, on his surface, two billions, four hundred and thirty thousand eight hundred millions of square miles; and his solid contents comprehend more than three hundred and forty-six thousand billions of cubical miles. And the sun is only one out of a hundred millions of similar globes which compose the visible universe; and, beyond all that is visible to human eyes, orbs of astonishing grandeur may exist, whose number may exceed the number of the sands that lie along the sea-shore. Hence the necessity of endeavoring to form as large and extensive an idea as possible of the number of units contained in a million, if we wish to take a comprehensive view of the immense spaces of the heavens, and the magnitude of the celestial orbs. For a million, great as this number is, forms, as it were, but a unit to thousands, tens of thousands, and hundreds of thousands of millions—to billions, trillions, and other higher numbers that sometimes enter into astronomical calculations.

What a vast and overpowering assemblage of human beings must be presented to view at that solemn day, when all the men and women, that have ever dwelt on the surface of our globe, shall appear in one great assembly before "God, the Judge of all!" The number that have already dwelt upon the earth, since the formation of the first man, is at least, one hundred and forty-six thousand two hundred millions; and, probably, more than double that number may appear before that decisive day draws nigh. The idea of such an assemblage of beings is absolutely overwhelming to our limited powers of conception. It may be proper, however, occasionally to ruminate on such subjects, as it is one of the principal modes by which we may acquire comprehensive views of the vast extent of creation, and of the ineffable glory and magnificence of the great Creator

CHAPTER V.

ON COMETS.

Beside the planetary bodies described in the preceding chapters, there is a class of celestial bodies, considered as connected with the solar system, which have obtained the name of comets. The word comet is derived from the Greek κομη, and the Latin *coma*, both of which signify the hair, and a comet was so denominated, because the lucid haze with which the body of a comet is attended sometimes resembles flowing hair. As comparatively little is known of the nature and destination of these erratic bodies, we shall just offer a very few remarks on what has been ascertained respecting their phenomena and motions.

Comets are distinguished from the planets and fixed stars by being usually attended with a long train of light, tending always opposite to the sun, which is called the tail, and which is of a fainter luster the farther it is from the body of the comet. The luminous point near the center or head of e comet, whence the tail seems to proceed, is called the nucleus, which appears to be the densest part of the comet. The tail of a comet at its first appearance is very short, and increases as it approaches toward the sun. Immediately after its perihelion, or nearest approach to the sun, the tail is longest and most luminous, and is then generally observed to be somewhat bent, and to be convex toward those parts to which the comet is moving; the convex side being rather brighter and better defined than the concave side. When the tail has attained its greatest length, it quickly decreases, and vanishes entirely from the sight about the same time that the comet itself ceases to be visible. Of what kind of matter the tail consists has been matter of conjecture, and various opinions have been broached on this subject but nothing is certainly known respecting it. It is evident, however, whatever may be the matter of this substance, that it is exceedingly rare, and so very pellucid that the light of the smallest stars suffers no sensible diminution in passing through it. Sir J. Herschel says, that he "could distinguish stars of the sixteenth magnitude, through the thickest part of a comet, as it passed over them, covering them with perhaps 50,000 miles of cometic matter."

The tails of comets are found sometimes to occupy an immense space in the heavens. The comet of 1680 stretched its tail across an arch of 104 degrees, and the tail of the comet of 1769, subtended an angle of 70 degrees. The real length of the tail of the comet of 1680, was estimated at 112 millions of miles; that of 1769, at 44 millions, and, that of 1744, at eight millions of miles. Sir W. Herschel estimated the length of the tail of the great comet which appeared in 1811, at one hundred millions of miles, a space larger than the whole distance between the earth and the sun; and its breadth was calculated at about fifteen millions of miles. We may just simply mention the opinions of different philosophers, respecting those long trains of light. Tycho Brahe supposed them to be the light of the sun transmitted through the nucleus of the comet, which he believed to be transparent like a lens. Kepler thought that the impulsion of the solar rays drove away the denser parts of the comet's atmosphere, and thus formed the tail. Sir I. Newton supposed that it is a thin vapor, raised by the heat of the sun from the comet. Euler maintained that the tail is occasioned by the impulsion of the solar rays driving off the atmosphere of the comet, and that the curvature observed in the tail is the joint effect of this impulsive force, and the gravitation of the atmospherical particles to the solid nucleus. Mairin imagined that comets' tails are portions of the sun's atmosphere. Dr. Hamilton supposed them to be streams of electric matter. Biot, the French philosopher, supposes that the tails are vapors produced by the excessive heat of the sun, and also that the comets are solid bodies before they reach their perihelion, but that they are afterward either partly or totally converted into vapor by the intensity of the solar heat. Notwithstanding these opinions of eminent philosophers, we must still admit that the true cause of the extraordinary phenomenon of the tails of comets remains yet unknown. When we consider that these vast streams of light extend, in some instances, to eighty and a hundred millions of miles in length, we cannot conceive that any of the causes assigned above will account for such a wonderful phenomenon. If they consist of vapor raised from the comet, why should this vapor extend to such a prodigious length through space, and why should it be illuminated throughout its whole extent? for if it were opaque, or unilluminated vapor, it would be invisible.

In ancient times, comets were generally supposed to be meteors, or exhalations, generated by inflammable vapors in the earth's atmosphere. But it is now ascertained, beyond a doubt, that comets move in regions far beyond the limits of our atmosphere, and form a portion of the solar system. But they differ in many respects from the various planetary bodies, formerly described. In regard to planets, their orbits are all confined to a certain zone, or region of the heavens, of no great breadth, except in the case of Pallas. This zone, in the case of the old planets, contains about eight degrees on each side of the ecliptic. But the orbits of the comets cut the ecliptic in every direction, and, in some instances their orbits are directly perpendicular to it. They likewise differ from the planets in the form of their orbits. The orbits of most of the planets, though elliptical, approach very nearly to circles; but those of comets are long narrow ellipses, whose length is many times greater than their breadth, and, in most cases, the full extent of their elongation cannot be traced. Only one small portion of these orbits lies within the limits of our observations, and their remotest boundaries are far beyond the range of human vision. Hence it is, that we perceive a comet only for a very short time, and during a very small part of its course, the remaining parts of its course being performed in regions beyond the reach even of our telescopic vision, and beyond the orbit of the remotest planet.

The following are some of the more remarkable comets which have appeared within the last century and a half. The most splendid of these bodies which have appeared in modern times was the comet of 1680. The tail of this comet is said to have reached from the zenith to the horizon, an extent of ninety degrees. When nearest the sun it was calculated to have been within 150,000 miles of his surface, and its rate of motion at that time was computed at about a million of miles an hour. The period of its revolution round the sun was calculated at 575 years; and if this computation be correct it will not again visit this part of the system until the year 2255. Another comet which has excited a considerable degree of interest and attention, is that which appeared in 1682, and is known by the name of Halley's comet. Dr. Halley computed the period of this comet at 75 or 76 years, and predicted that it would again appear about the end of 1758, or the beginning of 1759. It accordingly arrived at its perihelion on the 13th March, 1759. If 76 years be the real period of this comet, then it behooved to re-appear in 1835, which happened accordingly. It was seen at Rome on the 5th of August of that year, and arrived at its perihelion on the 16th November. The period of this comet then is determined, and it is proved, at the same time, that comets are permanent bodies belonging to the solar system. At the remotest point of its orbit, this comet is computed to be 3,400,000,000 of miles from the sun, or nearly double the distance of Uranus.

Another brilliant comet appeared in 1744, the diameter of the nucleus of which was nearly equal to the apparent disc of the planet Jupiter; and its tail, which was divided into six streams of light, was reckoned to be 23,000,000 of miles in length. In 1807, a large comet made its appearance in the month of October, and continued to be visible to the naked eye for nearly two months. The diameter of its nucleus was calculated by Schroeter to be 4600 miles, and the diameter of its coma, or nebulosity surrounding the nucleus, 120,000 miles; its motion was frequently at the rate of 55,000 miles an hour. A still more splendid comet made its appearance in September, 1811, which was visible to the naked eye for more than three months in succession. Schroeter computed the diameter of this comet at 50,000 miles, and Sir W. Herschel estimated the length of its tail at 100,000,000 of miles. When nearest the earth it was distant about 113,000,000 of miles. We shall notice only two other comets, remarkable on account of the shortness of their periods. The first of these comets to which I allude is called the Encke comet, from Professor Encke, who first ascertained its period. It performs its revolution in a period shorter than that of any comet yet known; namely, in 1200 days, or three years and three-tenths. Its orbit penetrates within the orbit of Mercury, but does not extend so far as the orbit of Jupiter. It is a very small body, and is scarcely distinguishable by the naked eye. The other comet is that of Biela, sometimes called Gambart's comet, which finishes its revolution in a period of 6¾ years. It was seen in 1826, 1832, and 1839, and in February and March, 1846. It is likewise a very small comet, and cannot be seen without a telescope.

The number of comets has been estimated to be very great. Seven or eight hundred of these bodies have been observed in different ages; but there are only a little more than a hundred of them, the elements of whose orbits have been accurately calculated, so as to identify them should they again make their appearance. By far the greater number are invisible to the naked eye, and even beyond the reach of telescopes, and many of them, doubtless, pass along our hemisphere in the day-time, when they cannot be perceived.

From calculations formed on probable grounds, M. Arago concludes that the number of comets which visit the solar system within the orbit of Uranus, is at least 3,000,000. Of late, within the space of fourteen months, five or six comets have made their appearance; one in December, 1843, in the constellation of Orion, another in August, 1844, not far from the star Arcturus, in the constellation Bootes; a third was seen in September of the same year, near the constellation Cetus; a fourth was seen in the month of January, 1845, in the West Indies and which was visible to the naked eye, but was not seen in this country on account of its great southern declination; a fifth was seen in this country in February, 1845, near the constellation of Ursa Major, and about the same time another was said to have been seen in the East Indies. We had an opportunity of seeing two of these comets, but they were both invisible to the naked eye.

In former ages, the appearance of a comet was viewed as the forerunner of disastrous events, such as wars, famine, pestilence, the revolutions of nations and empires, the death of kings and princes, inundations, earthquakes, and similar calamities. But we need scarcely say that there is not the least foundation for such apprehensions; for comets are every year making their appearance to the astronomical observer, while both the physical and the moral world is moving on in its regular course. The comets are, doubtless, messengers of the Deity sent forth to accomplish the designs he intended in their creation; but we have not the least reason to believe that they were ever intended to "shake from their horrid hair" wars, famine, and pestilence upon the nations. Their destination, whatever it may be, must be in full accordance with the benevolence of him whose "tender mercies are over all his works." It has, indeed, been apprehended by some that a comet in crossing the path of the earth, might happen to come into collision with it, and produce a shock which would shatter its present constitution, and prove destructive to its inhabitants. It is admitted that this is a possible circumstance, though the chances in favor of it, according to Arago, are only as one to 281,000,000. In France and other parts of the European continent, in 1773, an apprehension of this kind was excited, which was attended with many serious consequences. People of weak minds, it is said, died of fright, and women miscarried. A similar alarm was produced in 1832, when it was announced that the comet of Biela, on the 29th of October, would cross the plane of the ecliptic at a point near where the earth would be on the 30th of November following; but before the earth arrived at that point, the comet was distant from it 50,000,000 of miles. All such forebodings and alarms may be considered as entirely without foundation. At least, the believer in Divine revelation has nothing to fear, for he knows that the purposes of the Almighty in respect to this world are not yet nearly completed, and that many of the most prominent predictions of inspired prophets are not yet accomplished Wars must cease to the ends of the earth. The knowledge of Jehovah must cover the earth The Jews must be converted to the faith of Messiah. The kingdoms of this world must "become the kingdoms of our Lord, and of his Christ," and righteousness and praise must spring forth before all nations, before a comet or any other celestial agent shall be permitted to impinge upon our globe, or to alter its present constitution; and centuries must necessarily elapse before such objects are fully accomplished.

As to the destination of comets, or the purposes they are intended to serve, in the economy of the universe, we are in a great measure ignorant, as we are unacquainted with the nature and constitution of these singular and anomalous bodies. But as they are all the workmanship of Him who is "wonderful in counsel, and excellent in working," they must be intended to subserve important purposes in the system of creation, worthy of the perfections of Him who is infinite in knowledge, who "established the world by his wisdom, and hath stretched out the heaven by his understanding." So many thousands, or even millions of these blazing orbs, as are continually traversing the regions of the planetary system, were not created in vain. The adjustment of their motions, and the arrangement of their orbits, so as not to interfere with each other, nor with the motions of the planets, is an evidence of that Divine wisdom which is displayed throughout every part of creation. The number of these bodies, the vast magnitude of their blazing tails, and the amazing velocity with which they move in certain parts of their orbits, display the Almighty power of Him who at first set them in motion: and although we are partly ignorant of the ultimate designs they are intended to accomplish, yet we may rest assured that they form a part of that plan of Divine beneficence, which appears a prominent object in all the works of God. There seems no improbability in the supposition, that they are intended as habitations for various orders of intellectual beings, to whom the Almighty displays himself in a peculiar manner, different from that of the inhabitants of the planets, and whose corporeal organization is exactly adapted to the nature and properties of the world in which they are placed. For we have every reason to believe that an infinite variety exists in the universe, in respect both to the physical and mental constitution of the intelligences it contains.

CHAPTER VI.

ON THE ECLIPSES OF THE SUN AND MOON.

The term eclipse is derived from a Greek word, which signifies to be diminished, to faint away, to swoon, or to die. When the full moon, in her greatest luster, is deprived of the beams of the sun, she appears pale and languid, as if she were sick and dying. Hence the superstitious among the ancients imagined that the moon was in pain at such times, and therefore lunar eclipses were called the labors of the moon; and in order to relieve her in that fancied distress, they were accustomed to hold up on high lighted torches; to blow with horns and trumpets; to make a loud noise, by beating on vessels of brass and iron, to break, if possible, the enchantment that had fallen on the lunar orb. Before the true causes of eclipses were ascertained, those phenomena were considered as supernatural, and viewed with apprehension and alarm. It was believed that they were produced by the immediate interposition of God, as a token of his displeasure. When the sun was totally eclipsed, it was imagined, by many of the ancients, that he turned away his face, in abhorrence of some atrocious crime that had been committed, or was about to be perpetrated on the earth, and threatened mankind with everlasting night. When the Medes and Persians, several centuries before Christ, were preparing to engage in furious combat, they were so alarmed at an eclipse, which happened at that time, that the warriors on both sides laid down their arms, and entered into a treaty of peace. When the fleet of Pericles, the celebrated Grecian, was preparing to attack Peloponnesus, there happened an eclipse of the sun, which was considered as a most unfortunate omen; and the whole of the Athenian commanders and their men were thrown into the greatest consternation. Such facts should inspire us with gratitude for the advantages we now enjoy, in a land where science is cultivated, and useful knowledge disseminated, and where the light of Divine revelation has dispelled the darkness and superstitions of the heathen world.

Every planet and satellite is enlightened by the sun, and, consequently, casts a shadow toward the point of the heavens which is opposite to that luminary. An eclipse, therefore, is a privation of the light of the sun, or of some other heavenly body, by the interposition of another body between it and our sight. Eclipses are either of the sun, or the moon, or of the satellites which accompany some of the planets. In regard to circumstances, they are divided into total, partial, annular, and central. A total eclipse is when the whole face of the luminary is darkened; a partial eclipse is one when only a part of the disc is darkened; an annular eclipse is when the whole is darkened except a ring, or annulus, which appears round the dark part like an illuminated border. This can only happen in the case of an eclipse of the sun. In a central eclipse, the centers of the two luminaries and that of the earth are in one and the same right line, as when in an eclipse the moon passes through the center of the earth's shadow.

SECTION I.

On the eclipses of the moon.

An eclipse of the moon is produced by the interposition of the earth between the sun and moon, and, consequently, it can only happen at the time of full moon, when the moon is in opposition to the sun. As the earth is an opaque body, enlightened by the sun, it will cast a shadow toward those portions of space which are opposite to the sun, and if the moon happen to pass through those spaces where the shadow falls, she must necessarily be eclipsed. The sun and the earth are both spherical bodies, and, therefore, if they were of an equal size, the shadow of the earth would be cylindrical, as in fig. 54, and would continue of the same breadth, at all distances from the earth, and would extend to an equal distance, and might cause an eclipse of the sun to the superior planets. If the sun were less than the earth, the shadow would expand, and grow wider the farther it was from the earth, as in fig. 55. It would reach the orbits of Mars, Jupiter, Saturn, and Uranus, and eclipse them, when the earth interposed between them and the sun; and these eclipses, in the case of the most distant planets, would be of long duration, on account of the shadow being broader in proportion to the distance. But as such eclipses never happen, it forms a demonstrative proof that the sun is not less, but greater than the earth. The sun, then, being greater than the earth, the shadow of the earth is a cone, which ends in a point at a certain distance from the earth, as represented in fig. 56. This cone reaches to a distance of 840,000 miles from the earth, or about three and a half times as long as the distance of the moon from the earth.

Fig. 54.

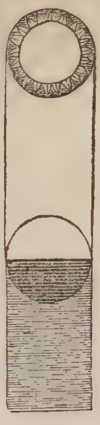


Fig. 55.

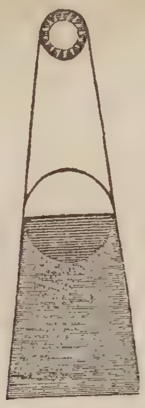

Fig. 56.

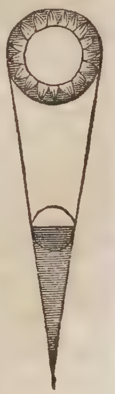

If the moon always moved in the plane of the ecliptic, she would suffer a total eclipse, at the time of every full moon, by passing through the center of the earth's shadow. But the moon's orbit is inclined to the plane of the ecliptic, at an angle of 5° 8′, and coincides with it only in two places, called the nodes, or the points where her orbit intersects the ecliptic. Full moon, therefore, may frequently happen without an eclipse, as at this period the moon may be either to the north or the south of the ecliptic. It has been calculated, that if the mean opposition of the sun and moon, or the full moon, happen within 7° 47′ of the moon's node, there must be an eclipse; but if the distance be greater than 13° 21′, there cannot be an eclipse. Let H G, fig. 57, represent the moon's orbit, E F the plane of the ecliptic, and N the node of the orbit, or point where it cuts the ecliptic; and A B C D four representations of the earth's shadow in the ecliptic. It is obvious that when the shadow is at A, and the moon at I, there will be no eclipse, because the moon is too far from the node, and the earth's shadow does not reach her. When the full moon is nearer to the node, as at K, only a part of her disc passes through the shadow, when she suffers a partial eclipse. When the full moon is at L, she passes through a portion of the shadow, and is totally eclipsed. When the moon's center passes through the center of the shadow, which can only happen when she is in the node at N, it is then both a total and a central eclipse; and such an eclipse is of the longest duration—at which time the total darkness continues about two hours.

Figs. 57, 58.

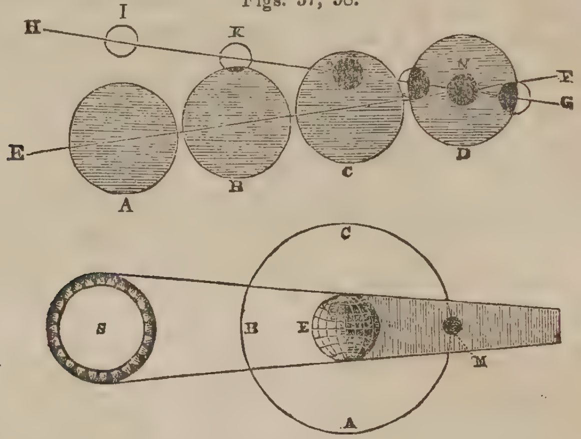

Fig. 58 represents, in a different point of view, a total eclipse of the moon. The circle A B C represents the orbit of the moon, in which it revolves round the earth. The moon is supposed to be in the node, and in her opposition to the sun—she therefore passes through the center of the earth's shadow. And as the shadow of the earth is nearly 6000 miles broad at the distance of the moon, and as the moon is only a little more than 2000 miles in diameter, she must be completely immersed in the shadow of the earth, and must move nearly three times her own diameter before she can emerge from the shadow.

The following facts may be stated in relation to lunar eclipses:—1. An eclipse of the moon always begins on the moon's eastern side, and goes off on her western side. 2. Lunar eclipses are visible in all parts of the earth which have the moon above their horizon, and are everywhere of the same magnitude and duration. 3. The moon's diameter is supposed to be divided into twelve equal parts called digits, and as many of these parts as are darkened by the earth's shadow, so many digits is the moon said to be eclipsed. The extent in which the moon is eclipsed above twelve digits shows how far the shadow of the earth is over the body of the moon on that edge to which she is nearest at the middle of the eclipse. 4. The moon, when totally eclipsed, is not invisible, if she be above the horizon and the atmosphere clear; but appears generally of a dusky color, somewhat like tarnished copper, especially toward the edges, being generally more dark about the middle of the earth's shadow. Some have supposed this to arise from the moon's native light, but the true cause of her being visible is, the scattered beams of the sun bent into the earth's shadow, by passing through its atmosphere. The moon is not eclipsed by the earth alone; the atmosphere, by refracting some of the rays of the sun, and reflecting others, casts a shadow, though not so dark a one as that which arises from an opaque body. Although in most lunar eclipses the body of the moon, though obscured, is still visible, yet it has sometimes happened otherwise. Hevelius mentions, in his "Selenographia," an eclipse of the moon which happened in August, 1647, when he was not able to distinguish the face of the moon even with a good telescope, although the sky was sufficiently clear for him to see stars of the fifth magnitude: but such cases are rare.

The duration of a lunar eclipse depends on the following circumstances:—1. On the largeness of the circle of the earth's shadow, whose diameter may be different at different times; the nearer the moon is to the earth, the larger is that portion of the earth's shadow through which she passes. 2. On the apparent diameter of the moon, which may be different, on account of her variable distance, as she moves in an elliptical orbit. 3. On the distance of the moon from her node at the moment of her being full, which will cause her to pass through a greater, or less, portion of the earth's shadow. Thus when the moon is at K, fig. 57, the eclipse will be of comparatively small duration; when at L, its duration will be much longer, but not so long as when she is at N, in the node, when she passes through the center of the shadow. 4. On the velocity of the moon's motion across the shadow of the earth, which is swiftest when she is in perigee, or nearest the earth, and the duration of a central eclipse will then be shortest. According to these circumstances will be the time of continuance of a lunar eclipse. When the moon is centrally eclipsed, and when she is at her greatest distance from the earth, its duration is 3 hours, 57 minutes, 26 seconds, from beginning to end: and when she is at her least distance, 3 hours, 37 minutes, 26 seconds. The moon may be totally eclipsed, although she do not pass through the center of the shadow; but in this case the duration of the eclipse will be shorter than what has been now stated. In some instances, the continuation of total darkness may amount only to a few minutes, when the moon passes near the extremity of the shadow.

SECTION II.

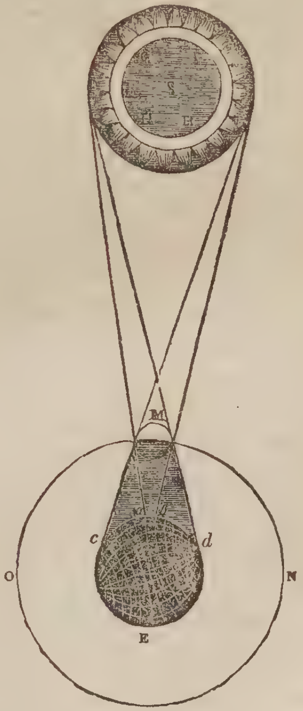
On eclipses of the sun.

An eclipse of the sun is caused by the interposition of the body of the moon between the sun and the earth, when she throws a shadow over a certain portion of the earth. This can happen only at the time of new moon, and when the moon is at or near one of her nodes. The eclipses of the sun and moon, though expressed by the same word, are in their nature very different; the sun, in reality, loses nothing of his native luster in the greatest eclipse, but is all the while diffusing streams of light around him in every direction, and illuminating without intermission all the bodies in the planetary system. Some of these streams, however, are occasionally intercepted in their course toward the earth by the moon coming between the earth and sun, and at that time the dark side of the moon is turned toward the earth. When the moon is eclipsed, she suffers a real diminution of her borrowed light; but when the sun is said to be eclipsed, there is no diminution of his light, and it is in reality an eclipse of the earth by the shadow of the moon falling upon a certain portion of our globe: and this shadow would be distinctly seen, by an inhabitant of the moon, passing along a certain zone of the earth, like a small, dark, circular spot. The moon being much smaller than the earth, and having a conical shadow—because she is less than the sun—can cover only a small part of the earth by her shadow: hence an eclipse of the sun is visible only to a few inhabitants of the earth, whereas an eclipse of the moon is visible to all who are on that hemisphere, where the lunar orb is seen.

The following diagram, fig. 59, will convey a general idea of the nature of an eclipse of the sun. In this figure, S represents the sun; M, the moon; E, the earth; and M N O, the orbit of the moon. The moon is supposed to be in that part of its orbit next the sun, having the enlightened side toward the sun, and its dark hemisphere wholly turned toward the earth, which is its position at new moon. It is also supposed to be in its node, in an exact line between the sun and the earth. In this situation the shadow of the moon falls upon a certain portion of the earth, and intercepts the rays of the sun, for a little, from the inhabitants of the earth on whom the shadow falls. Part of the cone of the shadow is represented at *a b*, and it is never more than about 180 miles in diameter, within the limits of which the sun will appear totally eclipsed. But sometimes it happens that the extremity of the cone of the moon's shadow falls short of the earth, in which case an annular eclipse of the sun is produced; in which the sun appears like a brilliant ring of light around the dark body of the moon. Beside the dark shadow, there is a penumbra or fainter shadow produced, which is represented at *c d;* and in all those parts where the penumbra falls, the sun will be only partially eclipsed. Thus, between *c* and *a*, the parts of the sun about A B cannot be seen; the rays coming from thence toward *c* or *a* being intercepted by the moon; but the portions of the sun about G and H will be visible. The nearer any place of the earth—within the penumbra—is to the dark shadow of the moon, the greater will the eclipse appear, and the nearer it is to the outside of the penumbra, the smaller will be that portion of the sun which is seen eclipsed. To those who live beyond the boundary of the penumbra, the whole disc of the sun will be seen and no eclipse will be visible. Hence it happens, that the sun may be totally eclipsed in Africa and the southern parts of Asia, and no trace of an eclipse perceived, at the same moment, either in Britain or America.

The following are some facts in relation to solar eclipses:—1. If the mean conjunction of the sun and moon takes place within 15 degrees of the moon's node, there must be an eclipse of the sun; but if the conjunction happen at a greater distance from the node than 21 degrees, there can be no eclipse. Therefore, between 15 degrees and 21 degrees there may or may not be an eclipse. 2. The penumbra covers a space of 4900 miles in diameter, within which the sun will appear more or less eclipsed. 3. The motion of the moon's shadow over the earth's surface is equal to her motion in her orbit, which is about 2200 miles in an hour; a velocity four times as great as that of a cannon ball. 4. The number of eclipses in any year cannot be less than two, and those both of

Fig. 59.



the sun; nor can they be ever more than seven: in which case there will be five of the sun, and two of the moon, and the moon's eclipses will be total. The usual number is four in a year, two at each node, and nearly half a year intervenes between the two sets of eclipses. 5. The sun is never totally eclipsed longer than about four minutes, but the moon may be immersed in the earth's shadow, or totally eclipsed, about 1 hour and 48 minutes. 6. Eclipses of the sun are more frequent than eclipses of the moon, because the ecliptic limits of the sun are greater; but we have more visible eclipses of the moon, because they are seen to the whole hemisphere next her; while eclipses of the sun only are visible from a very small portion of the earth's surface. 7. An eclipse of the sun begins on the western side, and ends on the eastern.

Periods of Eclipses.—It has been found that in 223 mean lunations, after the sun, moon, and nodes have been once in a line of conjunction, they return so nearly to the same state again, that the same node which was in conjunction with the sun and moon, at the beginning of the first of these lunations, will be within less than half a degree of a line of conjunction with the sun and moon again, when the last of these lunations is completed. Therefore, in that time there will be a regular period of eclipses for many ages. In this period there are 18 Julian years, 11 days, 7 hours, 42 minutes, 31 seconds; when the last day of February in leap years is four times included. Consequently, if to the mean time of any eclipse, either of the sun or moon, we add the above period, we shall have the mean time of the return of the same eclipse. During this period, there happen about 62 eclipses, 21 of the moon and 41 of the sun. If, then, we wish to know the mean time of an eclipse for any year, we have only to seek in old almanacs the exact time that any eclipse may have happened 18 years before, and add to such time the above mentioned period.

From what has been now stated respecting solar eclipses, it is evident that the darkness which accompanied our Saviour's crucifixion must have been supernatural. For it happened at the time of the Jewish passover; and that festival, by the appointment of the law, was to be celebrated at full moon, at which time it was impossible that the shadow of the moon could fall upon the earth, or the sun be eclipsed, according to the established laws of nature. Beside, in a total eclipse of the sun, the time of the continuance of total darkness is not more than about four minutes; but the darkness which overspread "the whole land" while our Redeemer hung upon the cross, continued without intermission for more than three hours. And again, although the sun had been totally eclipsed in a natural way, at that time, to the inhabitants of Jerusalem and its confines, it would have been only partially eclipsed to those who dwelt on the outskirts of the land of Judea; as the shadow of the moon, in an eclipse of the sun, covers only a small part of the earth's surface at one time. In confirmation of what has been now stated, it has been calculated by some astronomers, that an eclipse of the moon, which can only take place at the time of full moon, happened on the afternoon of that day on which our Saviour was crucified; so that, according to the language of the prophet, "The sun and the moon were both darkened in their habitation," at the time when this solemn and interesting event was accomplished.

Total eclipses of the sun have always been considered as remarkable events. Clavius remarks, that at the total eclipse of the sun which happened in 1560, the darkness at Coimbra, in Portugal, was greater or at least more striking than that of the night, and that the birds fell to the earth through terror. At Berne, in Switzerland, on May 1, 1706, the sun was totally darkened for four minutes, during which time a fixed star and a planet appeared very bright. The sun's passing out of the eclipse was preceded by a blood red streak of light from his left limb, which continued about six or seven seconds; then part of the sun's disc appeared all on a sudden brighter than Venus was ever seen in the night,—and in that instant gave light and shadow to objects as strong as the moonlight generally does. One of the most minute accounts of the circumstances accompanying a total eclipse of the sun is that which is given by Dr. Stukely, of the eclipse which happened in 1724, in a letter to Dr. Halley; of which the following is an abridgment:—

"I chose for my station, Haradon-hill, near Amesbury, east from Stonehenge avenue. In front is that celebrated edifice upon which I knew that the eclipse would be directed. I had the advantage of a very extensive prospect in every direction, being on the loftiest hill in the neighborhood, and, that nearest to the center of the shadow. I had two men in company who looked through smoked glasses. The sky, though overcast, gave out some straggling rays of the sun that enabled us to see around us. It was half-past five by my watch when they informed me that the eclipse was begun. We watched its progress by the naked eye, as the clouds performed for us the service of colored glasses. At the moment when the sun was half obscured, a very evident circular rainbow formed at its circumference with perfect colors. As the darkness increased we saw the shepherds on all sides hastening to fold their flocks, for they expected a total eclipse of an hour and a quarter duration. When the sun assumed the appearance of the new moon, the sky was tolerably clear, but it was soon covered with deeper clouds. The rainbow then vanished; the hill grew very dark, and on each side the horizon exhibited a blue tint like that at the close of day. Scarely had we time to count ten, when Salisbury spire, six miles to the south, was enveloped in darkness. The hill disappeared entirely, and the deepest night spread around us. We lost sight of the sun, whose place until then we had been able to distinguish in the clouds, but whose trace we could now no more discover than if it had never existed. It was now 35 minutes past six; shortly before the sky and the earth resumed a livid tint; there was also much black diffused through the clouds, so that the whole picture presented an awful aspect that seemed to announce the death of nature.

"We were now involved in a total and palpable darkness. It came on rapidly, but I watched so attentively that I could perceive its progress. It came upon us like a great dark mantle thrown over us. The horses we held by the bridle seemed deeply struck by it, and pressed closely to us with marks of extreme surprise. As well as I could perceive, the countenances of my friends wore a horrible aspect. It was not without an involuntary exclamation of wonder, I looked round me at this moment; I distinguished colors in the sun, but the earth had lost all its blue and was entirely black. A few rays shot through the clouds for a moment, but immediately afterward the earth and the sky appeared totally black. It was the most awful sight I had ever beheld in my life. Northwest of the point whence the eclipse came on, it was impossible to distinguish in the least degree the earth from the sky, for a breadth of 60 degrees or more. We looked in vain for the town of Amesbury, situate below us; scarcely could we see the ground under our feet. All the change I could perceive during the totality was that the horizon by degrees drew into two parts, light and dark; the northern hemisphere growing still longer, lighter, and broader, and two opposite dark parts uniting into one, and swallowing up the southern enlightened part.

"At length, upon the first lucid point appearing in the heavens where the sun was, I could distinguish pretty plainly a rim of light running alongside of us, a good while together, or sweeping by our elbows, from west to east; just then, having good reason to suppose the totality ended, I found it to be full three minutes and a half. The hill tops then resumed their natural color, and I saw no horizon at the point previously occupied by the shadow. My companions cried out that they again saw the steep hill toward which they had been looking attentively. Presently we heard the song of the larks hailing the return of light, after the profound and universal silence in which everything had been plunged. The heavens and the earth now appeared of a grayish cast, interspersed with blue, like the morning before sunrise. As soon as the sun appeared, the clouds grew denser, and for some minutes the light did not increase, as happens at a cloudy sunrise. The instant the eclipse became total, until the emersion of the sun, we saw Venus but no other stars. We perceived at this moment the spire of Salisbury Cathedral. The presence of the clouds added much to the solemnity of the spectacle, incomparably superior, in my opinion, to the eclipse of 1715, which I saw perfectly from the top of Boston steeple, when the sky was very clear. There, indeed, I saw the two sides of the shadow, coming from afar and passing to a great distance behind us; but this eclipse exhibited great variety, and was more awfully imposing. So deep an impression has this spectacle made on my mind, that I shall long be able to recount all the circumstances of it with as much precision as now."

There have been no total eclipses of the sun in Britain, since those of 1715 and 1724, nor will there be one visible here during the present century. The first total eclipse in England will happen on the 3d of February, 1916. The most remarkable solar eclipses for the next half century are those of March 15, 1858, and August 19, 1887. The last total eclipse of the sun visible in Europe, happened on July 8th, 1842, of which the following account is abridged from the Athenæum:

"Vienna, July 8, 1842.—The eclipse, the object of our journey to Vienna, was worth going any distance to see. No partial eclipse, however considerable, can give the faintest notion of what a total one is. All Vienna was in expectation for many days previous to the event, and strangers flocked to that capital in crowds to witness that phenomenon. The celebrated astronomer, Schumacher, came all the way from Denmark on purpose to see the eclipse with astronomical eyes. At four in the morning, I beheld the clear rays of the sun, shining opposite my window, while the general appearance of the sky indicated a favorable concurrence of circumstances. Soon after five, I was on my way to the Botanical Garden, and already the ramparts of the city were thronged with multitudes. About ten minutes before six the first spot of darkness was observed upon the sun. From that time until the total obscuration, there was no very unusual appearance. The sky, about half an hour before the commencement of the eclipse, became somewhat obscured by vapor, and blue mists arose increasingly from the horizon. A perceptible chillness crept into the air, and flights of swallows flew wildly and restlessly through the darkening atmosphere; but as long as the smallest portion of the sun was visible, there was considerable light. But now approached the important moment. A heavy bell tolled at intervals from the city, like the funeral knell of our beautiful orb of light and life, and the sharp shrill cries of the birds, which had disappeared, as if to take refuge from some impending convulsion of nature. Yet a moment, and on a sudden, an effect took place, unexpected and sublime. The whole aspect of heaven and earth underwent a change, with regard to light, coloring, everything: and the instant that preceded the total eclipse, resembled in nothing, and gave no idea of that which followed it.

"Round the black sun was an irregular halo of whitish light, defining clearly and strongly the obscured orb. In some places, this halo extended into longer gleams, forming altogether a faint glory. It was not so generally dark as I had supposed it would have been,—but the sudden diminution of light, at the moment of total obscuration, was sudden and startling. Also the sudden diminution of temperature, the thermometer falling 11 degrees instantaneously upon the complete immersion of the sun. One of the most striking and unexpected effects, was a red and lurid glow, that suddenly kindled upon the horizon; the blue pale vapor that had risen from the east, being converted into the semblance of a mighty conflagration. The principal light in the landscape came from thence, no longer from the sun. The rest of the atmosphere was of a sickly greenish tinge, overcast with duskiness, through whose spectral tints the crowds upon the ramparts were dimly discerned, all standing in solemn stillness, like the vast shadowy multitudes in one of Martin's pictures.

"The number of stars visible during this eclipse, at Perpignan, according to Arago, was only ten. The number was greater at Montpelier and Milan, Its effect upon animals was remarkable. One of the friends of Arago had five healthy linnets in a cage, three of which died during the sudden darkness of the eclipse. Oxen formed into a circle, with their horns thrust forward, as if to repel an enemy. At Montpelier bats and owls appeared, sheep lay as if for the night, and horses in the fields were in terror. M. Fraise, a naturalist, relates that a swarm of ants, in full march, stopped short at the moment of occultation, when the darkness was nearly at its hight."

The following table contains a statement of the principal solar eclipses during the present century:

In this table, the eclipses marked with an asterisk are calculated for the meridian of Paris; all the others are calculated for the middle of England.

Eclipses are not only striking and interesting phenomena of nature, but are of considerable advantage and utility. In the first place, from an eclipse of the moon we derive one conclusive argument to prove the globular figure of the earth, from the circular shape of the shadow of the earth in a lunar eclipse. 2. Eclipses of the moon prove that the sun is larger than the earth, because the shadow of the earth shortens in its breadth as it retires from the earth, and at length terminates in a point, which it could not do if the sun were smaller. 3. They also prove that the earth is larger than the moon, because the whole of the moon's body is sometimes involved in the

earth's shadow, and a section of this shadow at the moon is much less than the earth itself. 4. The longitude of places may be obtained by eclipses to a great degree of accuracy. An eclipse commencing at the same moment of time to all places at which it is visible, the difference in the observed time at any two places will give the difference of longitude between the places. 5. Eclipses have lent their aid in settling the precise date of ancient historical events. For if near the time of any memorable event recorded in history, a remarkable solar or lunar eclipse be also recorded, we may know whether the real time of this event be rightly determined, by calculating backward, and ascertaining whether any remarkable eclipse happened near the period supposed. For example, Thucydides relates that a solar eclipse happened on a summer's day, in the afternoon, in the first year of the Peloponnesian war, which eclipse was so great that the stars appeared. This is stated in modern authors to have been in the year 413 before Christ, and by computation it appears that on the 3d of August in that year, there was a great solar eclipse, which passed over Athens about six o'clock in the afternoon; which therefore corroborates the decision of chronologers.

CHAPTER VII.

ON THE SEASONS, AND THE DIFFERENT LENGTHS OF DAYS AND NIGHTS

We formerly had occasion to state that the earth revolves round its axis every 24 hours, and round the sun in about 365 days and nearly 6 hours. These motions are intimately connected with the different lengths of days and nights, experienced in almost every region of the globe, and with the seasons which diversify the different portions of the year.

The constant succession of day and night—though so common as to be almost unheeded—is in reality a very wonderful operation of the Most High. When, after a dark and tempestuous night, the sun first appears in the unclouded horizon, all nature appears animated by his presence. The magnificent scene of creation, which a little before was involved in obscurity, opens gradually to view—and every object around has a tendency to excite sentiments of delight and adoration, if man were disposed to contemplate the works of his Creator with intelligence and pious emotion. The heavens are adorned with azure, the clouds are tinged with the most lovely hues, the flowers expand their buds, and put forth their colors; the birds awake to melody, and the insect tribes are on their wing, all rejoicing in the light of the luminary of day. The curtain of darkness is likewise removed from the abodes of men, which are previously obscured, and we behold the cities, towns and villages, the lofty domes, the glittering spires, and the palaces and temples with which the landscape is adorned. After a night of darkness and tempest, such a scene appears almost like a new creation. The sun, after moving in all his brightness through the canopy of heaven is again hidden from our view in the western region of the sky, and we are then presented with a scene still more wonderful and sublime: the moon rises in unclouded majesty—the planets are beheld moving in their different courses, and an innumerable host of stars, spread over the whole concave of the firmament, diffuse their radiance from afar Such a spectacle, during the silence of the night, fills the contemplative mind with solemn thoughts, and with sentiments of wonder and delight, and has a tendency to raise the soul to a consideration of the Great First Cause, "by whom the heavens were made."

In the course of the annual revolution of the earth round the sun, the inhabitants of every country, and of every clime, experience, though at different times, all the variety of the seasons, and the different lengths of days and nights with which they are accompanied. Spring, summer, autumn, and winter, follow each other in constant succession, diversifying the scenery of nature, and distinguishing the different periods of the year. In the present constitution of the earth, and in the present state of man, this vicissitude of seasons is attended with manifold advantages both to the human race and to the other tribes of animated nature, and is necessary toward bringing to maturity the various productions of the earth. During one-half of the year, from March 21, to September 23, the regions of our globe within the north polar circle enjoy their summer, and part of their spring and autumn. At the north pole, the sun shines six months without intermission; and from 66½ degrees of north latitude, the inhabitants of these climes enjoy a length of day varying from 24 hours to six months;—the nearer the pole, the longer is the day. In Greenland and Davis' Straits, our whale fishers enjoy, during the greater part of the time they are employed in those regions, an almost uninterrupted day of three or four months in length. During the same time, the inhabitants of the antarctic circle around the southern pole, are altogether deprived of the sun, and shrouded in darkness, until the 23d of September; when he again appears on the verge of their horizon. These countries, within the polar circles, may be considered as having only two seasons—summer and winter. They have a summer of about four months, during which the days are very long and the heat considerable. The rest of the year may be considered as winter: for so rapid is the transition from heat to extreme cold, and from cold to heat, that spring and autumn are scarcely perceptible. It is only in temperate climates that four distinct seasons are particularly distinguished and enjoyed. In such climates, in spring, plants have time to shoot, and grow insensibly, without being destroyed by late frosts, or too much hastened by early heats. In summer, the heat gradually diminishes; so that the fruits of autumn have time to ripen by degrees, without being hurt by the winter colds. Throughout most of the European countries, particularly in Italy, and the south of France, these four seasons are distinctly perceptible. In the warmest countries too, as well as in the coldest, there may be said to be only two seasons, that materially differ from each other; as in the tropical climates, about the central parts of Africa, and the southern regions of Asia. In such countries, there is a dry and scorching season, during seven or eight months, until the rainy season commences, which continues generally four or five months; and this is the chief distinction between their summer and winter.

Every season of the year is characterized by its peculiar phenomena and effects. Spring is characterized as the season of the renovation of nature after the gloom and torpor of winter. At this period, animals and vegetables feel the influence of returning warmth, and prepare for the continuance and increase of their several species. The plants and flowers, which were hid in winter, as soon as genial showers refresh the soil, emerge from the ground, and begin to display their beauties. As the sun rises higher and higher above the horizon at noon, and the heat increases, the larger vegetables, shrubs and trees, unfold their leaves, and the winged tribes begin to build their nests, and to "sing among the branches." The landscape begins to be adorned with a lively green, interspersed with flowers of various hues, and all nature appears in ceaseless activity In this season, about the 21st of March, the sun crosses the equinoctial; when the days and nights are equal over all the globe, and the north polar regions, which were previously involved in darkness, now begin to feel the light and genial influence of the sun. The approach of spring and its progressive advances, fill the hearts of all, the mendicant as well as the monarch, with hope, and unmixed joy and satisfaction; for this season affords us a thousand new delights. It charms us with the beauty and perfume of flowers; the songs of the winged tribes; the length of the day rapidly advancing; and the preludes of approaching summer, and the pleasures of rural excursions.

Summer has generally been considered, on the whole, as the most delightful season of the year. Every object is then clothed in renovated beauty and gladness—the winter snows are completely melted from the hills; the trees are bursting with leaves; the flowers are painting themselves with every variety of color, and every thicket, and every hill ring with the modulations of various notes—everything in the animal and vegetable world now appears in a progressive state toward maturity, and the insect race seem animated with peculiar vigor and activity under the more direct influence of the sun. At this time (about the 21st of June), the sun rises highest in his meridian course, the heat increases, the day is at the longest, the night consists only of a few hours of twilight, and the rising sun is accompanied with peculiar sublimity and splendor. The fleecy clouds are painted with purple and vermilion, the mountain-tops are fringed with radiance, and every object on the face of nature displays its peculiar form and beauties. This season, too, is sometimes distinguished by excessive heats, which produce languor and inactivity, and sometimes the sky is covered with dark and lowering clouds, when, on a sudden, the forked lightnings flash, and the thunders roll in awful majesty along the sky, appalling the timorous mind and producing terror among the tribes of animated nature.

Autumn is the season when the fruits of the earth are brought to maturity, to supply the wants of man and beast. The silent and gradual progress of maturity is now completed, and the promise of spring fulfilled. The fields are covered with a golden harvest, the reapers in joyful groups are cutting down their sheaves, and the productions of the earth are gathered into the garner, to be stored up as provisions for the coming year. In every garden and orchard, delicious fruits of various hues are seen hanging on the branches, to gratify the eye, the palate, and the imagination, and presenting a specimen of the superabundance of Divine goodness in providing such a variety of comforts for the human family. "Oh that men would praise the Lord for his goodness, and for his wonderful works to the children of men."—For He crowneth the year with his goodness, his "paths drop fatness:—the little hills rejoice on every side. The pastures are clothed with flocks; the valleys also are covered over with corn; they shout for joy, they also sing." Toward the close of this season, the objects of the vegetable creation begin to lose their bloom and their beauty. The groves lose their leafy honors; the gaudy flowers disappear; and nature puts on a more bleak and somber aspect. But before the forests and the groves are stripped of their beauty, they assume a temporary splendor superior to even the verdure of spring, or the luxuriance of summer. The ever-changing hues of the leaves of the trees, melting into every soft gradation of color and shade, have long engaged the imitation of the painter, and in some measure enliven the gloom of the falling year. During this season (on the 23d of September), the sun crosses the equinoctial, in his course toward the south. He then sets to the north pole, and begins to diffuse his rays on the south polar regions, where spring now commences; and during all the period which intervenes from this time, until the 21st of the following March, the sun shines without intermission around the southern pole.

Winter succeeds autumn, and completes the circle of the seasons, in our northern latitude. The thickening fogs, the heavy rains, the hail showers, and the descending snows, now begin to deface the beauties of the rural landscape. The melody of birds is seldom heard in the groves; the flowers lie dead, and their beauties defaced; the trees are lashed by storms, stripped of their verdure, and spread their naked arms to the ruthless winds. The vapors sometimes thicken into an impenetrable gloom, and obscure the face of the sky. The rains descend in torrents; the brooks swell, the rivers burst their banks, and bury the meadows under a soaking deluge. The atmosphere is now and then hurled into tumultuous confusion, and everything trembles before the furious blast. The trees of the forest are dashed headlong to the ground, and the shepherd's cot carried aloft in the air, or shattered in pieces. The ocean swells with violent commotions, and tosses its waves toward the clouds. Ships are dragged from their anchors, and are whirled about as stubble along the vast abyss, and some of them plunged into the open gulf, with all their mariners, to rise no more. Such are some of the aspects and desolations of stern winter. But it is also accompanied with numerous benefits to mankind. The frost and cold which winter produces, prevent many hurtful vapors in the higher regions of the atmosphere from falling upon us, and purify the air from noxious exhalations. Far from being prejudicial to health, they often improve it, and prevent the humors from that putrefaction which heat might produce. Cold has a tendency to brace the animal system, and to promote the circulation of the blood. When the fields and gardens are covered with snow, this is necessary to preserve them from the cold, and to prevent the grain from corrupting. The earth requires repose, after having yielded in summer all that we require for our subsistence during the winter. While the cold continues, the means are at hand for procuring artificial heat, by the abundance of coals and wood which the Creator has provided. During this season, too, we enjoy the most brilliant and interesting views of the starry heavens, of the planets in their courses, and of the moon "walking in brightness." So that in every season, we have abundant evidence of the goodness of our bountiful Creator, and of the tender care he exercises over every portion of the human family. During the middle of winter the days are shortest and the nights the longest This happens more particularly about the 21st of December, when the sun, in our latitude, rises near the south-east, describes a short curve a little above the southern horizon, and sets near the south-west, after having remained only seven or eight hours above the horizon.

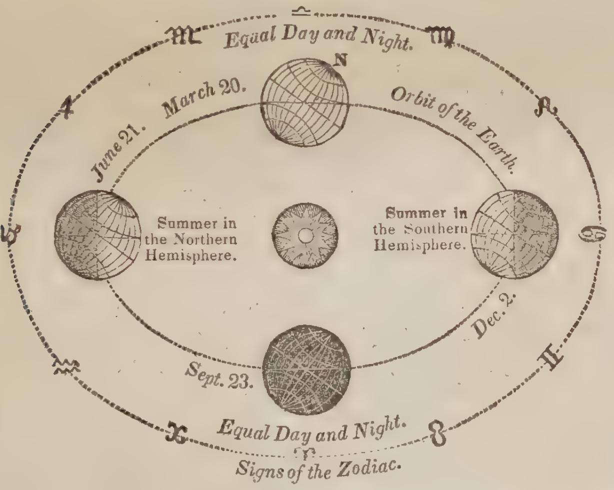
It is here worthy of remark, that all the diversified phenomena of the seasons, and the different lengths of days and nights throughout the year, are produced by the operation of a few apparently simple principles. In all the operations of the Almighty, we find that the most diversified and astonishing effects are produced by causes that are either unheeded, or by agents which, to our limited view, appear altogether inadequate to produce the results. From the simple principle of gravitation, for example, proceed all the beauties and sublimities which arise from the meandering rills, the majestic rivers, and the roaring cataracts; it causes the mountains to rest on a solid basis, and confines the ocean to its appointed channels; it produces the descent of the rains, and dews, and the alternate flux and reflux of the tides; it rolls the moon round the earth, and prevents her from flying off to the distant regions of space; it extends its influence from the earth to the moon, and from the sun to the remotest planets—preserving surrounding worlds in their proper courses, and connecting the solar system with other worlds and systems in the remote spaces of the universe. From the minutest atom to the vast luminaries of heaven, everything is subject to its all-powerful influence; and from this active invisible agent proceed all the order, beauty, and variety, which distinguish the works of creation. Thus, also, the principle called electricity—which manifests itself in sparks of fire, when a glass tube is rubbed in the dark—is found to be the cause which produces the lightnings of heaven, and all the sublime phenomena which accompany a violent thunderstorm; and, in combination with other agents, produces likewise the fiery meteor which sweeps through the sky with its luminous train, and the beautiful coruscations of the aurora borealis.

In like manner the vicissitude of day and night and the revolution of the seasons and their diversified phenomena, depend on the most simple principles and arrangements. The alternate succession of day and night is occasioned merely by the uniform rotation of the earth upon its axis. As our globe turns round on this imaginary line every 24 hours, and as only one-half of a globe can be illuminated at a time, it is evident that any particular place will sometimes be turned toward the sun, and sometimes opposite to it: and being thus constantly subjected to these various positions, a regular return of light and darkness will be experienced during the above period in every region not within the limits of the polar circles. When, by the diurnal revolution, any place is carried into the dark hemisphere, it is night; and when turned round into the enlightened hemisphere, it is day. The sun and all the other heavenly bodies appear to move along the heavens every day from east to west; but this motion is only apparent, and is caused by the real motion of the earth on its axis from west to east; but the apparent motion of these bodies is somewhat different at different seasons of the year, and in different regions of the globe. (See ante, p. 11.) All the planets on whose surfaces spots have been discovered, are likewise found to perform rotations round their axes, which will produce a similar revolution of day and night, as in our world, though in different periods of time, some of the planets finishing the periods of their rotation in about ten hours, some in ten and a half, and others in twenty-three hours.

As to the vicissitudes of the seasons—this is owing to the inclination of the earth's axis to the plane of its orbit. If the axis of the earth stood perpendicular to the plane of its orbit, there would be no variety in the length of days and nights; but they would of course be equal all over the globe, except at the poles, where the sun would neither rise nor set, but remain continually in the horizon, as he is seen at present in that position on the 21st of March and the 23d of September, at the north and south poles. This inclination is 23½ degrees from the perpendicular, which makes an angle with the earth's orbit, or the ecliptic, of 66½ degrees. The axis of the earth always keeps parallel to itself, in its motion round the sun, and points exactly to the same part of the heavens. This may appear somewhat strange, since the orbit of the earth is 190 millions of miles in diameter; but this extent, however great, is only as a point when compared with the immense distance of the fixed stars—the nearest of which is at least more than two hundred thousand times farther from us than we are from the sun. If we look along two parallel rods, four or five yards distant from each other, they will both seem to point directly to the moon when in the horizon, though at such a distance from each other, although they would not both point to the same object placed at a short distance. And perhaps four or five yards bear as great a proportion to the distance of the moon as 190 millions of miles bear to the distance of the stars.

The subject of the seasons may be illustrated by the following diagram, fig. 60, which represents the earth in four different positions in its orbit, the central figure representing the sun. It is known from observation that the axis of the earth is always directed to very nearly the same fixed point in the heavens, and therefore it will constantly preserve the same position, in whatever part of its orbit the earth may happen to be in its circuit round the sun, as may be seen in the figures here represented. Let us now suppose the earth to be in the situation represented at March, or at N, at the higher part of the diagram. A right line joining the centers of the earth and sun will cut the surface of the earth in the equator, and the boundary between light and darkness will pass through the two poles, and the days and nights will consequently be equal throughout the whole earth, except at the poles, which are in the boundary of light and darkness. But when the earth, in its annual course, is carried along the fourth part of its orbit to its position, as represented in June, toward the left hand of the figure, the north pole of the axis still continuing to point in the same direction, will advance into the enlightened hemisphere, and will be 23 degrees and a half from the boundary between light and darkness, and the south pole at the same distance within the dark hemisphere. It is evident that, in this position, the earth may turn round its axis a considerable number of times, and yet no places around the poles be within the boundary of darkness. And if the earth were to continue in this part of its orbit, the sun would never set to the inhabitants near the north pole, nor rise to those near the south. At the equator it would be always equal day and night; and in all places north of the equator their days would be longer and their nights shorter in proportion to their nearness to the arctic or north polar circle, while those on the south side of the equator would have their nights longer than their days.

Fig. 60.



But as the earth moves forward in its orbit toward September, represented in the lower part of the cut, the north pole will gradually approach the boundary between light and darkness, which boundary will again pass through both poles on the 23d of September; the days will gradually shorten until it arrive at this point, and day and night over the globe will be then equal as before. This is called the autumnal equinox, and this season is a kind of medium between summer and winter. As the earth proceeds through the other quarter of its orbit, the days will still shorten until December 21st; when the north pole of the earth will be just as far in the dark hemisphere, as it was in the enlightened one on the 21st of June. This position of the earth, represented at the right-hand side of the cut, is called the winter solstice. From this period to the vernal equinox in March, the days gradually lengthen as the north pole again approaches the boundary between light and darkness; and when the earth arrives at that point, the circle of the year and of the seasons is completed. From the description now given it will evidently appear that the inhabitants of the southern regions of our globe have the same variety of seasons which we enjoy, but in a reverse order. When it is summer in southern climes, it is winter with us; and when it is spring with us, it is autumn in the southern regions.

The different signs of the zodiac through which the earth, or the sun, passes in the course of the annual revolution are depicted in their several characters, in the outer circle of the diagram. They are as follows:—beginning at the bottom, at September, and proceeding toward the right hand, Aries, Taurus, Gemini, Cancer, Leo, Virgo, Libra, Scorpio, Sagittarius, Capricornus, Aquarius, Pisces. These are the names of the twelve constellations through which the sun apparently passes in the course of a year. In March, the real place of the earth is Libra, and consequently the sun will appear in the opposite sign in Aries, and be vertical to the equator. In June, the earth is in Capricorn and the sun in Cancer, when he is vertical to those who live under the tropic of Cancer. In September, the earth is in Aries and the sun in Libra, when he is again vertical to the equator. In December, the earth is in Cancer and the sun in Capricorn, when he is vertical to those living under the tropic of Capricorn; as the inhabitants of South Africa and the central parts of New Holland. The explanations now given of the seasons would, perhaps, appear more perspicuous to the astronomical tyro, were they to be illustrated by an orrery, a tellurion, or any other instrument calculated to elucidate the subject.

In the northern part of the globe, where we reside, our summer is nearly eight days longer than our winter. By summer, we understand the time which elapses between the 21st of March and the 22d of September; and by winter, the time between the 23d of September and the 21st of March; or the period between the autumnal and vernal equinoxes. In the former case the earth passes through 184 degrees of its orbit, which occupies 186 days, 11 hours; in the latter case it passes through only 176 degrees, which is performed in 178 days, 18 hours. The reason of this difference is, that the earth moves in an elliptical orbit, one portion of which is nearer the sun than another; in consequence of which the sun's apparent motion is slower when in the northern signs than while it traverses the southern ones. This orbit is more than three millions of miles longer in one direction than it is in another; consequently, the sun is farther from us at one season than he is at another. On the 1st of January he is three millions of miles nearer us than on the 1st of July, which is ascertained from the difference of his apparent diameter at those seasons. On the 1st of January his apparent diameter is 32 minutes, 35 seconds, whereas, on the 1st of July, he is only 31 minutes, 31 seconds, —being a difference of 1 minute of a degree and 4 seconds.

Here a question will naturally occur,—Why have we the coldest weather when the sun is nearest us, and the hottest when he is farthest distant? This is owing to various causes; the principal of which is, that the sun's rays in winter fall so obliquely upon us, and have so large a portion of the atmosphere to pass through, that they come with less force, and spread over a larger space than they do in the summer, when the sun is at a greater hight above the horizon. Beside, in the long nights of winter, we have a greater degree of cold than can be compensated by the return of heat in the short days, by reason of which the cold will be increased until the days sensibly lengthen. On the other hand, the greater length of the day contributes to augment the heat in summer; for the earth and air are heated by the sun in the day-time more than they can be cooled in the night, and on this account the heat will go on increasing in summer, until the days sensibly decline. In summer, too, the sun rises to a high altitude, and his rays pass through a much less portion of the atmosphere, and are less refracted and weakened by it than when they fall more obliquely on the earth, and pass through the dense vapors near the horizon. Hence it is, that it is colder near the time of sunset, and a little after sunrise, than when the sun is near his meridian altitude. It is owing to these and similar circumstances that the hottest and coldest seasons of the year are not about the time of the longest and shortest days, but generally about a month after these periods. For a body once heated does not grow cold instantaneously, but gradually; and so long as more heat comes from the sun in the day than is lost in the night, the heat will gradually increase until it comes to a certain maximum, when the increasing length of the night will cause it to diminish.

The subject of the seasons has been a favorite theme to poets as well as to philosophers; and they have frequently expatiated on the beauties and the beneficent designs connected with the varying aspects of the revolving year. And it must be admitted that, in the present constitution of our globe, and in the present moral state of the human race, there are many advantages enjoyed, and much of the Divine goodness is displayed in every one of the seasons as they successively appear, which brings along with it its peculiar beauties, pleasures, and enjoyments. But the earth, with the seasons as they now "roll," can scarcely be considered as an abode suited to an innocent creature that has retained its original purity and integrity;—the burning heats in summer, which are felt in the southern climes, the whirlwinds, tornadoes, inundations, thunders and lightnings, with which they are frequently accompanied; and the frosts and snows, storms and tempests, and insufferable cold which are felt in winter in different parts of the temperate climates, and in the polar regions—seem to be accommodated only to beings who are involved in guilt and tainted with moral depravity; and, therefore, we have no reason to believe that the seasons, as they now exist, would have presented the same aspects, or operated in the same manner, had man remained in his primeval innocence and allegiance to his Maker. A great change seems to have taken place in this and other respects at the period of the universal deluge, when the "fountains of the great deep" were broken up, the cataracts of heaven opened, and the solid strata of the earth scattered and disrupted: then, in all probability, the constitution of the atmosphere likewise underwent an extensive change as to its composition and properties, which is partly the cause of some of those storms and tempests and other phenomena which arise in the course of the revolution of the seasons. But, even in the present state of nature, we have reason to be grateful to God, that in all his dispensations toward his creatures "he remembers for us mercy in the midst of deserved judgment" —that while hurricanes, tempests, and earthquakes sometimes produce dreadful devastations, and sweep away multitudes of human beings from the living world, "his tender mercies" may be said, on the whole, to be diffused "over all his works;" for every season of the year brings along with it its own peculiar enjoyments, in a thousand different ways; and man, even in his present condition, might be a comparatively happy being, were his thoughts and affections, his temper and actions, regulated by the principles and precepts of Christianity and the moral laws of his Creator. The evil passions and depraved affections which prevail among mankind, are far more destructive to human happiness than all the storms and tempests, thunders and lightnings, earthquakes and volcanoes, that rage throughout the seasons and convulse the elements of nature.

The present state of man on earth, in the midst of the circling seasons, appears to be adapted only to a being who has but a short time to remain in this terrestrial sphere; whose aim ought to be to aspire after a nobler scene of existence—to enter in the prescribed path to this happier state, by believing in the name of the only begotten Son of God, who is "the Way, the Truth, and the Life"—and by cultivating, with vigilance and caution, those heavenly tempers and Divine virtues which will prepare him for the employments of an immortal existence. As the engagements of life and religion are such as human nature does not always willingly perform, and is apt to postpone them to what it considers a more convenient season—the vicissitudes of the seasons, and other arrangements in nature, have a tendency to stimulate us in the performance of present duty. Whatever we behold in the economy of nature around us, reminds us of the lapse of time and the flux of mortal existence. The day and night regularly succeed each other, and remind us that a certain portion of duration has fled. The sun appears in the eastern horizon; he soon attains his meridian altitude, then declines, and in a few hours sets in the west;—the stars in their courses mark the lapse of our fleeting moments;—the moon does the same every night, by changing its form; and the revolution of the seasons diversifies the year, and shows how large a portion of human life glides silently away. If the wheel of life passed on in undistinguishable uniformity, we should scarcely be able to mark its approaches to the end of the course. If one hour were uniformly like another—if the diurnal motion of the sun did not show that another day is on the wing—if the circling seasons did not impress us with the flight of another year—quantities of duration, equal to days, months, and years, might glide away without being observed, and without improvement. But the course of time, marked out by so many movements, objects and circumstances, continually reminds us of what progress we have made in gliding down the stream of life toward the ocean of eternity! and admonishes each of us by its rapidity "Whatsoever thy hand findeth to do, do it with thy might," since the day rolls on, and "the night cometh, when no man can work."

In fine, the several divisions of the seasons have been considered as bearing a striking analogy to the course of human existence. Spring has been represented as the youth of the year, the season of pleasing hope, blooming beauty, and lovely energy. Summer has been likened to perfect manhood, the season of confirmed strength, and persevering vigor. Autumn has been compared to that period when man is mellowed by age and brings forth the fruits of wisdom and experience And cheerless Winter has been termed the decrepit and hoary old age of the year. If a day be considered as an image of a year, and the year as a representation of human life—then the morning answers to spring, and the spring to childhood and youth; the noon corresponds to summer, and the summer to manhood. The evening is an emblem of autumn, an autumn of declining life; the night is an emblem of winter, in which the powers of vegetation are benumbed,—and winter points out the time when life shall cease, with all its hopes and joys. With such views, Thomson, the poet of the "Seasons," closes his description of Winter:

> ———— Behold, fond man!
> See here thy pictured life: pass some few years,
> Thy flowering Spring, thy Summer's ardent strength,
> Thy sober Autumn fading into age,
> And pale concluding Winter comes at last,
> And shuts the scene. Ah! whither now are fled
> Those dreams of greatness? those unsolid hopes
> Of happiness? those longings after fame?
> Those restless cares, those busy bustling days?
> Those gay-spent festive nights? those veering thoughts
> Lost between good and ill that shared thy life?
> All now are vanished! Religion sole survives,
> Immortal, never-failing friend of man,
> His guide to happiness on high!

CHAPTER VIII.

REFLECTIONS, MORAL AND RELIGIOUS, IN REFERENCE TO THE SOLAR SYSTEM.

Without entering at present on the consideration of any other topics connected with astronomical science, we shall conclude the present work with a few reflections, suggested by the subject we have endeavored to illustrate in the preceding pages.

The science of astronomy presents to our view objects which are calculated to raise our admiration, and to excite the soul to solemn reflection, and elevated contemplations. When we take but a cursory view of the nocturnal heavens, in a clear and serene evening, we are almost irresistibly overpowered with emotions of wonder and awe, at the amazing grandeur of the vast canopy around us, and the number of the brilliant orbs which shed their radiance upon us from afar. But when, with the eye of the intellect, assisted by the telescope and the discoveries of science, we endeavor to traverse the immense spaces above us, and to survey the number, the magnitude, the distances, and the rapid motions of the globes dispersed throughout the regions of immensity, we are completely overpowered, and lost in astonishment, at the extent and grandeur of the scene—their numbers cannot be told; their magnitude cannot be conceived; their distances are beyond human calculation and comprehension; and the amazing velocity with which they fly through the regions of space is confounding and almost terrifying to the imagination. Millions upon millions of those magnificent globes have been running their ample rounds for thousands of years, and will, doubtless continue their courses, though amidst numerous changes, throughout all the revolutions of eternity. The immense forces with which they are impelled in their career; the magnificent circles they describe; the beautiful order in which they are arranged; the regularity and harmony of their movements; and the noble and important ends to which they are destined, proclaim, in language not to be mistaken, that "the hand that made them is Divine;" and, therefore, that they ought to be studied, and contemplated with pious emotion, by every rational and religious mind:

"Come forth, O man! yon azure round survey,
And view those lamps which yield eternal day.
Bring forth thy glasses; clear thy wondering eyes;
Millions beyond the former millions rise;
Look farther;—millions more blaze from yonder skies."

Who can look up to the midnight sky, and behold its rolling wonders, without being struck with astonishment at the idea of that great Being, who formed such vast and magnificent works? "Canst thou by searching find out God? canst thou find out the Almighty unto perfection?" There is a length and a breadth, a hight and a depth, in the perfections of the Divinity, which finite intelligences will never be able fully to comprehend. Vast and magnificent as the structure of the starry heavens is, it was produced without materials—it emerged out of nothing. The voice of the Eternal "spake, and it was done." "He commanded," and the orbs of the firmament started into being. "Let there be light: and there was light." "By the word of the Lord were the heavens made; and all the host of them by the breath of his mouth." Our admiration of such wonderful works should lead us to humble ourselves in his august presence, and to reverence and adore him as the uncreated source of all felicity. "Let all the earth fear the Lord; let all the inhabitants of the world stand in awe of him."

But as we have not yet taken a survey of the starry heavens, and the wonderful scenes which they disclose, we shall chiefly confine our present reflections to the objects connected with the planetary system, of which we have given a brief sketch in the preceding pages.

In the first place, when we contemplate the grand machinery of the solar system, we are presented with a striking display of the Almighty power of Him who formed it. It presents to our view objects of overpowering magnitude and grandeur—planetary globes, a thousand times larger than the earth; and magnificent rings, which would reach nearly from the earth to the moon, and which would enclose within their vast circumference four hundred worlds as large as that on which we dwell. It exhibits a sun more than twelve hundred thousand times larger than our earthly ball, and five hundred times larger than all the planets, their satellites and rings, taken together, even although hundreds of comets were also included; and this sun extending its influence to bodies a thousand millions of miles distant, enlightening them by his beams, and retaining them in their orbits by his attractive influence. It presents before us motions, so astonishing as to overpower all our faculties—bodies, a thousand times larger than our globe, flying with a velocity of thirty thousand miles every hour, carrying along with them a retinue of revolving worlds, and continuing their rapid career, without a moment's intermission, for thousands of years—nay, motions at the rate of eight hundred thousand miles an hour have been perceived among some of the bodies connected with the solar system.

What a striking display do such objects present of the power and grandeur of Omnipotence, so frequently celebrated by the inspired writers. "Great is our Lord, and of great power: his understanding is infinite; his greatness is unsearchable;" wonderful works doth He, which we cannot comprehend. "Who is a strong Lord like unto thee? Who in heaven can be compared unto the Lord? Who among the sons of the mighty can be likened unto the Lord?" We are sometimes apt to be dazzled with the splendor of riches, and to admire, in the palaces of the great, the magnificence of the furniture, the beauty of the apartments, and the profusion of gold and silver ornaments that appears on every side. We are apt to reverence mighty potentates, when they bear rule over multitudes of subjects, and exercise their sway over extensive countries. We judge of the greatness of men by their actions, when they build spacious cities, and erect splendid palaces and temples; when they construct steam-engines and carriages, and impel them forward with a motion of fifty miles an hour. But, what are all the powers and energies of man, as displayed in his noblest achievements, compared with the magnificence and energies displayed throughout the planetary system? What are a few cities, palaces, and temples, compared with the grandeur and extent of mighty worlds? What is a small corner of the earth, compared with the expansive range over which the sun extends his influence? What is the motion of a small engine, even at fifty miles an hour, compared with the motion of a globe ten thousand miles in circumference, flying at the rate of a hundred thousand miles an hour? All human art, power, and grandeur must hide their diminished heads in the presence of Him who is the former and governor of spacious worlds. As the splendor of the stars is absorbed by the rays of the sun, so all the grandeur, power, and splendor of this world and its inhabitants vanish before the presence of Him who is "the King Eternal, Immortal, and Invisible," and before whom "all nations are accounted as nothing, and less than nothing and vanity." And, if such power is displayed in one sun, and one system of revolving worlds, how great beyond conception the effects of that Almighty energy which has brought into existence thousands and millions of other suns and systems, and dispersed them in countless numbers throughout the illimitable tracts of space! "Who can utter the mighty acts of the Lord?"—"Great and marvelous are thy works, Lord God Almighty!"

This attribute of the Almighty, so conspicuously displayed in the heavens, lays a sure foundation for the faith and hope and comfort of the Christian, amidst all the perplexities and afflictions to which he is subjected in the present state. For it assures him that whatever Jehovah has promised, "he is able also to perform." The promises addressed to us by a wise and benevolent Being can excite in us hope and dependence, only in so far as we are convinced of his power to secure their accomplishment. If omnipotence were not an attribute of the Divine Being, or were we unable to trace its operations in existing facts, we could have no rational dependence on his promises and declarations in regard to objects which are unseen and eternal, and which lie beyond the limits of human comprehension. But when we behold, in the arrangements of this lower world, and in the solar system, a display of omnipotent energy in incessant operation, far beyond the grasp of our limited faculties, we plainly perceive that there is not a promise recorded in Divine revelation, nor a future fact declared, but is within the power of Jehovah fully to accomplish and realize. "He doeth according to his will in the army of heaven, and among the inhabitants of the earth: and none can stay his hand, or say unto him, What doest thou?" Should afflictions assail us, he is able to comfort and support. Should calamities befall us, or dangers surround us, he is able to deliver. Should death stare us in the face, and heart and flesh begin to faint and fail, he is able to transport our spirits to a nobler scene of existence, and to re-animate our mortal frames at the resurrection of the just. Happy, then, is the man who hath this eternal God for his refuge, "whose hope is in the Lord his God: which made heaven and earth, the sea, and all that therein is: which keepeth truth forever." For He "is able to do exceeding abundantly above all that we can ask or think," "according to the working of his mighty power, which he wrought in Christ, when he raised him from the dead, and set him at his own right hand in the heavenly place."

2. The arrangements of the solar system display the wisdom and benevolence of its Creator. Were it possible to conceive a being possessed of such power as the planetary system displays, but devoid of wisdom and goodness, such a being would be the most terrible object which the human mind could contemplate. Power acting at random, without regard to the happiness of intellectual beings, could only produce terror and apprehension throughout the intelligent universe, uncertain whether or not its energies might be exerted for the purpose of promoting misery and destruction. But the attribute of omnipotence, when conjoined with infinite wisdom and boundless benevolence, conveys an idea the most glorious and transporting; and these perfections are conspicuously displayed throughout all the works of God. His wisdom is illustriously displayed in the arrangements of the planetary system, in placing near the center of this system that immense luminary, the sun, from whence light and heat might be distributed in due proportions to all the worlds that roll around it—in nicely proportionating the motions and distances of all the planets, primary and secondary—in uniting them in one harmonious system by one grand and universal law, which prevents them from flying off in wild confusion through the infinity of space—in nicely adjusting the projectile velocity to the sun's attractive power, so as to produce harmony of motion, and to prevent the planets, on the one hand, from rushing forward to the sun, and on the other, from flying off in a tangent through the regions of immensity—in the constancy and regularity of their motions, no one interfering with another or deviating from the course prescribed—in the exactness with which they run their destined rounds, finishing their circuits with so much accuracy as not to deviate from their periods of revolution the space of a minute in a hundred years—in the spherical figure given to all these mighty orbs, and the diurnal motions impressed upon them, by which a due proportion of light and heat is diffused over every part of their surfaces—and in the wonderful simplicity of the physical laws, on which so much beauty, harmony, and order depend. In all these and many other respects, the planetary system presents a display of "the manifold wisdom of God."

The benevolence of the Deity is likewise manifested throughout this system, in ordering all the movements and arrangements of the planetary globes, so as to act in subserviency to the comfort and happiness of sentient and intelligent beings. For the wisdom of God is never employed in devising means without an end; and the grand end of all his arrangements, so far as our views extend, is the communication of happiness; and it would be inconsistent with the wisdom and other perfections of God not to admit that the same end is kept in view in every part of his dominions, however far removed from the sphere of our observation. We cannot, indeed, explore the minute displays of Divine goodness in the distant regions of the planetary system, but we perceive certain general arrangements which clearly indicate that the happiness of intellectual natures is one of the grand ends of the Divine administration. For example—light is essential to the comfort and happiness of all living beings. Its rays illumine the vast expanse of the heavens, and unvail all the beauties and sublimities of creation around us. Without its influence the universe would be transformed into a desert, and happiness, even in the lowest degree, could scarcely be enjoyed by any sentient or perceptive existence. Now we find, in the arrangements of the solar system, that ample provision has been made for diffusing light in all its varieties over every planet and satellite belonging to this system. All the planets revolve round their axes, in order that every part of their surfaces may enjoy a due proportion of the solar rays: around the more distant planets, an assemblage of moons has been arranged to throw light upon their surfaces in the absence of the sun. And while the satellites perform this office, the primary planets reflect a still greater quantity of light upon the surface of the satellites: and one of these planets is invested with a splendid double ring, of vast dimensions, to reflect the solar rays during night both on the surface of the planet and on the surface of its moons; all which arrangements must necessarily have a respect to the enjoyment of intellectual natures: otherwise they would be means without an end, which would be inconsistent with the wisdom and intelligence of the Deity. If, then, the happiness of various orders of intelligent beings was intended to be promoted by such adaptations and arrangements, we have here presented to our view a most glorious display of the expansive benevolence of that almighty Being who "is good to all," and whose "tender mercies are diffused over all his works." If this earth on which we dwell "is full of the goodness of the Lord;" if countless myriads of living beings, from man downward to the minutest insect, are supported and nourished by the Divine bounty, how wide and expansive must be the emanations of that beneficence which extends its regards to worlds a thousand times more extensive and populous than ours! The benevolence of the Deity may be said to constitute his whole moral character, and to reflect a radiance on all his other perfections. Hence, in the records of inspiration, the Divinity is summarily described by this perfection alone, "God is love!" He is the uncreated source of all the happiness enjoyed by every rank of spiritual and perceptive existence, from the highest angel to the worm. "O give thanks unto the Lord; for he is good: for his mercy endureth forever."

3. The survey we have taken of the solar system has a tendency to moderate the pride of man and to promote humility. Pride is one of the distinguishing characteristics of puny man, and has been one of the chief causes of all the contentions, wars, devastations, systems of slavery, and ambitious projects which have desolated and demoralized our sinful world. Yet there is no disposition more incongruous to the character and

circumstances of man. Perhaps there are no rational beings throughout the universe among whom pride would appear more unseemly, or incompatible than in man, considering the situation in which he is placed. He is exposed to numerous degradations and calamities, to the rage of storms and tempests, the devastations of earthquakes and volcanoes, the fury of whirlwinds, and the tempestuous billows of the ocean, to the ravages of the sword, famine, pestilence, and numerous diseases; and at length he must sink into the grave, and his body must become the companion of worms! The most dignified and haughty of the sons of men are liable to these and similar degradations, as well as the meanest of the human family. Yet, in such circumstances, man—that puny worm of the dust, whose knowledge is so limited, and whose follies are so numerous and glaring—has the effrontery to strut in all the haughtiness of pride, and to glory in his shame.

When other arguments and motives produce little effect on certain minds, no considerations seem likely to have a more powerful tendency to counteract this deplorable propensity in human beings, than those which are borrowed from the objects connected with astronomy. They show us what an insignificant being—what a mere atom, indeed, man appears amidst the immensity of creation! Though he is an object of the paternal care and mercy of the Most High, yet he is but as a grain of sand to the whole earth, when compared to the countless myriads of beings that people the amplitudes of creation. What is the whole of this globe on which we dwell compared with the solar system, which contains a mass of matter so many millions of times greater? What is it in comparison with the hundred millions of suns and worlds which, by the telescope, have been descried throughout the starry regions? What, then, is a kingdom, a province, or a baronial territory, of which we are as proud as if we were the lords of the universe, and for which we engage in so much devastation and carnage? What are they, when set in competition with the glories of the sky? Could we take our station on the lofty pinnacles of heaven and look on this scarcely distinguishable speck of earth, we should be ready to exclaim with Seneca, "Is it to this little spot that the great designs and vast desires of men are confined? Is it for this there is so much disturbance of nations, so much carnage, and so many ruinous wars? Oh folly of deceived men, to imagine great kingdoms in the compass of an atom, to raise armies to decide a point of earth with the sword!" Soon may the time arrive when the prophesy shall be fulfilled:—

"The wolf shall dwell with the lamb,
And the leopard shall lie down with the kid;
And the calf and the young lion and the fatling together;
And a little child shall lead them.
And the cow and the bear shall feed;
Their young ones shall lie down together:
And the lion shall eat straw like the ox.
And the suckling child shall play on the hole of the asp,
And the weaned child shall put his hand on the cockatrice' den.
They shall not hurt nor destroy in all my holy mountain:
For the earth shall be full of the knowledge of the Lord,
As the waters cover the sea.
And in that day there shall be a root of Jesse,
Which shall stand for an ensign of the people;
To it shall the Gentiles seek:
And his rest shall be glorious."

Isa. xi, 6—10.

It is unworthy the dignity of an immortal mind to have its affections absorbed in the vanishing splendors of earthly grandeur, and to feel proud of the paltry possessions and distinctions of this sublunary scene. To foster a spirit of pride and vain-glory in the presence of Him "who sitteth on the circle of the heavens," and in the view of the overwhelming grandeur and immensity of his works, is a species of presumption and arrogance, of which every rational mind ought to feel ashamed: and, therefore, we have reason to believe, that those multitudes of fools, "dressed in a little brief authority," who walk in all the loftiness of pride, have not yet considered the rank they hold in the scale of universal being—and that a serious and profound contemplation of the immensity of creation would have a tendency to convince us of our ignorance and nothingness, and to humble us in the dust in the presence of the Former and Preserver of all worlds. We have reason to believe that the most exalted beings in the universe—those who are furnished with the most capacious powers, and who have arrived at the greatest perfection in knowledge—are distinguished by a proportional share of humility; for in proportion as they advance in their surveys of the universal kingdom of Jehovah, the more will they feel their comparative ignorance, and be convinced of their limited faculties, and of the infinity of objects and operations which lie beyond their ken. At the same time, they will feel that all the faculties they possess were derived from Him who is the original Fountain of existence, and are continually dependent for their exercise on his sustaining energy. Hence we find that the angelic tribes are eminently distinguished for the exercise of this heavenly virtue. They "cover their faces with their wings," in the presence of their Sovereign, and fly with cheerfulness at his command to our degraded world, "to minister to them who shall be heirs of salvation," and to execute whatever purposes he prescribes.

Throughout the sacred records pride is uniformly represented as abhorrent in the sight of the Almighty, while humility is marked with his approbation. "Every one that is proud in heart is an abomination to the Lord." "God resisteth the proud, but giveth grace unto the humble." "Thus saith the high and lofty One, who inhabiteth eternity, whose name is Holy: I dwell in the high and holy place, with him also that is of an humble and contrite spirit, to revive the spirit of the humble, and to revive the heart of the contrite ones." This is a consideration which deserves the serious attention of young men when they first set out in the pursuit of science. They are apt to be puffed up with a vain conceit of their acquirements, when they have acquired only a smattering of learning, and have scarcely entered the porch of the temple of knowledge, and to vaunt themselves as if they were raised to a high elevation above the vulgar throng. Let such remember that even the illustrious Newton, after the vast acquirements he had attained, and the noble discoveries he had made, when he approached the hour of his dissolution, declared, "I do not know what I may appear to the world, but to myself I seem to have been only like a boy playing on the sea shore, and diverting myself with now and then finding a pebble or a prettier shell than ordinary, while the great ocean of truth lay all undiscovered before me."

4. The subjects of astronomy to which we have directed the attention of the reader, afford a striking view of the condescension of the Divine Being toward man, especially in regard to the redemption of our fallen world. This sentiment seems to have been deeply impressed upon the mind of the Psalmist, when contemplating the

nocturnal heavens. Viewing the resplendent orbs everywhere around him in the canopy of the sky—the moon displaying her radiance—the planets in their courses, and the innumerable host of stars—his thoughts seem to have taken a flight into the regions of immensity, and by the guidance of his rational powers, and the assistance of the Spirit of inspiration, he takes an expansive view of the multitude, the magnitude, and the grandeur of those magnificent globes which roll in the distant tracks of creation. Overwhelmed with his views of the immensity of the universe, and of the perfections and grandeur of its Creator, he breaks out in the language of astonishment and wonder, "When I consider thy heavens, the work of thy fingers, the moon, and the stars which thou hast ordained; what is man that thou art mindful of him? and the son of man that thou visitest him?" Surveying with his intellectual eye the boundless extent of God's universal empire, he shrinks as it were into nothing, and seems almost afraid lest he should be forgotten or overlooked amidst the immensity of beings over which the Divine government extends. And when he considered himself as a guilty creature in the presence of the Most High, his astonishment at the Divine condescension and grace must have been increased.

In no dispensation of the Almighty is this Divine condescension so strikingly displayed as in the economy of our redemption. Though countless myriads of worlds and intelligences are under his superintendence, and are incessantly celebrating his praise in the loftiest strains; and, consequently, though all the apostate inhabitants of our world might have been forever annihilated without being missed amidst the immensity of creation, yet, amazing to relate! the joyful announcement was made to our rebellious race, "God so loved the world, that he gave his only begotten Son, that whosoever believeth in him should not perish, but have everlasting life." Soon after the fall of man this glorious intelligence was announced; and in every succeeding age God raised up a succession of prophets to announce the coming of the great Deliverer, "to foretell the sufferings of Christ, and the glory that should follow." And when the time appointed in the decree of Heaven arrived, the promised Messiah was at length ushered into the world. A messenger from the celestial world, surrounded with refulgent splendor, was dispatched to the plains of Bethlehem, to make known his appearance in the world: "Behold," says he, "I bring you good tidings of great joy, which shall be to all people. For unto you is born this day in the city of David, a Saviour, which is Christ the Lord." And immediately a multitude of angels, having winged their flight from their heavenly mansions, joined in a chorus of congratulation and praise, "Glory to God in the highest, and on earth peace, good-will toward men." Our Redeemer having passed through the scene of his public ministry, and manifested himself to be "the Son of God with power," by a series of beneficent miracles, which he performed in every region of the land of Judea—was "led as a lamb to the slaughter," delivered up to the severest sufferings for our sake, and "became obedient unto death, even the death of the cross!" And while he hung on the accursed tree, the most awful and striking miracles were exhibited to surrounding spectators, in order to display the dignity of Him who suffered, and the importance of that "decease which was accomplished at Jerusalem." The sun was clad in black, the heavens were arrayed in sackcloth, the day was turned into night, and, for three hours, darkness covered the whole land. The rocks rent asunder, the foundations of the earth did quake, the vail of the temple was rent in twain from the top to the bottom, the graves were opened, and many bodies of the saints who slept arose.

This was the most wonderful event, and the most illustrious display of Divine love that was ever announced to our world. What displays of Divine love and mercy may have been made to other worlds, and other orders of beings, we are not in a situation to determine. We dare not affirm that, in other regions of the Divine empire, similar displays have not been made; for we have never traversed the depths of immensity to ascertain all the dispensations of the Almighty in every province of creation. But we may boldly affirm that the mission and the death of Christ were the most wonderful events, and the most astonishing displays of mercy and love, that were ever made to our sublunary world. As the apostle of the gentiles has declared, there is a hight and a depth, a breadth and a length in the love of God which is in Christ Jesus, that passeth knowledge. When we consider the depths of misery from which it raises us, the hights of felicity to which it exalts us, the boundless nature of its operations, and the everlasting continuance of all its blessings, we have reason to exclaim, in the language of admiration, with the apostle John, "Behold, what manner of love the Father hath bestowed upon us that we should be called the sons of God!" "Unto him that loved us, and washed us from our sins in his own blood, and hath made us kings and priests unto God and his Father; to him be glory and dominion forever and ever!"

5. The studies connected with the science of the heavens have a tendency to prepare the soul that has been previously enlightened and regenerated, for the employments of the future world. In that world the glory of the Divine perfections, as manifested throughout the illimitable tracks of creation, is one of the objects which unceasingly employ the contemplations of the blessed; for they are represented in their adorations, as celebrating the attributes of the Deity as displayed throughout the material universe: "Great and marvelous are thy works, Lord God Almighty. Thou art worthy, O Lord, to receive glory and honor and power; for thou hast created all things, and for thy pleasure they are and were created." Before we can enter that world and mingle with its inhabitants, we must acquire a relish for their employments and some acquaintance with the objects which form the subject of their sublime investigations; otherwise we could feel little enjoyment in the society of heavenly intelligences, and the exercises in which they engage. The investigations connected with astronomy, and the frequent contemplation of its objects, may tend to prepare us for such celestial employments; as they awaken attention to such subjects—as they invigorate the faculties and enlarge the capacity of the intellect—as they suggest sublime inquiries, and excite desires for further information which may afterward be gratified—as they form the ground-work of the progress we may afterward make in that state, in our surveys of the Divine operations—and as they habituate the mind to take large and comprehensive views of the empire and moral government of the Almighty.

Those who have made progress in such studies, under the influence of holy dispositions, will certainly have higher and more perfect conceptions of the attributes of Jehovah than those who have given little or no attention to them; and it is not perhaps an unwarrantable supposition, that by such employments as most familiarize us with the glorious works of the Creator, and lead us to the contemplation of his moral perfections, we may be the better prepared for directing the views and investigations of such as have enjoyed fewer opportunities of instruction in the present state. For, we are informed in the sacred records, that "they who are teachers of wisdom shall shine as the brightness of the firmament, and they that turn many to righteousness as the stars forever and ever:" plainly intimating, that those who have made eminent advances in Divine knowledge, and applied it to its proper use, shall be distinguished with peculiar honors.

It is here of some importance to remark, that it is not merely a scientific view of the mechanical fabric of the universe that will prepare us for the employments of the celestial world, but the moral principles and the holy affections with which we are animated in all our studies and contemplations. A man under the influence of evil principles and passions, whose mind is actuated by pride, malignity, avarice, or revenge, is unqualified for a right contemplation of the works of God, for joining in the associations of pure and holy beings, and for engaging in the exalted services of the heavenly world. Unless the principles of "love to God" and "love to man" be engraven on our hearts, and interwoven throughout the whole of our mental frame, and manifested in the general tenor of our conduct, we can never enjoy true happiness either in the present state or in any other region of the universe; and such principles and dispositions can never be expected to be implanted in the soul, and brought forth into action, unless we comply with the requisitions contained in the word of God. The foundation of future felicity must be laid in "repentance toward God, and faith toward our Lord Jesus Christ." As sinners against the most high God, we stand in need of pardon, peace, and reconciliation. And "this is the record of God, that he hath given to us eternal life, and this life is in his Son." "This is his commandment, that we believe on the name of his Son Jesus Christ,—whom God hath set forth to be a propitiation, to declare his righteousness for the remission of sins."

This is the first step in the path which leads to life eternal. And having entered on this course, we must be careful to bring forth "the fruits of righteousness," and to "glorify God in our bodies and spirits which are his." We must "add to our faith virtue; and to virtue knowledge; and to knowledge temperance; and to temperance patience; and to patience godliness; and to godliness brotherly kindness; and to brotherly kindness charity. For if these things be in us and abound," we shall neither "be barren nor unfruitful in the knowledge of our Lord Jesus Christ. For so an entrance shall be ministered unto us abundantly into the everlasting kingdom of our Lord and Saviour Jesus Christ." Prosecuting such a course with activity and perseverance, holding communion with the "Father of our spirits," and exhibiting a pattern of every Divine virtue and grace, we shall enjoy all that happiness which is consistent with our present state of trial and imperfection, and be gradually prepared for being "partakers of the inheritance of the saints in light:" where there is "fullness of joy," and "pleasures for evermore." In short, animated by such Divine principles and affections, we shall be fitted for holding intercourse with all the holy beings that constitute the moral and intelligent system, or the whole family of God throughout the universe, in whatever regions of the vast creation they may reside; for the principles and dispositions to which we have adverted must be common to all the pure intelligences that people creation, that have retained their primeval innocence and rectitude. When implanted in the heart, and interwoven through the whole of the mental constitution, they assimilate us to angels and every other class of holy intelligences, and qualify us for associating with the superior orders of intellectual natures—for entering into their sublime and comprehensive views—for bearing a part in their extensive schemes of universal beneficence—and for contributing along with them to the order and prosperity of God's universal and everlasting kingdom!

APPENDIX.

I.

NEW DISCOVERIES IN THE PLANETARY SYSTEM

The Planet Neptune.—The discovery of this planet forms a remarkable era in the history of astronomy. It was ascertained to exist by calculations founded on the principles of physical astronomy, and on the discrepancies which were found to exist between the observed and the calculated places of *Uranus*. It was conceived that probably some disturbing body existed beyond that planet, which had hitherto eluded the observation of astronomers, and which produced the irregularities to which we allude. The following is a brief sketch of the history of this discovery:—

The Rev. Dr. Hussey, in 1834, wrote to Professor Airy, of the Royal Observatory, Greenwich, that he conjectured the possibility of some disturbing body beyond Uranus, and that he had found that Bouvard and Hansen had been in correspondence on a similar conjecture. In 1842, the late distinguished astronomer, Bessel, in conversation with Sir John Herschel, in reply to the question whether the deviations in question might not be due to the actions of an unknown planet, stated, that he thought it highly probable that such was the case. But, until September, 1845, there was not produced by any astronomer a research that was calculated to decide this question. It was about this time that Mr. J. C. Adams, fellow and assistant of St. John's college, Cambridge, communicated to Professor Challis, of the Cambridge Observatory, values which he obtained for the heliocentric longitude, eccentricity of orbit, longitude of perihelion, and mass of an assumed exterior planet, deduced entirely from unaccounted-for perturbations of Uranus. The same results, somewhat corrected, were left at the Observatory of Greenwich, about the end of the following October, in a paper containing the following statement:—"According to my calculations, the observed irregularities in the motion of Uranus may be accounted for, by supposing the existence of an exterior planet, the mass and orbit of which are as follows:—

Mean distance (assumed nearly in accordance with Bode's law)	30.84
Mean sidereal motion in 365¼ days	1° 30.′ 9
Mean longitude, 1st October, 1845	323° 34′
Longitude of perihelion	315° 55′
Eccentricity	0.1610
Mass, that of the sun being unity	0.0001656

These were the first intimations of the new planet that were ever made public; and at, or near the position here assigned to it, it was afterward seen by Professor Challis of the Cambridge Observatory. Had Mr. Airy attended to the above, as he ought to have done, Mr. Adams would have enjoyed the undivided merit of being the first discoverer of this planet; and we cannot but feel indignant at the apathy and neglect of the Royal Astronomer, especially when we consider that Mr. Adams made two journeys to Greenwich to explain this matter, and left his papers and calculations at the Observatory.

In the *Comptes Rendus*, for June 1, 1846—eight months after Mr. Adams had made known the elements of the new planet's orbit to the English astronomers—M. Le Verrier gave a memoir on the theory of Uranus, in which he affirmed the necessity of admitting the hypothesis of an exterior planet. No elements of the orbit or *mass* were given, but its longitude, it was stated, should be, for the beginning of 1847, about 325°. He communicated his principal conclusion to the astronomers of the Berlin Observatory on September 23d, and, guided thereby, and comparing the observations with a star map, M. Galle found the planet on the same evening.

Professor Challis, before this time, in consequence of a laborious research, had actually seen the planet. On July 30th, he went over a zone of the heavens, nine minutes broad, in such a manner as to include all stars up to the eleventh magnitude. On August 4th, he took a wider zone, and recorded a place of the planet. His next observations were on August 12th, when he met with a star of the 8th magnitude, in the zone which he had gone over on July 30th, which did not then contain this star. Of course, this was the planet—the place of which was thus recorded a second time, in four days of observing. A comparison of the observations of July 30th and August 12th, would, according to the principle of search which he employed, have shown him the planet; but he did not make the comparison until after the detection of it at Berlin. The planet, however, was secured, and two positions of it recorded, *six weeks* earlier than in any other observatory, and in a systematic search expressly undertaken for that purpose, so that Mr. Challis, though not acknowledged as the first discoverer, has at least the satisfaction of having seen and recorded the position of this new-found planet six weeks earlier than he who is considered the real discoverer.

This planet appears like a star of the 8th magnitude, and consequently may be seen with a moderate degree of magnifying power; but it will be difficult to distinguish it from small neighboring stars, unless with a very high power, when a disc may be perceived. Its distance from the sun is reckoned about 30 times that of the earth, or 2,850,000,000, that is, two thousand eight hundred and fifty millions of miles, or, more than a thousand millions of miles beyond the orbit of Uranus. The apparent disc of this planet subtends an angle of something more than 3 seconds, and its diameter will consequently be nearly 50,000 miles. Of course, it is about 250 times larger than the Earth, and three times larger than Uranus; and above a hundred times larger than the whole mass of the Earth and Moon, Venus, Mercury, Mars, Ceres, Pallas, Juno, and Vesta taken together. So that here we have a planet, which has been hid from the view of mortals in the profundity of space for thousands of years, exceeding in bulk a large retinue of spacious worlds; Jupiter and Saturn alone are its superiors. Its apparent motion when discovered was retrograde at 4 seconds per day. Its revolution round the sun is supposed to be accomplished in 190 years.

Mr. Lassell of Starfield, near Liverpool, stated that soon after its discovery, he had different views of it, and believes that he may confidently assert that *it is surrounded by a Ring* like that of Saturn, placed three diameters from the body of the planet. This discovery appears to be confirmed by some late observations of Professor Challis. "I have been able," says he, "with the Northumberland telescope, to verify Mr. Lassell's suspicions of a *Ring*. I first received the impression of a ring on the 12th January, 1847. Two independent drawings, made by myself, and my assistant, Mr. Morgan, gave the same representations of its appearance and position. The ring is very little open. Its diameter makes an angle in the south preceding quadrant of 66 degrees with the parallel of declination. The ratio of the diameter of the ring to that of the planet is by estimation that of 3 to 2. I am at a loss to account for my not having noticed the ring earlier."

It also appears that Neptune is attended with at least one *satellite*, which Mr. Lassell has several times seen. In a letter dated September 20, 1847, he informs the editor of the *Times*, that "he has ascertained the period of this satellite to be 5 days, 20 hours, 50 minutes, 45 seconds. The projected orbit is a narrow ellipse, with an axis inclined to about 28 degrees to the ecliptic, and with its semi-axis subtending about 18 seconds, so that the satellite is about 250,000 miles from the planet. This satellite is much brighter in the preceding than in the following half of its path. This variation seems to show that one side of the satellite has less light than the other." It is likewise evident that this satellite must be a body of very considerable size, otherwise, it could not be visible at such an immense distance. It is probably much larger than any of the satellites of Jupiter or Saturn, and may far exceed our globe in magnitude. The heliocentric longitude of this planet, on the 4th of August, 1846, was 326° 39′, and the north polar distance 102° 57′.

The discovery of this far distant planet, in the manner in which it was effected, constitutes not only a new era in the progress of celestial science, but also evinces the perspicacity of the human intellect, and the certainty and uniformity of those physical laws by which the bodies of the planetary system are directed, and that the law of gravitation is extensive in its influence, reaching far beyond what were formerly considered the boundaries of our system, and probably exerting its energies throughout all the worlds that roll through the spaces of infinitude. We have here *a new confirmation* of the theory of universal gravitation. The first step in the exhibition of that law was, the discovery made by Newton that the earth attracts the moon. The principle was also found to explain the revolution of the planets round the sun. Beside, it was found that the movements of the secondary planets round their primaries are owing to the same cause. The application of this law likewise explained certain anomalies in the motion of the moon and planets, which were otherwise difficult to account for. A great inequality in the movements of Jupiter and Saturn, which was long unaccounted for, was at length traced to their reciprocal action on one another by the operation of this law. The effects of the attraction of planets that could be observed, and whose names were known were thereby calculated. In respect to the newly discovered body—the mean distance and position—the *mass* and the form of its orbit, were all unknown. But, by its observed effects, these were all so well determined as to guide the observer almost to the very point of the heavens where it was first seen. This fact stands almost alone in the records of astronomical science. There has been no discovery of the same kind before it in the annals of astronomy, and it may lead to other discoveries of a similar kind. We have now no reason to conclude, that we have as yet descried the utmost boundaries of the solar system, since a body of so great magnitude has been ascertained to exist and to prosecute its annual course around the sun, at nearly double the distance of Uranus. If there be another planet or more beyond the orbit of Neptune, the observations of a number of years upon the movements of this body may lead to a like result again, and to bring to view other spacious orbs which have hitherto been concealed in those distant regions of space. It is in this way that the Creator crowns the exertions of human genius and the investigation of his works with success—by opening to our view a more expansive prospect of his boundless and eternal empire.

THE PLANET HEBE.

The brilliant discovery of the planet Neptune by Adams and Le Verrier, has been closely followed by that of another, which has been detected by M. Hencke, the discoverer of Astræa. On the 1st of July, 1847, at 10h. 40m., P. M., M. Hencke, of Dresden, discovered a second star, not previously marked in his map, of about the 9th degree of magnitude, in 257° 6′ right ascension, and 3° 42′ south declination. This new planet was observed on the 5th July from the Observatory of Berlin in the meridian, and in the refracting telescope. This body is considered as belonging to the smaller planets between Mars and Jupiter. This planet has been subsequently observed by M. Schumacher, M. Encke, M. Rumker, Mr. Hind, Professor Challis, Dr. Peterson and Mr. Lassell. Mr. Hind has computed its elements as follows:

Epoch of mean anomaly, July, 1847, Greenwich mean time	283° 56′ 54″
Longitude of perihelion	8° 17′ 24″
Inclination	137° 25′ 35″
Eccentricity	238910
Mean diurnal motion	886′
Sidereal period	4.004 years.

From these statements it appears that this planet comes between Vesta and M. Hencke's other planet Astræa. It has been named *Hebe*, following the nomination of the illustrious Gauss, to whom the office was delegated by Hencke.

THE PLANET IRIS.

On the night of Friday the 13th of August, 1847, only about six weeks after the discovery of Hebe—Mr. Hind, the astronomer at Mr. Bishop's observatory, Regent's Park, London, discovered an asteroid, which he believed was a new planet belonging to the group between Mars and Jupiter. Subsequent observations have confirmed the accuracy of that opinion, and placed beyond doubt this further triumph of English astronomers

Mr. Hind has since favored the scientific world with the following particulars of this interesting wanderer, now, for the first time recognized as belonging to our solar system.—"In addition to the Berlin maps," says Mr. Hind, "which we have revised, and in some instances corrected, elliptical charts of stars down to the 10th magnitude have been formed for some of the hours of Right Ascension, which it is Mr. Bishop's intention to publish as soon as they are completed. On the 13th of August, I compared Wolf's map with the heavens, and was surprised to find an unmarked star of 8·9 magnitude in a position which was examined on June 22d and July 31st, without any note being made. The mere existence of a star in a position where before there was none visible, would not have been sufficient to satisfy me as to its nature, because during an eight months' search, I have met with very many variable stars, a class which I believe to be far more numerous than is generally supposed. But, on employing the wire micrometer, we were enabled, in less than half an hour, to establish its motion, and thus to convince ourselves that I had been fortunate enough to discover a new member of the planetary system. It may appear to many rather bold to announce the existence of a new planet from the detection of so small an amount of motions as 2".5 in right ascension; but such is the firm mounting of the large refracting telescope, and the perfection of the micrometers, (for which we have to thank Mr. Dollond), that a far smaller change would have been sufficient to convince us of the nature of the object in question." The following are all the observations yet made:—

				R. Ascen. of Iris.			S. Declin.
	h.	m.	sec.	h.	m.	sec.	
August 13,	9	39	46	19	57	30	13° 27′ 21″.5
	10	37	24	19	57	28	13 27 27 .6
14	9	23	58	19	56	38	13 29 14 .0
15	9	0	39	19	55	47	13 31 4 .3

The name *Iris* was fixed upon by Mr. Bishop as an appropriate name for this new planet. The symbol adopted for its designation is a semicircle with an interior star. Mr. Hind says, "This planet has been detected in a systematic search instituted expressly with the view to the discovery of such a body, and commenced in November, 1846. The Berlin maps were employed as far as they extend: small stars of the 9th or 10th magnitude, not marked in the maps, being inserted from time to time, as they came under examination." Observations of *Iris* have likewise been made by Professor Challis, Mr. Graham, Dr. Peterson at Altona, M. Rumker at Hamburg, and Professor Encke at Berlin.

THE PLANET FLORA.

Since the discovery of the planet *Iris*, Mr. Hind, at Mr. Bishop's observatory, South Villa, Regent's Park, has discovered another, within little more than two months after Iris was discovered. This new body was discovered on October 18, 1847. A few hours' observation proved it to be a new planet—the eighth of the remarkable group between the orbits of Mars and Jupiter. Since the epoch of discovery the brightness of the planet has considerably increased, and now equals that of a star of the eighth magnitude. At Mr. Bishop's request, Sir John Herschel has named it "*Flora*" with a flower (a rose) for the symbol. This new body has also been observed by Professor Challis, E. I. Cooper, Esq., Mr. Graham, Professor Encke, Professor Schumacher, M. Peterson and M. Rumker.

From the above statements it appears that three new primary planets have been brought to light during the year 1847, and that, too, within less than the space of four months, the first of them having been discovered on the first of July, and the third on the 18th of the following October. It is remarkable, too, that they all belong to that class of comparatively small bodies, sometimes called *Asteroids*, which move between the orbits of Mars and Jupiter, and are all invisible to the naked eye. Those bodies revolve nearly at the same distance from the sun, and the times of their revolutions round the sun are not much different from each other, and they are now found to be at least *eight* in number. There is a considerable degree of mystery that hangs over the facts and circumstances connected with these bodies, which prevents us from forming precise and definite conceptions respecting their nature and destination. It is generally supposed that they once formed the component parts of a large planet, which formerly revolved near the regions they now occupy, but, by some powerful internal force, had been disrupted into a number of smaller planets, which form the bodies which have been lately discovered. How many of these smaller bodies may exist it is now impossible to determine, since others may still be discovered; for it would be as unreasonable to conclude that we have now discovered the whole of them, as it would have been when only two or three of them were discovered. Between the beginning of 1801, and 1807, four of these bodies had been detected, but no further discovery was made in reference to them until December, 1845, when Astræa was discovered.

Various inquiries are suggested to the mind when contemplating the peculiar phenomena which these bodies present. If these small planets once formed the component parts of a large planet, at what period did the disruption take place? Was that planet then inhabited? And if inhabited what was the fate of its inhabitants? Were they entirely destroyed by the awful catastrophe? or, did the inhabitants of the different fragments fly off along with that portion of the original planet which they occupied? Are these bodies still inhabited? or, are they flying like shattered masses, and barren deserts, through the voids of space? And if so, are they ever again to be repeopled? To such inquiries, however, no satisfactory answers can be expected while we remain in the present state. On the other hand, if we do not admit the hypothesis of a large planet having been disrupted, it is very difficult to account for the present position, motions, and other phenomena of these bodies, so very different from the harmony, proportion, and order, which characterize the other arrangements of the solar system. As already stated, they are nearly of the same distances from the sun, and perform their revolution nearly in the same periods; their orbits are more eccentric, and have a much greater degree of inclination than those of the other planets; and what is very singular and unaccountable, *their orbits cross each other*, so that there is a possibility of these planets impinging upon each other in the course of their revolutions. These circumstances seem to indicate that the bodies in question are not in that order and arrangement in which we should suppose an all-wise Creator would have placed them at their original creation, so that, whatever view we take of these anomalous bodies, there appears to us something inexplicable, mysterious, and incomprehensible. But we may rest assured that their present state, whatever it may be, is in full accordance with the wisdom, rectitude, and benevolence of the *Moral Governor* of the universe.

RAPID PROGRESS OF ASTRONOMICAL DISCOVERY.

Since the beginning of the 17th century, a little before the telescope was applied to the heavens, no less than thirty-one bodies, unknown before, have been added to our views of the Solar System. In the year 1608, seven bodies were known to belong to our system, namely, the Sun and Moon, Mercury, Venus, Mars, Jupiter, and Saturn. In 1700, there had been added eleven moving bodies, namely, four satellites of Jupiter, five of Saturn, the Earth itself, which was now fully recognized as a planet, and Halley's comet, though the prediction had not been verified. In 1800, there had been added *nine*, namely, Uranus and its six satellites, with two satellites of Saturn. These were all discovered by the late Sir Wm. Herschel; and this celebrated observer, at his death, left the solar system half as large again, in number of bodies, as he found it. Since the beginning of the year 1800, there have been added twelve, namely, Vesta, Juno, Ceres, Pallas, Astræa, Hebe, Iris, Flora, Neptune, the satellite discovered by Mr. Lassell as revolving round the planet Neptune, Encke's comet, and Biela's comet.

Notwithstanding the discoveries which have lately been made in the planetary system, and in other regions of the heavens, we are not to imagine that we have yet arrived at boundaries in creation, beyond which we cannot pass. Only a few years have yet passed since the planet Saturn was considered as the utmost boundary of our planetary system, whose orbit is removed 900 millions of miles from the sun. But now, planets have been discovered at double and treble this distance, at eighteen hundred millions, and at three thousand millions of miles from this central luminary, and at such immense distances retained in their orbits, and guided by the influence of the attractive powers of the sun. The planet Neptune moves in an orbit five thousand seven hundred millions of miles in diameter, and about eighteen thousand millions of miles in circumference; and were a steam carriage to move round this vast circle at the rate of twenty miles an hour, it would require more than a hundred thousand years before it would complete the vast circuit. As we have no reason to conclude that we have not reached the utmost bounds of our system, it is not at all improbable that planets of a large size may exist far beyond the orbit of Neptune, which may yet be discovered by the persevering efforts of our astronomers, and some of which may never be visible to mortal eyes. It will now be more difficult than formerly to make delineations of the orbits of the planets, when they are intended to be represented in the relative proportions of their distances from the sun, unless the delineation be made on a very large scale, for otherwise the orbits of Mars, the Earth, Venus, and Mercury, would appear so close to each other as scarcely to be distinguished.

On the whole, what further discoveries may yet be made in the celestial regions it is scarcely for us to anticipate. But in proportion to the number of those who devote themselves to celestial observations, and in proportion to the improvements that may be made on telescopes, and other instruments of observation, may we expect that still more brilliant discoveries will be unfolded to our view. It is to be hoped that American astronomers will, ere long, be instrumental in making new discoveries in the heavens, since some of them have lately procured most powerfu instruments of observation. It is to be hoped that Professor Mitchell, of Cincinnati, who has been furnished with an observatory, and an excellent instrument of observation, will soon comply with the requisition of Strüve, and measure all the double and multiple stars south of the equator. It is also confidently expected that Mr. Bond of Cambridge, Massachusetts, will follow up his discovery of analyzing the great nebula of Orion by similar discoveries in the nebulous regions of the heavens. The great Cambridge achromatic telescope is an instrument which does honor to the Harvard University, and to the United States. From what it has already performed, it appears scarcely inferior to the monster telescope of the Earl of Rosse, 54 feet in length, and 6 feet in diameter.

II.

BRIEF SKETCH OF THE HISTORY OF ASTRONOMY.

Astronomy was undoubtedly one of the earliest of the sciences cultivated by the human race. Some of its facts and first principles must have been known from the beginning of the world. For when the shades of night have opened to view the azure firmament, diversified with a multitude of shining orbs—the moon walking in brightness—the planets moving in their courses—and the host of stars displaying their diversified radiance—such a scene must have attracted the attention of every spectator, and led him to observe their apparent motions, and to inquire into their order and arrangement, and their use in measuring the exact length and proportions of days, and months, and years. Hence our English poet, Milton, very properly represents our first progenitors, Adam and Eve, celebrating the praises of their Maker, after taking a survey of the nocturnal heavens.

Adam. "These are thy glorious works, Parent of Good,
Almighty! thine this universal frame,
Thus wondrous fair; thyself how wondrous then!
Eve. Unspeakable! who sittest above these heavens
To us invisible or dimly seen
In these thy lowest works; yet these declare
Thy goodness beyond thought, and power divine."

Hence we find that Josephus, in his book of the "Antiquities of the Jews," relates that "Seth and his descendants were persons of happy tempers, and lived in peace, employing themselves in the study of astronomy, and in other researches after useful knowledge." He also remarks that, "God indulged the antediluvians with a long life, that they might bring astronomy and geometry to perfection." And the long lives of men, at that period, when many reached the age of eight or nine hundred years, had a tendency to improve the science of astronomy; since the same individual might observe the planet Saturn go through more than thirty revolutions. We have, therefore, reason to conclude that many of the antediluvians were intelligent astronomers: but their observations, if they were ever recorded, must have perished in the general deluge, unless Noah, who was a wise and good man, had secured some of the most valuable of them in the ark, and transmitted the results to his posterity.

After the deluge, the nations most noted for the cultivation of the science of the heavens were the Chaldeans, the Egyptians, and the Chinese. It is remarked by Josephus that Abraham was a most attentive observer of the stars; that he was a person of great sagacity, both for understanding all things, and persuading his hearers, and that he first brought astronomy from Chaldea into Egypt.

The Egyptians appear to have made some progress in astronomy, at as early a period as the Chaldeans. Their Pyramids, the most ancient monuments in the world, prove their skill in practical astronomy, as they are all situated in such a manner, that their several sides front very exactly the four cardinal points, east, west, north, and south. The system adopted by the Egyptians was the following: they conceived that the planets Mercury and Venus revolved like satellites, around the sun, their orbits being carried along with him in his revolution round the earth. They supposed the earth immovable as the center of the system, and the other celestial bodies to turn around the same center; first the moon, then the sun, about which they supposed Mercury and Venus to revolve, next the planet Mars, then Jupiter, next to Jupiter Saturn, and lastly the sphere of the fixed stars. The Chinese pretend that their nation studied astronomy soon after the flood, and date their astronomical knowledge from Fohi, the first of their kings; supposed by some to have been Noah, as it is understood that he journeyed with his children in the direction of China, about the time of the building of the tower of Babel.

Among the Greeks, astronomy was cultivated by Thales, the Milesian, Anaxagoras, Anaximander, Pythagoras, Aristarchus and others. Pythagoras, who flourished about five hundred years before the Christian era, taught that the sun was in the center of the universe; that the earth is globular, and moves round the sun; that Venus is the morning, as well as the evening star; that the moon reflects the sun's rays, and is inhabited; that the stars are worlds, and that comets are wandering stars. This is nearly the system which was restored by Copernicus, in the fifteenth century.

Hipparchus, born at Nice, in Bithynia, appears to have made considerable advances in the cultivation of every branch of astronomy. He flourished about one hundred and forty years before Christ. He was among the first astronomers on record who attempted to number the stars, and to determine their exact positions. He was first induced to commence this labor in consequence of the appearance of a new star, in order that succeeding astronomers might learn whether any changes take place in the heavens.

Ptolemy, a native of Pelusium, in Egypt, born in the year 69, is the most ancient astronomer whose works have been handed down to our times. His Almagest, or the great composition, is that to which we are indebted, not only for his own observations, but for almost all that remains of Hipparchus, Aristillus, Timocharis, and the ancient Babylonians. According to the system of Ptolemy, the earth is immovable in the center of the universe, and the planets move round it in the following order: first the moon, then Mercury and Venus; next to Venus the sun; then Mars, Jupiter, and Saturn, in the order here stated; and above all these, the firmament of the fixed stars, all which were conceived as revolving around the earth every twenty-four hours. He supposed that the planets moved round the earth, each in a vast solid transparent globe, having the planet attached to its surface; and as these transparent spheres did not account for all the motions and apparent irregularities of the heavenly bodies, he contrived other and still more complicated machinery, such as cycles, epicycles, deferents, etc., in order, if possible, to solve appearances. This system, notwithstanding its absurdity, and its contrariety to the appearances of the universe, continued in vogue, even among the learned, for the space of more than one thousand four hundred years, or until the middle of the fifteenth century. During this period, a few individuals appeared who cultivated astronomy, such as Almansor, Almanon and others among the Arabians; Ulugh Beigh, a prince of Tartary; Alhazen, an Arab in Spain; Alphonso X, king of Castile; Roger Bacon, and several others; but they all adopted the absurd hypothesis of Ptolemy.

About the beginning of the sixteenth century, Copernicus, a bold and original genius, began to be distinguished for his attainments in astronomy. Perceiving that the clumsy and unnatural system of Ptolemy could never account for the motions and appearances of the celestial orbs, he adopted the Pythagorean system, which had been broached five hundred years before Christ, and wrote a profound treatise in confirmation of it, entitled, "Astronomy Restored; or, The revolutions of the Celestial Orbs." With a bold and daring hand, he dashed the crystalline orbs of Ptolemy into pieces, swept away his cycles, epicycles, and deferents, placed the sun in the center of the system, removed the earth from its quiescent state, and set it in motion through the regions of the firmament, in company with the other planetary orbs. This system was at first violently opposed, both by the vulgar, the dignitaries of the Romish church, and pretended philosophers, as contrary both to sense, reason and Scripture, and many of its abettors were subjected to violent persecutions. But it is now universally received by all men of learning, and by every one who has investigated the motions and other phenomena of the heavens. It has opened to our view the harmony and order of the planetary system, the wisdom and intelligence of its great Author, and laid the foundation of all the discoveries which have subsequently been made in this science. It was afterward ably supported by the writings and observations of Galileo, Kepler, Gassendi, Hevelius, Huygens, Cassini, and other celebrated astronomers, by whom its principles have been established on a foundation stable and permanent as the laws of the universe.

About sixty or seventy years after the publication of this system, the invention of the telescope, and the discoveries made with this instrument by Galileo, tended to confirm its principles, and to expand our views of the sublimity, the variety, and multitude of the objects which the universe displays. This illustrious astronomer first discovered, by his telescope, the satellites of Jupiter, the phases of Venus, the spots of the sun, and the rotation of this globe round its axis, the mountains and vales in the moon, the stars in the Milky Way, and an extraordinary phenomenon, which he imagined to be two small globes, connected with the planet Saturn. These discoveries were made about the year 1610, soon after the telescope was invented. About forty-eight years afterward, Huygens, a celebrated mathematician and astronomer, in Holland, with telescopes of a much larger size than those of Galileo, discovered that the phenomenon connected with Saturn was, in reality, an immense ring surrounding that planet, and thirty thousand miles distant from every part of it He, at the same time, discovered the fourth satellite of Saturn; and in these and other observations he used telescopes of his own construction of twelve, twenty-three, and even one hundred and twenty feet in length. Some time afterward, Cassini, a French astronomer, discovered the first, second, third, and fifth satellites of Saturn, and the periods of the rotation of Mars and Venus.

About the period to which we now allude, flourished the illustrious Sir Isaac Newton, who laid the foundation of physical astronomy. About the year 1666, when in the twenty-fourth year of his age, he retired from Cambridge into the country on account of the plague, and sitting one day in an orchard, under a tree, an apple happening to fall upon his head, led him into a number of reflections. Reflecting on the power by which all terrestrial bodies gravitate toward the earth, it occurred to him, that as this power is not sensibly diminished in any distance to which we can recede from the earth's center, there seemed reason to conclude that it extended much farther than it was generally supposed, and even might extend as far as the moon; and if this were true, he concluded that her motion would be influenced by it, and that probably it was this very force which retained her in her orbit. Following out these sublime conceptions, he began the composition of his immortal work, the "Principia," which was published in 1687, in Latin, under the title of "Mathematical Principles of Natural Philosophy." He also invented a reflecting telescope, which bears his name.

Contemporary with Newton were Dr. Hooke, Flamstead, Halley, Bradley, Roemer, Richer, Picard, Maraldi, and others, whose labors greatly contributed to the improvement of astronomy. Flamstead was the first astronomer royal in the Observatory at Greenwich, and, for nearly half a century, was assiduous in his observations of the heavenly bodies. He formed a catalogue of more than three thousand stars, with their right ascensions, longitudes, solar distances, and apparent magnitudes. Roemer, a Danish astronomer, was the first who discovered the progressive motion of light. By comparing the eclipses of the first satellite of Jupiter with the times of their immersions and emersions given by the tables of Cassini, he found that the error of the tables depended on the distance between Jupiter and the earth, and hence he concluded that the motion of light was not instantaneous, and that it moved across the diameter of the earth's orbit in about sixteen minutes, or at the rate of 192,000 miles in a second.

Few discoveries were made in the heavens from the beginning of the eighteenth century until the period when Sir W. Herschel applied his large telescopes to the spaces of the firmament. His discoveries have greatly extended our views both of the planetary system, and of the sidereal heavens. On the 13th March, 1781, he discovered a new planet beyond the orbit of Saturn, to which he gave the name of Georgium Sidus; but it is now generally distinguished by the name of Uranus. On the 11th January, 1787, he discovered the second and fourth satellites which move round this planet; in 1790 and 1794, he discovered four other satellites revolving round the same body. In 1789 he discovered the sixth and seventh satellites of Saturn; he also determined the rotation and figure of this planet—discovered that it had a double ring, and was marked with several belts parallel to its equator. His son, Sir J. Herschel, has also distinguished himself by his unwearied observations on the heavens. In conjunction with Sir J. South, he produced a catalogue of 380 double stars, whose distances and angles of position they had determined with the utmost precision. Sir J. Herschel afterward produced a list of upward of 3300 double and triple stars, from his own solitary observations, accompanied with all the micrometrical measurements; and about ten or twelve years ago, he went to the Cape of Good Hope for the purpose of making observations in the southern region of the heavens, and made some interesting discoveries. On the 1st of January, 1801, M. Piazzi, a Sicilian astronomer, discovered a small planet between the orbits of Mars and Jupiter, which has been named Ceres. On the 28th March, 1802, Dr. Olbers, of Bremen, discovered another planet, near the same region, which is named Pallas. On the 1st September, 1804, Mr. Harding, of Lilienthal, discovered another, which is named Juno, distinguished for the great eccentricity and inclination of its orbit. On the 26th March, 1807, Dr. Olbers discovered a fourth planet, which he named Vesta. The latest discovery of this kind we have to record was made by Mr. Hencke, of Driesen, on the 8th December, 1845, when he discovered another planet somewhat similar to the four now mentioned, which is nearly at the same distance from the sun, and accomplishes its revolution in nearly the same period as the others. This planet has been named Astræa.

In the present day there are many distinguished cultivators of astronomical science, from whose observations and researches new discoveries may be expected. The names of South, Herschel, Airy, Smyth, Robinson, the Earl of Rosse, Schumacher, Strüve, Harding, Bessel, Arago, and a multitude of others, are well known as distinguished cultivators of the science of the heavens. It is to be hoped that the Earl of Rosse, by means of the large and splendid telescope he has lately erected, will be enabled to make new discoveries, and to enlarge our views of the grandeur of the sidereal heavens. He has already analyzed some of the nebulæ, and shown them to consist of immense clusters of stars which could not be perceived by any former telescopes; and this, we would hope, is only a prelude to still more sublime discoveries. What further advances astronomy may yet make, we dare not venture to anticipate. The number of individuals who devote themselves to this study is gradually increasing; its instruments of observation are rapidly improving; and we can scarcely set boundaries to the discoveries that may yet be made. In future ages, man, by the improvements in optical and other instruments, may be able to penetrate much farther into the distant regions of the universe than he has hitherto done, and may descry myriads of objects which have hitherto remained invisible in the unexplored regions of immensity. And after all the discoveries which mortals can bring to view from this terrestrial sphere, the greater part of the works of the Almighty will still remain to be explored throughout the ages of eternity.

III.

EXPLANATION OF ASTRONOMICAL TERMS

Aberration, an apparent change of place in the fixed stars, which arises from the motion of the earth combined with the motion of light.

Achernar, a fixed star of the first magnitude, in the constellation Eridanus, R. A. 1 hour, 31 minutes.—Dec. 58 degrees, 16½ minutes.

Achronical rising or setting of a planet, or star, is when it rises at sunset, or sets at sunrise.

Aldebaran, a fixed star of the first magnitude in the head of the constellation Taurus; sometimes called the *Bull's eye*.

Aerolites, or air-stones, are semi-metallic substances which are found to fall from the atmosphere in different countries. Some philosophers have imagined that they are the fragments of a planet that had been burst asunder.

Algol, a star in Medusa's head which varies from the second to the fourth magnitude.

Alioth, a fixed star in the tail of the Great Bear.

Almicanters, imaginary circles, which are supposed to be drawn parallel to the horizon, and to pass through every degree of the meridian, to show the altitude of a celestial object above the horizon.

Altitude, the hight of the sun, moon, or stars above the horizon, reckoned in degrees and minutes, on a vertical circle.

Amphiscii, a name given to the inhabitants of the torrid zone, on account of their shadows falling at one time of the year toward the south, and at another time toward the north.

Amplitude, an arc of the horizon, contained between the east or west point of the heavens, and the center of the sun or a star at the time of its rising or setting.

Anomaly (the true), the distance of a planet in signs, degrees, etc., from that point of its orbit which is farthest from the sun. The mean anomaly is, that which would take place if the planet moved uniformly in the circumference of a circle.

Antœci, a name given to those inhabitants of the earth, who live under the same meridian, and at equal distances from the equator, but on opposite sides of it.

Antipodes, those inhabitants of the earth who live diametrically opposite to each other, or walk feet to feet, on opposite sides of the globe.

Aphelion, that point in the orbit of a planet in which it is at its greatest distance from the sun.

Apogee, that point in which the sun, or a planet, is farthest distant from the earth.

Apsides, the two most remote points of a planet's orbit, otherwise termed its aphelion and perihelion. A line joining those points is, the line of the apsides.

Armillary sphere, an instrument composed of the principal circles which are drawn on an artificial globe.

Ascii, the inhabitants of the torrid zone; so called because the sun being twice a year in their zenith, their bodies at those times cast no shadow.

Axis of the earth, or of a planet; an imaginary line passing through the center from one pole to another, round which they perform their diurnal rotation.

Azimuths, great circles which pass through the zenith and nadir perpendicular to the horizon. The azimuth of a celestial body is an arc of the horizon contained between the east and west points, and a vertical circle passing through the center of that object.

Belts, zones surrounding the body of Jupiter and Saturn.

Bissextile (or Leap Year), which happens every fourth year, contains 366 days; one day being added to the month of February.

Cardinal points of the compass; the east, west, north and south points.

Cardinal points of the ecliptic; the first points of the signs, Aries, Cancer, Libra, and Capricorn.

Centrifugal force, that force by which any revolving body endeavors to fly off from the center of motion in a tangent to the circle it describes.

Centripetal force, the tendency which a body has to the center of its revolution.

Comets, erratic bodies belonging to our system, which move round the sun in very eccentric orbits, distinguished by their fiery tails and nebulous aspects.

Colures, two imaginary circles or meridians, one of which passes through the solstitial points Cancer and Capricorn, and the other through the equinoctial points Aries and Libra.

Conjunction, is when two or more stars, or planets, are in the same part of the heavens.

Constellation, an assemblage of stars.

Cosmical rising or setting of a planet, or star, is when it rises with the sun in the morning, or sets with him in the evening.

Crystalline heavens, two solid orbs by means of which the ancients attempted to account for the apparent motions of the fixed stars.

Cusps, the points or horns of the moon, or of a planet.

Cycle of the moon, a revolution of nineteen years, in which time the conjunction and lunar aspects are nearly the same as they were nineteen years before.

Day (astronomical), the time between two successive transits of the sun's center over the same meridian, which always begins and ends at noon.

Day (sidereal), the time which elapses during the rotation of the earth from one star until it returns to the same star again, and consists of 23 hours, 56 minutes, 4 seconds.

Declination is the distance of any celestial object north or south from the equator, reckoned in degrees, minutes, etc., upon a circle which is perpendicular to it.

Degree, the 360th part of a circle, or the 30th part of a sign.

Disc of the sun, or moon, is its round face, which, on account of the great distance of the object, appears flat.

Digit, the 12th part of the sun's diameter, which is used in the calculation of eclipses.

Diurnal motion of the earth, its rotation on its axis.

Eccentricity, the distance between the center of a planet's orbit, and the focus round which it revolves.

Eclipse, a deprivation of the light of the sun, by the interposition of the moon; or of the light of the moon, by the interposition of the earth.

Ecliptic, a great circle in the heavens through which the sun apparently makes its annual revolution; but which is in reality the earth's path round the sun. It makes an angle with the equator of 23 degrees, 28 minutes.

Elongation, the annular distance of a planet from the sun, as it appears from the earth. It is applied only to the inferior planets, Mercury and Venus.

Emersion, the re-appearance of a celestial body after having been eclipsed.

Equation of time, the difference between real and apparent time, or between that shown by a true clock and a sun-dial. It depends on the obliquity of the ecliptic, combined with the unequal motion of the earth in its orbit.

Equator, or a great circle of the earth which separates the northern from the southern hemisphere. When referred to the heavens, it is called the *Equinoctial*.

Equinoxes, two opposite points in Aries and Libra, where the ecliptic cuts the equinoctial. When the sun is in these points the days and nights are equal to each other.

Foci of an ellipse, two points in the longest, or transverse axis, on each side of the center; from each of which if any two lines be drawn to meet each other in the circumference, their sum will be equal to the transverse axis.

Galaxy, or the Milky Way, a luminous and irregular zone which encompasses the heavens, which is found to be composed of an immense number of stars.

Geocentric place of a planet, is that position which it has when seen from the earth.

Gibbous, a term used in reference to the enlightened part of the moon, from the first quarter to the full, and from the full to the third quarter.

Gravity or *Gravitation*, that force by which all masses of matter tend toward each other.

Halo, a luminous circle round the body of the sun, or moon.

Heliacal rising of a star, is when it emerges from the sun's rays, and appears above the horizon before him in the morning.

Heliacal setting of a star, is when it is so hid in the sun's beams as not to be seen above the horizon after him in the evening.

Heliocentric place of a planet, is that in which it would appear to a spectator placed in the sun.

Hemisphere, the half of a globe or sphere.

Heteroscii, a name given to the inhabitants of the temperate zones, because their shadows at noon always fall one way.

Horizon (the sensible), a circle which separates the visible from the invisible hemisphere, and forms the boundary of our sight.

Horizon (the rational), a great circle which is parallel to the former, and whose poles are the zenith and the nadir.

Hour circles, the same as meridians—marking the hours.

Immersion, the moment when an eclipse begins, or when a planet enters into the shadow of the body that eclipses it.

Inclination, the angle which the orbit of one planet makes with that of another, or with the plane of the ecliptic.

Inferior planets, those that move at a less distance from the sun than the earth, which are Mercury and Venus.

Latitude of a place, its distance from the equator, reckoned in degrees and minutes upon the arc of a great circle.

Latitude of a star, or planet, is its distance from the ecliptic, reckoned in degrees, etc., on the arc of a great circle.

Lesser Circles of the sphere, those whose planes do not pass through the center, and which divide the sphere into two unequal parts. *Great circles*, as the equator, meridians, etc., divide the sphere into two equal parts.

Libration of the moon, an apparent irregularity in her motion on her axis, by which we sometimes see more than the usual half of her disc.

Longitude of a place, its distance east or west from the first meridian, reckoned in degrees, etc., upon the equator.

Longitude of a star or planet, its distance from the first point of Aries, reckoned in degrees, etc., upon the ecliptic.

Lunation, the time between one new moon and another; which is, on an average, 29 days, 12 hours, 44 minutes, 3 seconds.

Maculæ, dark spots which appear on the face of the sun; and *Faculæ* are bright spots sometimes seen on the solar disc.

Magellanic clouds, certain whitish appearances in the heavens, in the southern hemisphere, supposed to consist either of an immense number of stars, or nebulæ.

Magnitudes, the stars are divided into six classes; the brightest are called stars of the first magnitude; the next in brightness, the second magnitude, etc.

Mean motion of a planet, that which would take place if it moves in a perfect circle, and equally every day.

Meridian, a great circle of the sphere which passes through the zenith and the poles, and perpendicular to the horizon.

Micrometer, an instrument fitted to a telescope to measure very small angles; as the diameters of the planets, etc.

Nadir, that point in the heavens directly opposite to the zenith, or immediately under our feet.

Nebulæ, luminous spots in the heavens, or clusters of small stars, discovered by the telescope.

Nocturnal arc, that space of the heavens which the sun apparently describes from the time of his setting to his rising.

Nodes, two points when the orbit of the moon, or of a planet, intersects the plane of the ecliptic.

Nucleus, a term used to denote the head of a comet.

Oblique ascension, an arc of the equinoctial contained between the first degree of Aries, and that point of it which rises with the center of the sun or star.

Oblique sphere, that position of the globe in which either of the poles is elevated above the horizon any number of degrees less than ninety.

Occultation is when a star, or planet, is hid from our sight by the interposition of the moon or some other planet.

Opposition, an aspect of the stars or planets when they are 180 degrees distant from each other, marked thus ☍

Orbit, the curve which a planet describes in its revolution round the sun.

Parallax, the difference of the place of any celestial object, as seen from the surface of the earth, and from its center.

Parallax of the earth's annual orbit, the angle at any planet subtended by the distance between the earth and the sun.

Parallels of latitude, small circles of the sphere which are drawn parallel to the equator.

Penumbra, a faint shadow observed between the perfect shadow and the full light in an eclipse.

Perigee, that point of the solar and lunar orbit which is nearest the earth.

Perihelion, that point of the orbit of a planet nearest the sun.

Periscii, the inhabitants of the frigid zones, because their shadows go around them for six months, or fall toward opposite points of the compass.

Phases, the different appearances of the illuminated parts of the moon, or planets.

Phenomenon, any extraordinary appearance in the heavens; as a comet, etc.

Planetarium, an astronomical machine for showing the motions and other phenomena of the planets.

Pleiades, or the seven stars, an assemblage of stars in the constellation of Taurus.

Polar circles, two small circles, 23 degrees and a half from the poles; the arctic in the north and the antarctic in the south.

Pole star, a star of the second magnitude in the tail of the Little Bear; so called, because it is near the north pole.

Precession of the equinoxes, a slow motion of the two points where the equator intersects the ecliptic, which go backward about 50 seconds in a year.

Quadrant, the fourth part of a circle; or an instrument for measuring angles, and taking the altitudes of the sun and other heavenly bodies.

Quadrature, the position of the moon when distant 90 degrees from the sun; as in the first and third quarters.

Refraction, the bending of the rays of light in passing through the atmosphere, by which the heavenly bodies appear more elevated than they really are.

Retrograde, an apparent motion of the planets, in some parts of their orbits, when they seem to go backward, or contrary to the order of the signs.

Right ascension is that degree of the equator which comes to the meridian with the sun, moon, or star, reckoning from the first point of Aries.

Rotation, the motion of any heavenly body round its axis.

Satellites, secondary planets or moons, which revolve round the primary planets.

Sextile, an aspect of the heavenly bodies, when they are 60 degrees distant from each other.

Sidereal, of or belonging to the stars.

Solstitial points, the first degree of Cancer and Capricorn at which the ecliptic touches the tropics.

Selenography, a representation of the moon, with a description of her different spots and appearances.

Sign, the twelfth part of the ecliptic, or 30 degrees.

Sphere, the concavity of the heavens in which the stars appear.

Superior planets, th se which move at a farther distance from the sun than the earth; as Mars, Jupiter, etc.

System, a number of bodies revolving round a common center, as the planets round the sun.

Syzigy, a term usually applied to the moon, when in opposition, or in conjunction, or when at the new or full.

Telescope, an optical instrument for the purpose of viewing distant objects, particularly the sun, moon, planets, and stars. Telescopes produce their effects either by refraction through glasses, or reflection from speculums.

Telescopic stars, those stars which are only visible by means of Telescopes. All stars beyond those of the sixth magnitude are reckoned telescopic stars.

Torrid zone, that part of the earth which is contained between the two tropics.

Trajectory, a term applied to the orbit of a comet.

Transit of a planet denotes its passing over another planet, or star, or across the disc of the sun.

Trine, an aspect of the planets when they are 120 degrees distant from each other.

Tropics, two circles parallel to the equator, and 23 degrees 28 minutes distant on each side of it. They are named Cancer on the north, and Capricorn on the south.

Vector Radius, a line supposed to be drawn from any planet to the sun, which, moving with the planet, describes equal areas in equal times.

Vertical circles, the same as azimuth circles, or such as are drawn perpendicular to the horizon.

Prime vertical, is that azimuth circle which passes through the east and west points of the horizon.

Year (the solar), the time which the sun takes to pass from one tropic until it returns to the same again, and is 365 days, 5 hours, 48 minutes, 49 seconds.

Year (sidereal), the time which the sun takes to pass from any fixed star to the same again, and is 365 days, 6 hours, 9 minutes, 9 seconds.

Zenith, that point of the heavens immediately over head.

Zodiac, a zone surrounding the heavens, 18 degrees broad, in the middle of which is the ecliptic. The orbits of all the old planets are included in this zone.

Zodiacal light, a brightness sometimes observed in the heavens, somewhat similar to the Milky Way.

Zone, a division of the sphere between two parallels of latitude. There are five zones; one torrid, two temperate, and two frigid.

IV.

THE TELESCOPE.

As those who have acquired a taste for celestial observations, may wish to know something respecting the telescope, we subjoin the following very brief description.

There are two kinds of telescopes generally distinguished,—the refracting and the reflecting telescope, the former composed of lenses, or convex glasses, and the latter of speculums or mirrors combined with lenses. A common refracting telescope, for viewing some of the celestial bodies, may be constructed as follows:—Procure a convex glass, whose focal distance is about three feet. This may be known by holding the glass in the sun's rays, and measuring the distance between the glass and the place where the solar rays are condensed into a small spot. Place this lens at the end of a tube about three feet two inches long, in which there is a small sliding tube for fixing the eye-glass, and adjusting the focus for distinct vision. At the distance of three feet one inch, place a convex glass one inch focal distance. The object-glass will form a picture, in its focus, of all the objects which are directly opposite to it, and this picture will be seen magnified in looking through the eyeglass. The magnifying power, in this case, will be in the proportion of three feet, or thirty-six inches to one inch; that is, the instrument will magnify the diameters of all objects thirty-six times, or make them appear thirty-six times nearer than when viewed by the naked eye; but as the image formed by the object-glass is in an inverted position, all terrestrial objects will appear through it as turned upside down. The opening at the object-glass which lets in the light, should not exceed an inch in diameter.

With such a telescope, which may be constructed for five or six shillings, if the tubes be made of paper or pasteboard, the satellites of Jupiter, the crescent of Venus, the solar spots, and the inequalities on the surface of the moon may be distinguished. Galileo's telescope, with which he made the first discoveries in the heavens, did not magnify more than such a telescope.

THE

ATMOSPHERE

AND

ATMOSPHERICAL PHENOMENA:

ITS NATURE, PROPERTIES, ETC.

CONTENTS

PART I.

PAGE

THE NATURE, PROPERTIES, AND BENEFICIAL EFFECTS OF THE ATMOSPHERE IN THE SYSTEM OF NATURE, AND THE EVIDENCES WHICH ITS CONSTITUTION AFFORDS OF THE WISDOM AND BENEFICENCE OF THE CREATOR.

INTRODUCTION.

The works of God deserve our serious contemplation. His wisdom displayed in the various scenes connected with sublunary nature. His power displayed in the luminaries of heaven. His perfections manifested even in the invisible regions of nature. Atmosphere an important appendage to our globe. Outline of subjects in reference to the atmosphere.............. 7

CHAPTER I.

Proofs that air is a material substance. Various experiments illustrative of this position. It produces sound, and shows a resistance to bodies passing through it. It excludes all other bodies from the place it occupies. A common bellows shows the materiality of air. Its waves frequently become an object of sight.. 9

CHAPTER II.

The weight and pressure of the atmosphere, and the quantity of matter it contains. Comparative weight of air and water. Experiments illustrative of its pressure. Barometer, and the mode of its action. Pascal's celebrated experiment with water and wine, to prove the pressure of the atmosphere. Remarks and reflections in reference to such experiments. Atmospheric pressure on the body of a man. This pressure varies. Weight of the whole atmosphere. Air decreases in density as we ascend to the higher regions. Scenes beheld from balloons. The pressure of the atmosphere illustrated by a great variety of simple experiments......... 10

CHAPTER III.

Facts illustrated by the pressure of the atmosphere. It explains suction. The process of a child sucking the breast. Why two smooth surfaces adhere with great force. Action of a boy's sucker. Adherence of shellfish to the rocks on which they are found. Why frosts occasion a scantiness of water. Why a cask will not run unless open at top. Mode of taking a draught of water, and the principle on which it depends. Action of the syphon. Remarks and reflections in reference to the atmospheric pressure. Its discovery struck the learned throughout Europe with surprise. Amazing pressure on the human body. How our dwellings are prevented from being crushed to atoms. Wisdom and benevolence of the Divine Being in such operations.. 14

CHAPTER IV.

The elasticity of the air, and the phenomena it explains. Important purposes effected by the atmosphere. Various illustrations of the elasticity of air. Effects produced in various substances by this property. Spring of the air equal to its weight—is susceptible of dilatation and compression. Elasticity of air not capable of being destroyed. This property explains a great variety of appearances in nature and art.. 16

CHAPTER V.

The hight of the atmosphere, or the elevation to which it extends beyond the surface of the earth—hight of the atmosphere, were it of uniform density—its hight, as ascertained from the twilight—mode of finding its hight from the effects of refraction—probably extends to a much higher elevation than is generally supposed. Hight of fire-balls, and other meteors. Universal space may be filled with ethereal fluids.. 1

CHAPTER VI.

The composition of the atmosphere—atmosphere a compound fluid—history of this discovery—component parts of which it consists. Properties of oxygen gas. Properties of nitrous oxyde—its extraordinary effect on the animal spirits, illustrated in a variety of instances—its singular effects on a student in Yale College—its effects on the author, and other individuals—on insects, etc. Reflections on this subject. Properties of nitrogen gas. Carbonic-acid gas—where found—its specific gravity—fatal to all animals that breathe it—*Grotto del Cani*—hints and cautions in reference to avoiding the pernicious effects of this gas. Atmosphere of our globe not to be considered the same as those of other planets—adapted only to mortal men—may be improved, and rendered more salubrious, by the universal cultivation of the soil. Millennial era. Man has it in his power to effectuate important changes, were his moral dispositions renovated. State of the atmosphere before the deluge. Atmospheres of other planets. Reflections.. 20

CHAPTER VII.

The beneficial effects of the atmosphere in the system of nature. Air is essential to the growth of plants. Pressure of the atmosphere preserves water in its liquid state—supports fire and flame—respiration of all animals depends upon it. Various interesting experiments in relation to respiration. Reflections. Respiration in fishes. Atmosphere essential to the process of evaporation. Density of the atmosphere gives buoyancy to the clouds—is the source of winds, which are of essential use in the system of nature. Air is the vehicle of smell, the medium of sounds; and produces all the harmonies of music—the cause of that splendor and universal light around us, and of the morning and evening twilight. Disastrous effects which would follow were the atmosphere swept away. Divine wisdom and beneficence displayed in the arrangements of the atmosphere—its transparency—not capable of being frozen—man has acquired a certain degree of sovereignty over it. Moral reflection in reference to this subject.. 24

CHAPTER VIII.

The wisdom and benevolence of the Creator, as displayed in the constitution of the atmosphere. Wisdom and goodness are manifest in the proportion which subsists between the different gases—in determining the relative specific gravity of these gases—and in the process for supplying the waste of oxygen, and promoting the renovation of the atmosphere. Concluding reflections. Folly of denying the reality of a future and invisible state of existence. Many of the objects of religion lie beyond the range of our corporeal vision, but are not, on that account, to be considered unreal. What ought to be our great object in our study of the sciences, and the investigation of the phenomena of nature?.. 31

PART II.

ATMOSPHERIC PHENOMENA.

CHAPTER I.

AQUEOUS METEORS.

1. Evaporation—Bishop Watson's experiments on this subject—various facts in relation to this process. Quantity of water annually evaporated from our globe. 2. Clouds—their hight, size, etc.—Classes into which they have been arranged, cirrus, stratus, cirro-cumulus, nimbus, etc. Electrical clouds, and the ravages they sometimes produce. 3. Rain—imperfect knowledge of its cause—quantity which falls in different seasons, and in different

regions—prognostics of rain—uses of rain. 4. Snow—how formed—its flakes assume regular figures—representation of some of these figures. Avalanches, and the ravages they produce. Uses of snow. 5. Hail—storms of hail in different countries, and the effects they produce—hail-rods for preventing the formation of hail-showers. 6. Dew—its formation. Hoar-frost. Fogs.. 34

CHAPTER II.

WINDS.

1. Winds in general explained. 2. General or permanent winds. Trade-winds. 3. Periodical winds, or monsoons. 4. Land and sea-breezes. 5. Variable winds. Destruction occasioned by stormy winds. 6. Noxious and poisonous winds—the harmattan—sirocco—samiel—the simoon—hurricanes—tornadoes. Reflections in reference to noxious winds. Velocity of winds. Uses of winds.. 39

CHAPTER III.

LUMINOUS AND FIERY METEORS.

1 The *Aurora Borealis*—its general appearances. Description of several striking auroras. Their appearance in the polar regions. Their supposed cause. 2. *Luminous arches*—their phenomena and elevation. 3. *Fire-balls*—description of their phenomena, size, motion, etc. 4. *Shooting, or falling-stars.* November meteors—their striking appearance in the United States, in 1833—their supposed origin. 5. *Parhelia*, or mock-suns—their general appearance—description of one seen at Rome, illustrated with a figure. 6. *Thunder and lightning*—description of a thunder-storm, with its accompaniments—how to estimate the distance of a thunder-cloud. Different kinds of lightning. Identity of lightning and electricity. Thunder-guard. Maxims to be observed during a thunder-storm. Concluding reflections......................... 42

THE ATMOSPHERE

AND

ATMOSPHERICAL PHENOMENA.

PART I.

THE NATURE, PROPERTIES, AND BENEFICIAL EFFECTS OF THE ATMOSPHERE IN THE SYSTEM OF NATURE, AND THE EVIDENCES WHICH ITS CONSTITUTION AFFORDS OF THE WISDOM AND BENEFICENCE OF THE CREATOR.

INTRODUCTION.

All the works of God, throughout the immensity of the universe, display the character, perfections, and agency of the Supreme Creator, to every rational and Christian mind that surveys them with attention and intelligence. From the magnificent luminaries of heaven to the comparatively small globe on which we dwell, and the smallest microscopic animalcule that glides through its waters, we perceive the impress of omnipotence and skill, which infinitely surpass all the puny labors and inventions of man. These works were evidently intended by their Divine Author to be investigated, contemplated, and admired by all his intelligent offspring, that their conceptions of the Divine character may be expanded, and that they may be led to give unto Him "the glory due unto his name." The enlightened Christian, therefore, ought to devote a portion of his time and attention to the study and contemplation of the works of God, not only as a rational amusement, but as a solemn duty: for, in numerous passages in the sacred records, this duty is expressly inculcated: "Lift up your eyes on high, and behold who hath created these things."—"Stand still, and consider the wondrous works of God"—"The works of the Lord are great, sought out of all them that have pleasure therein"—"Great and marvelous are thy works, Lord God Almighty."

When we look around on the surface of the earth, and behold the beautiful and sublime landscapes which diversify its aspect, the variety of colors with which it is adorned, the myriads of trees, shrubs, and flowers which spring from its surface, and the rich perfumes they shed around them—the numerous animated beings which traverse the air, the ocean, and the earth, and the ample provision which is made for their subsistence and comfort—we can scarcely fail of being impressed with the conviction, that the Creator is a being of unbounded beneficence, that "His tender mercies are over all his works," and that the happiness of his sensitive and intelligent offspring is one great end of all his arrangements. When we consider the curious and exquisite structure of all the vegetable tribes, the numerous vessels with which they are furnished, the thousands of delicate tubes, invisible to the naked eye, through which their sap and juices are continually flowing to the leaves and branches, the millions of pores through which they shed their delicious odors, and the curious contexture and the numerous beauties which the microscope alone can discover in their leaves, prickles, stamens, petals, and flowers:—when we consider the numerous orders of animated beings—the wonderful diversity of structure they exhibit, in their eyes, ears, feet, joints, claws, wings, and movements—their numberless contrivances, which enter into their construction and functions—the thousands of adjustments, adaptations, borings, claspings, and polishings, which enter into the body of an animal a thousand times less than a mite—the adaptation of all these contrivances to the purposes of life, motion, and enjoyment, and their correspondence to the surrounding elements in which such creatures pass their existence:—and, in particular, when we contemplate the structure and functions of our own corporeal frames; the hundreds of bones of different shapes and sizes which support it; the hundreds of muscles of different conformation, which give motion to its different parts; the thousands of glands, secreting humors of various kinds from the blood; the thousands of lacteal and lymphatic tubes, absorbing and conveying nutriment to the circulating fluid; the millions of pores, through which the perspiration is continually flowing; the infinite ramification of nerves, diffusing sensation throughout all the parts of this exquisite machine; and the numerous veins and arteries which convey the whole mass of blood through every part of the body ten times every hour:—when we consider these adaptations and arrangements throughout the vegetable and animal kingdoms, we perceive the marks of a Divine intelligence and skill, which completely throw into the shade the most exquisite contrivances of human genius, and which convince us that the *wisdom* of the Creator is *infinite*, and "his ways past finding out."

In short, when we lift our eyes beyond the boundaries of the globe on which we dwell, and look upward to that boundless firmament where suns unnumbered shine, and planets and comets run their ample rounds—when we behold ten thousand times ten thousand of luminous and opaque globes of vast dimensions scattered in magnificent profusion throughout every region of infinite space; when we contemplate the sun occupying a space which would hold one million three hundred thousand worlds such as ours; and when we contemplate globes fourteen hundred times larger than our world, flying through the voids of space with a velocity of thirty thousand miles an hour, and carrying along with them in their rapid career a retinue of surrounding worlds —we behold the effects of a Power which all the subordinate intelligences in the universe can never control, a power before which the mightiest achievements of human art sink into the same scale with the flutterings of a microscopic animalcule; a power which astonishes and confounds the imagination, which sets at defiance human calculations, but which conveys to the mind a most impressive idea of the grandeur of the Divine Being, and of the magnificence of that universe which his hands have formed!

It is not merely in the scenes of the visible world that the attributes of Deity are conspicuously displayed. Even in the invisible regions of creation, which are impalpable to the organs of human vision, the perfections of the Eternal Mind are no less apparent to the philosophic and Christian inquirer, than in those external scenes of beauty and magnificence which arrest the attention of every spectator. Could we descend to the central regions of our globe, and contemplate the processes which are going on in those unexplored and unexplorable recesses; could we penetate into the depths of the ocean, and survey the multiplicity of objects which lie concealed in its unfathomable caverns; could we ascend on the wings of the wind with the vapors which rise from its surface, and contemplate all the regions and transformations through which they pass, until they again descend in refreshing rains on the mountains and vales; could we wing our flight beyond the denser regions of the atmosphere into those places where fire-balls and shooting stars have their origin, and where the aurora borealis displays its fantastic coruscations; could we ascend to the ethereal spaces which intervene between us and the celestial bodies, and investigate those apparently empty regions which surround the atmospheres of all the planets; or, could we penetrate into the chemical processes and changes which are incessantly going on among the invisible atoms of matter, in the union and disunion of the different gases, in the various modifications of crystallization, in the circulation of the sap and juices in the minutest flowers, and in the internal vessels of microscopic animalcules; we should doubtless behold the operations of a Wisdom and Intelligence no less admirable and astonishing than what is displayed in the visible scenes of nature which are obvious to every eye.

Of those invisible regions of nature now alluded to, the ATMOSPHERE is one in which we are particularly interested, and which exhibits a striking scene of Divine wisdom and beneficence.

The term atmosphere may be defined to be "that body of air, vapors, electric fluid, and other substances which surround the earth to a certain hight." This mass of fluid matter gravitates toward the earth, presses upon its surface with a certain force, revolves with it in its diurnal rotation, and is carried along with it in its course round the sun, at the rate of sixty-eight thousand miles an hour. This fluid mass is invisible to the corporeal organs; and hence, the great body of mankind are apt to imagine that the regions around us, in which the birds fly, and the clouds move, are nothing else than empty space; and, were it not that they sometimes hear its sound in the breeze, and feel its effects in the whirlwind and the storm, they would be disposed to deny that such a thing as the atmosphere had an existence. There is, however, no appendage to our globe which is so essentially requisite to the comfort, and even to the very existence of animated beings; for, were the earth and the ocean, the springs and the rivers, to remain as they now are, but were the hand of Omnipotence to detach from our globe the atmosphere with which it is now environed, it is absolutely certain that, in a few minutes, and after a few sighs and groans, all the eight hundred millions of men that now people the earth, and all the other animated beings that traverse the air, the waters, and the land, would sink into the slumbers of death, and disappear forever from the living world.

In elucidating this subject, the observations that will be made may be arranged under the following heads:—

I. To prove that air exists, and that it is a material substance.
II. To consider its weight or gravity, and the force with which it presses on all bodies on the surface of the earth.
III. To exhibit several facts which the pressure of the atmosphere tends to illustrate.
IV. To illustrate the elasticity of the air, and the effects it produces.
V. To offer some considerations for illustrating the hight of the atmosphere, or its elevation above the surface of the earth.
VI. To illustrate its composition; or, the chemical principles of which common atmospherical air is composed.
VII. To illustrate its beneficial effects in the system of nature.
VIII. To exhibit the evidences which its constitution affords of the wisdom and benevolence of the Creator.

CHAPTER I.

AIR IS A MATERIAL SUBSTANCE.

The first inquiry, then, is, What is that air, of the importance of which we hear so much asserted? We *see* nothing, it may be said—we *feel* nothing. We feel ourselves at liberty to move about without any let or hindrance. Whence, then, the assertion that we are surrounded by a substance called air? A few facts and illustrations only will be sufficient to elucidate this position.

1. If we take a rod, and make it pass rapidly through what appears empty space, we shall hear a sound and feel a slight resistance, as if something had intervened to prevent the motion of the rod.

2. If we take a large fan, or an umbrella, when fully stretched, and push it forcibly from us, we shall feel a very considerable resistance, and a person opposite will feel a certain impression made upon his face, as if some substance had come in contact with it. Were we to take a very large umbrella—say from twelve to fifteen feet diameter—and stand on the top of a high stair, or a building, twenty or thirty feet high, we might jump from such a position, while we hold it fully stretched, and gradually descend to the ground without violence or injury. It is on this principle that the instrument called a parachute is constructed, by means of which an aëronaut, while pursuing his aërial excursions, has left his balloon, when elevated nearly a mile above the surface of the earth, and descended in a few minutes to the ground, without shock or accident. Perhaps some contrivance of this kind might be useful to prevent accidents in the case of fires in large towns—when persons have attempted to jump from the windows of a third story to preserve themselves from being involved and destroyed in the burning mass. The circumstances now stated prove, that there is a certain material substance, though invisible, around us, which offers a sensible resistance to any body having a large surface when it is pushed rapidly through it.

3. That air is a material substance, appears from its excluding all other bodies from the place it occupies. Thus, if we take a glass jar, and plunge it with its mouth downward into a vessel of water, only a very small quantity of water will get into the jar, because the air, of which the jar is full, keeps the water out; otherwise, if it were empty of every material substance, the water would rush in and completely fill the jar. Hence, we may learn why a vessel cannot be filled with water by plunging its orifice downward, and why a funnel, if its pipe fit closely to the neck of a bottle, is not convenient for pouring off liquors; for, in order to put water or wine into a bottle, the air must pass between the neck of the bottle and the funnel, to let the air out as the water rushes in. And hence, the practice in such cases, suggested by necessity, of pulling up the funnel a little when the liquor stops, in order to let the air rush out between the pipe and the neck of the bottle. It is on the principle now stated, that the diving-bell is constructed, by which a person may descend to a considerable depth into the sea, and yet not be immersed in water, nor deprived of air for breathing.

4. If we take a smooth cylindrical tube shut at one end, and fit a plug or cork exactly to its open end, so as to slide along it, if the plug be so tight and soaked with grease, as to prevent all passage of any fluid by its sides, we shall find that no force whatever can push it to the bottom of the tube. There is, therefore, something within the tube, though invisible, which prevents the entry of the plug, and, therefore, possessing the characteristic of matter, and this something is air.

5. Let us take a pair of common bellows, and, after having opened them, if we shut up the nozzle and valve-hole, and try to bring the boards together, we shall find it impossible. There is something included that prevents this, in the same manner as if the bellows were filled with flax or wool; but, on opening the nozzle, we can easily shut them by expelling this something that is within, which will issue with considerable force, and impel anything that lies in its way. This something can be nothing else than the air of the atmosphere.

6. The air, though for the most part invisible, may, in certain cases, be rendered an object of sight. If we take a telescope of high magnifying power, and, in the forenoon of a hot summer day, when the sun is shining, look through it to distant objects, we shall perceive the air undulating about the objects somewhat like the waves of the sea, and rendering them undefined and obscure. This is the principal reason why very high magnifying powers cannot be used, with effect, on telescopes for land objects, in the day-time, when the sun produces undulations in the atmosphere; and the same cause frequently prevents distinct vision of celestial objects.

The above are clear proofs that the air, though not generally an object of sight, is, in reality, a material substance, as much so as water, wood, stones, or iron. This substance, in a state of rest, we call air; in a state of motion, we call it wind; and, in this state, its force is sometimes so great as to drive our wind-mills, impel our ships across the ocean, and even to overturn buildings, to tear up from their roots the largest trees, and to dash whole fleets to pieces of wreck.

CHAPTER II.

THE WEIGHT OF THE ATMOSPHERE, AND THE QUANTITY OF MATTER IT CONTAINS.

As AIR is demonstrated to be a body, like all other material substances, it must have weight, and the proportion its weight bears to other known substances is determined by experiment. If a bottle which contains about a quart be emptied of its air by means of an air-pump, or in any other way, and then accurately weighed in a nice balance, it will be found to be about sixteen grains lighter than it was before it was emptied of its air; which shows that a quart of air weighs sixteen grains. A quart of water weighs about 14,620 grains, or nearly two pounds. If this last number be divided by sixteen, the quotient will be nine hundred and thirteen, which shows that air is nine hundred and thirteen times lighter than water; or, in other words, that it would require above nine hundred quart-bottles of air to weigh one quart-bottle of water. Other experiments which have been made to determine this point, lead to the result that for every cubic foot of air, five hundred and twenty-three grains, or, one and one-fifth ounce avoirdupois, are to be allowed; and, since a cubic foot of water weighs 1,000 ounces, the one divided by the other gives a result of eight hundred and thirty-three, the number of times that water is heavier than air. It is impossible to arrive at very great nicety in such estimates; but the general results of all the experiments which have been made on this point, lead to the conclusion that air is somewhere between eight hundred and nine hundred times lighter than water. These results, however, must be understood solely to apply to the air near the surface of the earth; for, as we ascend into the higher regions of the atmosphere, the air becomes gradually thinner and lighter, being less pressed with the air that is above.

We may now attend to the pressure which the atmosphere exerts upon the surface of the earth, and upon all bodies connected with it.

It has been proved by a variety of accurate experiments, that the atmosphere presses on every part of the earth's surface with a force, at an average, equal to about fifteen pounds on every square inch. This has been ascertained by what is called the Torricellian experiment. Take a glass tube about three feet long, open at one end, and hermetically sealed at the other: fill it with quicksilver, putting the finger upon the open end, turn that end downward, and immerse it in a small vessel of quicksilver, without admitting any air, then take away the finger, and the quicksilver will remain suspended in the tube about twenty-nine and a half inches above its surface in the vessel, sometimes more and sometimes less, according to the state of the atmosphere. It is evident, then, that the quicksilver is kept up in the tube to this elevation by the pressure of the atmosphere upon the surface of the mercury in the basin; for, if the basin and tube are put under a glass, and the air extracted, all the quicksilver in the tube will fall down into the basin; and, if the air be readmitted, it will rise to the same hight as before; or, if an opening be made in the top of the tube and the air admitted, the quicksilver will sink into the basin. The pressure, therefore, by the atmosphere on the earth, is the same as if a coating of quicksilver twenty-nine and a half inches thick were spread over every part of the earth's surface.

Now, it is proved that a square column of quicksilver twenty-nine and a half inches in hight, and one inch thick, weighs just fifteen pounds, which counterpoises a column of air of the same thickness, extending to the top of the atmosphere; and, consequently, that air presses with this force upon every square inch of the earth's surface; and, of course, 2160 pounds on every square foot, and 19,440 on every square yard. The experiment now described is, in fact, nothing else than the common barometer. The tube of the barometer is filled with quicksilver, or mercury; it then stands in a basin of quicksilver, is connected with a ball containing quicksilver, on the surface of which the atmosphere presses, and, in most cases, stands at an elevation of about twenty-nine and a half inches, but subject to certain variations, according to the state of the atmosphere. When the weather is steady and serene, it rises to above thirty inches; when it is stormy and rainy, it frequently sinks to twenty-eight inches, or under, thus indicating the changes that take place in the weight of the air; and hence it has obtained the name of the weather-glass.

Were the same experiment made with water, instead of mercury, a tube must be provided of about thirty-six feet long; and then it would be found, that the water in the tube would be supported by the atmospheric pressure to the hight of thirty-two or thirty-three feet. This costly experiment, which has been seldom repeated, was first performed by the celebrated Pascal, at Rouen, in Normandy, in 1647. He exhibited the experiment both with water and with wine, in order to show the different hights to which these fluids would rise, according to their respective densities. He procured, at a glass-house, tubes of crystal glass forty feet long, which were fixed to the mast of a ship, that was contrived to be raised or depressed, as occasion required. He appointed a day for performing this experiment, and invited all the philosophers and others who doubted of the pressure of the atmosphere to attend, and to be witnesses of the wonderful nature of his experiment. The result was, according to the calculations he had previously made, that the altitude of water in the tube was thirty-one and one-ninth Paris feet, equal to thirty-two feet two and a half inches English; and the altitude of the wine was somewhat greater, namely, thirty-one and two-thirds Paris feet, or thirty-two feet ten inches English; the wine, on account of its superior levity, rising about seven and a half inches higher than the water. He performed this experiment to convince the Aristotelian philosophers of those times of the folly of a notion which then prevailed, that the rise of the mercury in the Torricellian experiment and the rise of water in pumps were produced, not by the pressure of the atmosphere, but by an occult quality, which they denominated "Nature's abhorrence of a vacuum." They asserted that, in the upper part of the tube, deserted by the quicksilver, there were contained some *spirits*, evaporated from the quicksilver; which, being rarefied, filled up that space, thus assisting Nature, in a great emergency, against her mortal enemy, a vacuum. "Well, then, gentlemen," says Pascal, "take your own way. Here are two tubes, the one I am to fill with water, and the other with wine. You will all readily admit that there is a greater quantity of spirits in wine than in water: and, consequently, that if the empty space between the upper surface of the fluids and the top of the tube be filled with spirits, there will be a greater quantity of spirits, in the upper part of the tube containing the wine than in the tube containing the water; and, of course, the wine will not rise so high as the water." To this they all readily assented. But, when the experiment was made, the wine was found to rise nearly eight inches higher than the water, as Pascal had previously calculated and predicted. This experiment was decisive; and, since that period, the figment of "Nature's abhorrence of a vacuum," along with many other absurdities, has been consigned to the slumber of the dark ages whence it originated.

A few years before the period now alluded to, the engineers of the Grand-duke of Florence, having received orders to raise a portion of water to the hight of fifty or sixty feet, by means of a common pump, perceived, when they had made the attempt, that the pump refused its assistance when the water was to be raised above thirty-two feet. They communicated the circumstance to Galileo, an eminent philosopher of that age, and asked him the reason of it. Galileo was not a little surprised, and was unprovided with an answer. He, however, put a good face on the affair, and gravely replied, that "Nature abhorred a vacuum only to the hight of thirty-two feet." Torricelli, the disciple of Galileo, vexed at the water's refusing to ascend more than thirty-two feet in a tube void of air, made a new experiment with quicksilver, in the manner already described. He saw the quicksilver in the tube fall down, and leave an empty space at top, and remain suspended at the hight of twenty-nine inches.—"How," says he, "Nature abhors a vacuum only to the hight of thirty-two feet when it is water that ascends in a tube void of air, and only to twenty-nine inches when it is mercury! Vacuum does not frighten her beyond these measures! But why does she fear it to far more than twenty-nine inches when it is water that rises? Very likely this horror at vacuity is an idle fancy, a mere philosophical cant, which we take for good coin without understanding it." Reasoning in this way, and repeating a variety of similar experiments, he was, at length, led to the conclusion "that the diversity of the elevation of the two different fluids proceeded from the diversity of their weight, and that they were supported and counterpoised by a column of air, of the same diameter, reaching the top of the atmosphere." Here the matter rests, and will rest throughout all succeeding generations.

This short sketch of the history of the experiments which relate to the pressure of the atmosphere will not be altogether out of place, if it has a tendency to guard us against the influence of preconceived notions, foolish prejudices, and of the authority of great names, which are some of the greatest obstructions to the expansion of the human mind, and the reception of useful knowledge. It was not before men began to emancipate themselves from such shackles that science commenced that brilliant career which has issued, in our times, in so many interesting and important discoveries. Similar prejudices are still prevalent in relation to the affairs of common life, the facts of science, and the important truths of religion. We are only yet beginning to cast off the yoke of that ignorance, under the guise of wisdom, under which the men of other times bowed with such abject submission. Religious prejudices, in particular, derived from education and submission to mere authority, are frequently so strong that no species of reasoning, however convincing to an unbiased mind, is sufficient to subdue them. When certain dogmas or opinions, however futile, have got a firm hold on the mental faculties, all the arguments that can be derived from reason and philosophy, and even from the most cogent announcements of Divine revelation, are found altogether insufficient to displace them. And, as the fostering of erroneous opinions, in relation to religion, may endanger our best interests, both in relation to the life that now is and the life to come, it is of the utmost importance to all, and especially to young persons, that they examine, with care and without prejudice, every doctrine and opinion they embrace, without regard to human authority; founding all their views and sentiments on the dictates of enlightened reason, and the plain declarations of the word of God.

From what has been now stated, we may easily compute the weight sustained by the body of a middle-sized man, in consequence of the pressure of the atmosphere. Suppose the average stature of the human body to be about five feet nine inches; suppose the breadth in front to be about one foot, and the breadth on each side half a foot; by allowing a little deduction for the narrowness of the head and feet, we may reckon about five feet in front, and five for the back part, and two and a half square feet for each side of the body, or fifteen square feet in all. It has already been stated that the atmospheric pressure on one square foot is 2160 pounds. Multiply this sum by fifteen, the number of square feet on the surface of the human body, and the product will be 32,400 pounds, or somewhat more than fourteen tons, or the weight of more than fourteen ordinary cart-loads of heavy goods. This is the pressure sustained by every middle-sized man—a pressure which would be insupportable, and even crush us to pieces, were it not that it is equal in every part; pressing with the same force upward, downward, and on every side; and is at the same time, counterbalanced by the spring of the air within us, which is diffused through the whole body, and reacts with an equal force against the outward pressure. This pressure, however, is somewhat different at different times. When the air is lightest, the pressure is 31,150 pounds, and, when heaviest, about 33,660 pounds, making a difference of about 2500 pounds, the weight with which we are compressed more at one time than at another. This great difference in the atmospheric pressure is found greatly to affect the animal functions and the state of health. A person laboring under an asthmatical complaint will find his disorder increased when the air is light, as it has then less elasticity, and is not so capable of expanding the lungs. The air is generally the lighest in hazy and rainy weather, when the clouds descend, and the mists cover the mountain tops. Every one then feels the effect, by a certain degree of lassitude and depression of spirits, occasioned by the surrounding gloom, and by being deprived of an atmospheric pressure amounting to more than 2000 pounds. The fibers of the body are relaxed, the contractile force of the muscles diminished, and a languid circulation of the fluids ensues, which sometimes produce obstructions, fevers, and headaches; and, in most persons, a sort of indolence and gloomy inactivity. Whereas, when the air is heavy, and the clouds ascend to the higher regions, and appear like fine fleeces on the blue vault of heaven, the nerves and fibers of the animal system are braced by the additional pressure of the atmosphere, the blood-vessels exert their full power, the solids are compressed, the fluids circulate with increased vigor, we feel light and alert, and the elevation of the animal spirits is increased by the splendor and activity of the surrounding scene.

Weight of the whole Atmosphere.—From the facts now stated, we may form an estimate of the weight of the whole body of the atmosphere which surrounds the surface of the earth. The surface of the globe contains, in round numbers, 200,000,000 of square miles; every square mile contains 27,878,400 square feet; and these two numbers multiplied together, produce 5,575,680,000,000,000; or, five thousand five hundred and seventy-five billions, six hundred and eighty thousand millions, equal to the number of square feet on the surface of the earth; which multiplied by 2160 pounds (equal to the pressure on every square foot), produces the sum of 12,043,468,800,000,000,000; that is twelve trillions, forty-three thousand four hundred and sixty-eight billions, and eight hundred thousand millions; which is equal to the number of pounds which constitute the weight of the whole atmosphere, or 5,000,000,000,000,000; that is, about five thousand billions of tons. A more definite idea of this weight may be obtained by supposing a ball of lead, extending from London to Oxford, stretching sixty miles perpendicularly above us, and in every direction; or, in other words, a ball of lead one hundred and ninety miles in circumference, and about sixty miles in diameter. Suppose this ball placed on one end of an immense balance, and the whole atmosphere on the other, they would nearly counterpoise each other. So that this invisible fluid, which we are apt to consider as almost a nonentity, when considered as a whole, contains a weight which it is difficult for numbers to express.

It need only be observed further on this point, that the air decreases in density in proportion as we ascend to the higher regions of the atmosphere. At the hight of seven miles, the air is four times rarer than at the surface of the earth; at the hight of fourteen miles, it is sixteen times rarer; at the hight of twenty-eight miles, it is two hundred and fifty-six times rarer; at the hight of ninety-six miles, it is 268,435,456 times rarer; and at the hight of five hundred miles, it has been computed, that a cubic inch of such air as we breathe at the surface of the earth, would be so much rarefied, that it would fill a hollow sphere equal in diameter to the orbit of the planet Saturn, which is 1,800,000,000 of miles in diameter. This is a necessary consequence of the elasticity of the air, and of its want of compression in the higher regions; and that this is in reality the case, is proved by experiment as well as by calculation. When we take a barometer to the top of a mountain only half a mile in perpendicular elevation, the mercury falls from thirty to twenty-seven inches; and the fall of the mercury is in proportion the higher we ascend. Those travelers who have climbed to the tops of lofty mountains know, by experience, that the air is much thinner in those regions than in the plains below. Their breathing becomes difficult and painful, their hands and feet swell, and they are sometimes seized with a vomiting of blood. They also find, that the atmosphere becomes clearer as they ascend, and is unable to support the clouds. We are informed by Don Ulloa that, while he stood on the top of the Andes, in Peru, "the clouds, which were gathered below the mountain's brow, appeared like a tempestuous ocean, all dashing and foaming, while the lightnings were breaking through the waves, and the thunders rolling beneath his feet, far below the spot on which he stood. In the meantime he enjoyed a serene and cloudless sky, and left the war of the elements to the unphilosophical mortals on the plains below."

Those who have taken a flight to the higher regions of the atmosphere in balloons, have beheld scenes of a similar kind. Mr. Baldwin, who ascended in a balloon from Chester, in 1785, relates that at a certain elevation, the earth was entirely hid from his view by an immense mass of vapors, which he compares to a sea of cotton, tufted here and there by the action of the air, and, soon after, the whole became an extended pavement of white cloud. The reason of all this is obvious: the clouds are vapor, or water rarefied by heat. Vapor is lighter than air near the surface of the earth, and, consequently, ascends in it; but, in the higher regions, the air is thinner and lighter than these vapors, and, of course, is unable to support them beyond a limited hight; which circumstance undeniably proves that the air is lighter the higher we ascend.

The pressure of the atmosphere may now be illustrated by a few simple experiments. The instrument called the air-pump affords, on the whole, the best means of illustrating the pressure of the atmosphere. This instrument bears a certain resemblance, in its principle and action, to the common house pump. It consists of a hollow cylinder or tube, in which a piston is alternately raised and depressed by means of an iron rod attached to the handle of the pump. In the piston there is a valve, which opens by any pressure from below, and is shut by any superincumbent pressure, like the flapper of a pair of bellows. When the piston is forced down, the valve is opened from below by the pressure of air, or whatever fluid the pump may contain. The fluid then gets above the valve, and is lifted up by the raising of the piston, and carried out of the pump, the valve being then shut by the pressure of the air above it. At the top, is a metal plate ground to a perfect plane surface, on which is placed an inverted glass jar or receiver, whence the air is to be extracted. A hole in the plate is connected with a tube which communicates with the pump-barrels. By working the handle of the instrument for some time, the receiver will soon be nearly exhausted of all the air it contains, and the effects produced in a vacuum, or place void of air, may then be exhibited. The following, among other experiments, may be shown by the air-pump. If the receiver be open at both ends, and the upper orifice be stopped by the hand, when the air is exhausted, the pressure of the external air will be such as to prevent the removal of the hand, and will cause a certain degree of pain. If a piece of bladder be tied tightly over the orifice, as the exhaustion proceeds, the bladder will be pressed inwards, and will finally burst with a loud noise. In the same manner, if a flat piece of window-glass be placed upon the orifice, when the air is exhausted, the glass will be broken into a number of pieces by the external pressure of the atmosphere.

But as comparatively few persons have an opportunity of performing experiments with the air-pump, a few simple experiments equally convincing, which every person has it in his power to perform, may here be described.

1. Take a wine or an ale-glass, and fill it with water; take a smooth piece of writing paper, and press it firmly against the edges of the glass, so that no air get in between the paper and the water, then turn the glass upside down, and the water will be supported by the pressure of the atmosphere upon the paper. That it is the external pressure of the atmosphere upon the paper which supports the water will appear, when we consider that the paper, instead of being convex, by the pressure of the water downward, is concave, by the pressure of the air upward. If a lighted candle be placed under the paper, with its flame touching the paper, we may hold it for an indefinite length of time, without its producing any effect upon the paper, or setting fire to it.

2. Take a wine-glass, and burn a piece of paper in it, and while the paper is burning, if we place the palm of our hand firmly upon the edges of the glass, the glass will stick fast to the hand, producing a certain degree of pain, and it will require a considerable degree of force before the hand can be detached from the glass. In this experiment, the burning of the paper rarefies the air, nearly expels it from the glass, and then the atmosphere presses with its whole weight upon the hand.

3. Take a glass tube two or three feet long, of a narrow bore; plunge one end of it in a basin of water; apply the mouth to the other end, and draw out the air by suction; the water will instantly rise into the tube by the pressure of the atmosphere on the water in the basin; and, if we immediately place our thumb firmly on the upper part of the tube, and withdraw it from the water in the basin, the water will be suspended in the tube by the pressure of the atmosphere, although the tube is open below; but, when the thumb is removed from the upper part of the tube, the water in it will run out, in consequence of the pressure of the atmosphere from above.

4. Take a tin vessel, six or eight inches long, and about three in diameter, with its mouth about a quarter of an inch wide, as E F (fig. 1). Pierce a number of small holes in its bottom, about the diameter of a common sewing-needle. Plunge this vessel in water, and, when full, cork it up, so that no air can enter at the top. While it remains corked, no water will run out, being prevented by the atmospheric pressure upon the bottom of the vessel; but the moment it is uncorked, the water will issue from the small holes by the pressure of the air from above. The same experiment may be made with a tin-plate tube, about an inch in diameter, open at the top, and having its bottom pierced with a small hole. When filled with water and tightly corked at the top, it may be carried for miles without losing a drop of water, notwithstanding the hole in the bottom.

Fig. 1.

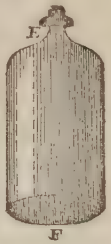


Fig. 2.

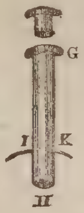


5. In order to show the lateral pressure of the atmosphere, take a tube, as G H (fig. 2), six or seven inches long, having a small hole on each side, as I K. When filled with water, and tightly corked, no water will run out from the sides of the tube, but the moment the cork is taken out, the water will run out at I and K, as represented in the figure.

6. Take a wine-glass and burn in it a piece of paper; then invert the glass, while the paper is burning, over a saucer full of water, the water will rush up into the wine-glass, in consequence of the air being rarefied or driven out by the burning paper, and in consequence of the pressure of the atmosphere upon the surface of the water in the saucer.

These experiments show that the atmosphere presses in all directions, upward, downward, and laterally. This subject has been dwelt on somewhat particularly, because the atmospheric pressure forms an important element, and a mechanical power in the construction of steam-engines, atmospheric railways, and other modern inventions, which are now of such great utility in propelling carriages along railways, and steam-vessels across seas and oceans.

CHAPTER III.

FACTS ILLUSTRATED BY THE PRESSURE OF THE ATMOSPHERE

Let us now attend to a few facts which the pressure of the air tends to explain and illustrate.

1. The atmospheric pressure explains the nature of the process vulgarly termed suction. When we attempt to take a draught of water out of a basin, or a running stream, it is commonly said that we draw in the water by suction; whereas the fact is, that instead of drawing the water into the stomach, we only draw the air into the lungs, and the atmosphere performs the other part of the operation. The process is simply this:—We immerse our lips into the water, so as to prevent the entrance of air into the mouth; we then make a vacuum in the mouth by drawing the air into the lungs, after which the pressure of the atmosphere upon the surface of the water forces it upward into the mouth. That such is the process of receiving a draught of water when the mouth is held downward, appears from this circumstance, that if the lips do not *touch* the water, we might draw in the air by what is called suction for twenty years, and not receive a single drop into the mouth.

The same principle explains the action of a child sucking the breast of its nurse. The operation of cupping is performed in the same way. In this case the operator takes a small glass, close at the top, and holding it for some time over the flame of a candle or lamp, the air is thereby rarefied, and part of it drawn out. The glass is then suddenly placed on the part of the body to be cupped, and adheres to the flesh by the external pressure of the air. The flesh rises in the glass, and the blood and serosities are forced from the wounded vessels into the glass by the atmospheric pressure on the parts around.

2. It is owing to the atmospheric pressure that two polished surfaces, which accurately fit each other, adhere with great force. This fact is well known to glass-grinders and polishers of marble. A large lens, when ground very smooth, requires more than the strength of a single individual to pull it directly from the tool. If the surface is only a square inch, it will require fifteen pounds to separate them perpendicularly, though a very moderate force will make them slip along each other. Were the surface six inches square, the force requisite to separate the two pieces would be equal to five hundred and forty pounds. But this cohesion is not observed, unless the surfaces are wetted or smeared with oil or grease, otherwise the air gets between them, and they separate without any trouble. That this cohesion is owing to the atmospheric pressure, is evident from the ease with which the plates may be separated in an exhausted receiver by means of the air-pump. The same cause contributes in a powerful degree to give effect to the cohesion of bodies by means of mortar and cements. When two pieces of wood are to be glued together, their surfaces are first made as smooth as possible; a glutinous substance is then applied to fill up all the pores and inequalities; they are then pressed together, which prevents the air from insinuating itself between them, and the external air then presses upon them with a force of fifteen pounds on every square inch. There can be no question that the stability of our houses and garden walls depends, at least in a great measure, upon the same principles; for the more completely every crevice between the bricks or stones is shut up, by means of mortars and cements, from the insinuation of the external air, the more firm and stable is the building.

To the same cause is to be attributed the action of a boy's sucker in lifting large stones from the ground. The sucker is made of stiff wetted leather fastened to a string; the moisture upon the leather, when it is pressed down upon the stone, prevents the air from getting in between the leather and the stone, and if the sucker be four inches square, it will require a force of two hundred and forty pounds to separate it from the stone. In certain cases, such contrivances, on a large scale, might be sometimes useful as a mechanical power.

3. Another circumstance which is accounted for on this principle is, the strong adhesion of snails, periwinkles, limpets, and other molluscous animals, to the rocks on which they are found. The animal forms the rim of its shell so as to fit the shape of the rock on which it intends to cling. It then fills its shell either with its own body or with water. In this condition, it is evident, that we must act with a force equal to fifteen pounds on a square inch before we can detach it from the rock. This may be illustrated by filling a drinking-glass to the brim with water, and, having covered it with a piece of thin wet leather, place it upon a table, and it will be found to require a very considerable force to pull it straight upward. But, if we place a snail adhering to a stone in an exhausted receiver, it will drop off by its own weight. It is owing to the same cause that bivalve mollusca, such as *oysters* and *mussels*, keep their shells so firmly shut, and require such a degree of force to open them. But, if we grind off a bit of the convex shell, so as to make a small hole in it, the air gets in, and it opens with the greatest ease. The same thing takes place when it is put under the exhausted receiver of an air-pump. It has been lately discovered that it is owing to the same principle that flies and other animals have the power of walking on a perpendicular pane of glass, or on the ceiling of a room, with their backs downward. This has been proved to arise from a power they possess of squeezing out the air between the inside of their feet and the surface on which they tread, and thus being supported against the outside of their feet by the pressure of the atmosphere.

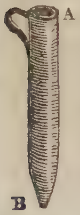
4. It is owing, in a great measure, to the pressure of the atmosphere, that frosts occasion a scantiness of water in our fountains and wells. This is not caused, as is generally supposed, by the freezing of the water in the bowels of the earth. The most intense frost of a Siberian win-

ter would not freeze the ground two feet deep, but a moderate frost will consolidate the whole surface of a country, and make it impervious to the air, especially if the frost has been preceded by rain, which has soaked the surface. When this happens, the water which was filtering through the ground is all arrested, and kept suspended in its capillary tubes by the pressure of the air, in the same manner as water is suspended in a tube which is closed at one end, as in the third experiment stated in the preceding chapter (p. 13). A thaw melts the superficial ice, and allows the water to run out in the same manner as it does when the thumb, in that experiment, is removed from the top of the tube.

5. It is well known that a cask full of water, or spirits, will not run by the cock, unless a hole be opened in the top, or some other part of the cask. The reason is, that the air presses upon the opening in the cock, and prevents the liquor from flowing; whereas, when an opening is made at the top, the pressure of the air from above forces it down. If, indeed, the hole in the cask is of large dimensions, it will run without any other hole, because air will get in at the upper side of the hole, while the liquor runs out by the lower part of it. For the same reason, a small hole is made in the lid of a tea-pot to insure its pouring out the tea, otherwise, when the tea-pot is quite full, it would be difficult to make the tea run out at the spout, the pressure of the air from below tending to prevent it.

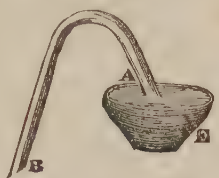
On the same principle depends the performance of an instrument used by spirit dealers, for taking out a sample of their spirits. It consists of a long tin-plate tube, A B, fig. 3, open at the top at A, and ending in a small hole at B. The end B is dipped into the spirits, which rise into the tube; then the thumb is clapped on the mouth A, and the whole is lifted out of the cask. The spirit remains in it until the thumb be taken off; it is then allowed to run into a glass for examination. We are informed by certain travelers, that some of the rude tribes of Asia and Africa, with whom they have traveled, have a similar method of acquiring a draught of water, though they do not understand the principle on which it depends. They provide themselves, in their journeys, with a long hollow cane, and, when they wish to drink, or to give their companions a draught of water from a stream or pool, they place the hollow cane in the water, and apply their mouth to the upper end, and draw out the air, when the water rushes in and fills the interior of the cane; they then apply their thumb to the upper end, take the cane out of the water, and apply it to the lips of their thirsty companion, when the water rushes into his mouth. This mode of taking a draught of water may, in some cases, be very convenient when we cannot easily apply our lips to the surface of a running stream.

Fig. 3.



The action of the syphon depends on the same principle. A syphon is a bent tube, the one end of which is longer than the other, as A B, fig. 4. If the tube be filled with water, and the shorter leg be placed in a vessel of water, E, immediately upon withdrawing the finger from the longer leg, the water will flow out until the liquid in the vessel is emptied. By means of this instrument, we can convey water from a cistern over a rising ground, provided its perpendicular elevation above the level of the fountain does not exceed thirty-two feet, and that the leg, from which the water runs off, is *below* the level of the cistern; because the weight of a column of water, about thirty-two or thirty-three feet high, is equal to the weight of a column of air reaching from the surface of the earth to the top of the atmosphere. The pressure of the atmosphere upon the water of the vessel, or cistern, produces this effect.

Fig. 4.



It might be shown, that the common pump for raising water, the fire-engine, the steam-engine, the forcing-pump, and many other pneumatic and hydraulic engines, derive their power and utility chiefly from that extensive and universal agent—the pressure of the atmosphere; without the assistance of which many of our most powerful engines would be arrested in their operations, and sink into feebleness and insignificancy. But this chapter shall be concluded by a few general remarks, suggested by this subject.

The discovery of the pressure of the atmosphere, and of its agency in the system of nature, formed a new era in the history of science. However common it is now to perform the Torricellian experiment, and to talk about the pressure of the atmosphere, it was a subject which, less than two centuries ago, struck with astonishment all the learned throughout Europe. So wonderful and incredible did it at first appear, that it was not until after the lapse of several years—until after opinions which had prevailed for ages had been overturned, and the most decisive experiments had been performed, in every possible way, that it was cordially received. And, indeed, when we consider the effects of this powerful agent, in the numerous operations both of nature and art, there is something which tends to excite our admiration more than all the fairy tales which the human fancy has created. We behold its operation in compressing the bodies of all animated beings—in counterpoising the internal pressure of the circulating fluids, and preventing the elastic force of the internal air from bursting the arteries and veins. We behold its operation in forcing-pumps and fire engines—in raising water from deep pits, and carrying it to the tops of the highest buildings—in giving motion to our spinning-machines, and in propelling large vessels along seas and rivers—in the action of Hiero's fountain, of syphons, and barometers; and in many other cases where its agency could scarcely have been suspected. What can be more unlike than the working of a fire-engine, when spouting a column of water to the top of a building in flames, and the crawling of a fly upon a window-pane, or the ceiling of a room? Yet both these operations are performed by the same means, the pressure of the atmosphere.

But what appears no less striking than such operations, is, the pressure of the atmosphere upon our own bodies. It has already been stated, that this pressure amounts to above thirty thousand pounds. Were the half of this weight to fall on one side of our bodies, without being counteracted by any other power, it would produce an effect similar to that of a heavy wall, or the roof of a house falling flat upon us, and would infallibly drive the breath from our lungs, and crush to pieces every bone. What is it, then, which prevents such a terrible effect? A small quantity of air within us, which would not weigh above a single ounce, by its strong elastic force, counterpoises the effects of this tremendous pressure; so that, instead of lying as a mountain on our loins, it acts like wings to our feet, or like sinews to our limbs. When a flat bottle is empty, and laid on its side, we might imagine that the weight of the air would break it to pieces; but the air which is contained within the bottle, whether stopped or not, has the same power, by its elasticity, to prevent its breaking, as the air without has to crush it to atoms. But, if we apply a syringe to the neck of such a flat bottle, and exhaust the air which is enclosed within, the extraction of that small body of air, which, by its elastic spring, supported the sides of it, gives room to the external air to act on the surface of the bottle with all its force, and the bottle will fly into a thousand pieces. Such would be the case with respect to our own bodies, if an exact balance were not kept up between the pressure of the atmosphere without, and the elastic force of the air within; and, in this instance, as well as in a thousand other instances, we have a striking evidence of the wisdom and of the benevolence of Him who at first created and arranged all the powers and elements of nature, so as to render them subservient to the preservation and comfort of every species of animated existence.

It is owing to the same admirable arrangement of the Creator, that our dwellings are not crushed to atoms. Suppose an apartment only twelve feet square, and nine feet high, the pressure of the air upon the four sides, and the roof, containing five hundred and seventy-six square feet, is equal to one million, two hundred and forty-four thousand, one hundred and sixty pounds! This enormous pressure is balanced by the resistance of the small quantity of the air in the room, which weighs only ninety-seven pounds; so that here is a small weight of ninety-seven pounds counteracting a pressure of 1,244,160 pounds! Without this wonderful balance no house could be habitable, no creature could remain alive; our glass-windows would be shattered to atoms; an army-tent, a peasant's house, or a shepherd's hut, yea, even our most stately edifices, would be crushed to atoms.

It appears, then, that we are immersed in an invisible fluid, which, on the one hand, by its enormous pressure, threatens to crush us to the earth, and, on the other, by its elastic force, to burst our blood-vessels, and tear our whole frame to pieces. The equality or equipoise of these two formidable and death-menacing powers, is our only safeguard and defense; and shows us how "fearfully and wonderfully" we are every moment preserved by that Almighty Being, "in whose hand our breath is, and whose are all our ways." Here we have a striking evidence of its benevolence and skill, in having, by his wisdom, reconciled and balanced two such formidable and contending powers, and so tempered them, that the impetuosity of the one is checked by the activity of the other; and all nature, instead of being shattered and destroyed, is preserved in safe and harmonious order. Were it his design to destroy the inhabitants of our world, or to render them miserable, we see how easily this could be effected. He has only to permit one of those powers now described to act without control, and the work of destruction is at once accomplished. So that in his "hand is the soul of every living thing, and the breath of all mankind." He upholdeth our souls in life, and his merciful visitation sustains our spirits. It is the province of true philosophy to trace the attributes of the Almighty, in every part of his operations, in the system of nature; and there is no scene throughout the universe, where his voice is not heard, and where his power and wisdom are not conspicuously displayed to those who have ears to hear, and eyes to see, and spiritual discernment to recognize the footsteps and the agency of an almighty, though invisible, Intelligence; "for in Him we live, and move, and have our being."

CHAPTER IV.

THE ELASTICITY OF THE AIR, AND THE PHENOMENA IT EXPLAINS.

The atmosphere is that ocean of air which surrounds our globe on all sides, and in which we live and breathe. We are plunged into the bottom of the vast aërial sea, as the fishes are plunged into the depths of the ocean. Before we were brought into the world, we were furnished with a diaphragm and lungs, with cartilages, ribs, and muscles, to enable us to draw in this vital fluid. The first rush of the air into the lungs, and the cries which accompany it, announce life and sensation. More than a hundred muscles are employed in drawing in and expelling this aërial fluid; and this operation is continued, without intermission until death. In this element we pass the whole of our existence, from the cradle to the grave; it surrounds us wherever we go, whether on sea or land, and almost all our enjoyments depend on its benign agencies. This element, however, is impalpable to our senses. By its transparency, it escapes our ocular inspection; by its thinness, it eludes our grasp; it cannot be perceived by our smell or taste, nor even by our organs of hearing, unless when it is in a state of tremor and agitation. But we are fully assured, in numerous instances, that the powers of nature may be in complete existence, though they are imperceptible to every organ of sensation; and hence we ought to guard against an error common both to the vulgar and to philosophers, that "the things which we cannot see have no real existence." The atmosphere, though invisible, is one of the most important and essential constituents of our terrestrial habitation. We could live for a few days without food, or drink, or sleep; we could pass weeks and months without the light of the sun, or the glimmering of a star; but if we are deprived only for a few minutes of the vital air, the lungs refuse to play, the heart ceases to beat, the blood stagnates in the arteries and veins; we faint, we sicken, we die. The powers of the animal machine are broken; the thoughts and perceptions vanish; the dust returns to its kindred dust, and the spirit returns to God who gave it.

We shall now chiefly attend to the illustration of the elasticity of the atmosphere. By the elasticity of the air, is meant that property by which it contracts itself into less space, when an additional pressure is laid upon it, and by which it recovers its former dimensions when the pressure is removed. When I take a piece of whalebone, or a watch-spring, and bring the two ends together as soon as the force thus employed is removed, the spring returns to its former position. In such cases, we say that the body is elastic. When I take a small quantity of wool into my hand, and compress it, upon opening my hand, it recovers its former bulk, by the natural spring of its fibers; and hence we conclude that this substance possesses a certain degree of elasticity. In like manner, if I take a bladder and fill it with air and apply a force to the sides of it, so as to compress it into a smaller space, when the force is removed it immediately expands, and fills the same space as before, which clearly proves that the air contained in the bladder is of an elastic nature.

In consequence of this elastic property, the air always endeavors to expand itself, and to occupy more space. This is proved by taking a bladder, containing only a small quantity of air, tying its neck close, so as to prevent the escape of the air, and then placing it under the receiver of an air-pump. So long as the bladder is exposed to the pressure of the atmosphere, it will remain in the same state; but, when the air is exhausted from the receiver, and the external pressure removed, the side of the bladder, which was flabby and lax, stretches itself out, swells, and becomes tight, being raised by the elastic power. And, if the air be again let into the receiver, the bladder returns to its former shape. By a similar experiment it is shown, that the expansive power of the small quantity of air in the bladder is capable of raising leaden weights of a considerable size. In consequence of this strong elastic power of the air, a person, by blowing into a pipe connected with several bladders, has been able sensibly to raise a mill-stone, which was placed upon the bladders; which demonstrates the very strong expansive power of a very small quantity of air.

On the same principle, were a bladder, containing a very small quantity of air, taken to the higher regions of the atmosphere, it would gradually expand the higher it was carried, in consequence of the pressure of the atmosphere being gradually diminished, until, at length, it would burst the bladder, by the expansive force with which it is indued. In like manner, heat increases the elasticity of air. If a bladder, containing a small quantity of air, be placed, before a strong fire, the small portion of air it contains will expand until the bladder appears quite full, and ready to burst. There is another striking experiment which demonstrates this elastic force of the air. When a thin bottle with flat sides is firmly corked, so as to prevent the included air from escaping, is placed under the receiver of an air-pump, and the air exhausted, the spring of the air within it will dilate with so much violence as break the bottle to pieces. In like manner, were the pressure of the external air completely removed from our bodies, and the escape of the internal air prevented, the elastic force of the air within us would immediately tear the lungs and other vessels to pieces, force the blood through the arteries and veins, and put an end to all the functions of the animal machine. If an animal, as a cat, mouse, or bird, be put under a receiver, and the air exhausted, the animal will be at first oppressed as with a great weight, then grow convulsed, their bodies will swell, and if they are allowed to remain only for a few minutes, they inevitably die. Were we to take a shriveled apple, and put it under the receiver of the air-pump, and exhaust the air, the skin will gradually swell as the pressure of the air diminishes, the wrinkles will be filled up, and the apple will appear as if fresh-gathered. When the air is let in, it returns again to its former withered state. The effect now stated, is owing to the elasticity of the air in the inside of the apple, which expands when the atmospheric pressure is removed.

From a variety of experiments it is demonstrated, that the spring of the air is equal to its weight, and produces the same effects as its pressure; for, action being equal to re-action, the force which the elasticity of the air exerts, in endeavoring to expand itself, is equal to the force with which it is compressed, just as it is in the spring of a watch, which exerts no force, but in proportion as it is wound up. If a quantity of air therefore, is included in a vessel, and is of the same density with the surrounding air, its pressure against the sides of the vessel is equal to that produced by the external atmosphere. Hence it is that we can break a square glass bottle, either by the direct pressure of the atmosphere, after the air has been extracted from it, or by removing the pressure of the atmosphere, and allowing the elasticity of the air within to exert its expansive force.

It is owing to the elasticity of the air that it is susceptible of dilatation and compression To what degree air of the same density which it possesses at the surface of the earth is capable of being compressed, has not yet been fully ascertained. Dr. Halley informs us, that he has seen it compressed, so as to be sixty times denser than in its natural state. Some have supposed that no bounds can be fixed to the condensation of air. But it appears from some experiments made in London, and by the Academy of Florence, that no force whatever is able to reduce air into eight hundred times less space than that which it naturally possesses at the surface of the earth. It is owing to the power of being artificially condensed, that forcing-pumps produce their effects, and that an air-gun is enabled to discharge a ball to a considerable distance with great violence The air is forced into a certain compartment of the gun by means of a syringe or condenser, which drives the air in, and suffers none of it to come back until it be sufficiently condensed. When the valve which confines the air is opened, the air by its elastic power rushes in behind the ball, and forces it out of the barrel with great violence. It would be better for mankind, however, that no such instruments were ever constructed. Science ought always to have for its object the construction of instruments and machines which have a tendency to promote the comforts of mankind, not those which may be employed by unprincipled men as weapons of destruction; and, therefore, the construction of this instrument is alluded to merely as an illustration of the powerful effect of the elasticity of the air. Would to God that guns, and cannons, and warlike instruments of all descriptions were forever unknown among men; that swords were beaten into plowshares, and spears into pruning-hooks; that nation might no longer lift up sword against nation, but delight themselves in peace!

The dilatation or expansion of air, in virtue of its elastic force, is found to be very surprising. In several experiments made by the honorable Mr. Boyle, it dilated at first into nine times its former space, then into thirty-one times, then into sixty, and then into one hundred and fifty. Afterward, it was brought to dilate 8,000 times its space, then into 10,000 times; and, at last, into 13,679 times the space it originally occupied, and all this was effected by its own expansive force, without the help of fire, or the principle of heat. Hence it appears that the air we breathe near the surface of the earth is compressed by its own weight into at least the 13,000th part of the space it would occupy *in vacuo*. And, as it has been found that it may be compressed into a space sixty times less than that which it generally occupies, it follows, that the space which it will possess, when most dilated to that which it occupies when condensed, will be nearly as 820,000 to one! The amazing force of this elastic power of the air, were it properly directed, might be made to act as a strong mechanical power, and there can be little doubt that many of the terrific operations of nature—such as earthquakes, volcanoes, the rising of new islands from the bottom of the ocean, and the detachment of rocks and fragments of mountains amidst the ranges of the Alps, the Andes, and other mountainous regions—are to be ascribed, at least to the partial operation of this power, in combination with other physical agents.

It has been a subject of inquiry among philosophers, whether the elastic power of the air is capable of being diminished or destroyed. Mr. Boyle endeavored to discover how long air would retain its spring, after having assumed the greatest degree of expansion his air-pump could give it, but he never observed any sensible diminution. M. Desaguliers says, that air, which had been inclosed half-a-year in a wind-gun, had lost none of its expansive power; and Mr. Roberval asserts that he has preserved air in the same manner for sixteen years; and after that period, he observed that its projectile force was the same as if it had been newly condensed.

Various causes have been assigned by philosophers to account for the elasticity of the atmosphere. The general opinion which now prevails is, that it depends upon the latent caloric, or principle of heat, which it contains, and which enables it to retain its fluid form; and that caloric is the most elastic body in nature. But this is only an explanation of elasticity by an assumption of elasticity. It removes the difficulty only one step farther on, and leaves us still in the dark as to the nature of elasticity, and the reason why caloric is endowed with an elastic power. In this, as well as in many other instances, we must rest contented in resolving it into the will of the Deity, that such a property should be possessed by atmospheric air in order to accomplish some wise and beneficent purposes in the economy of creation.

The elasticity of the air explains a variety of appearances in nature and art. For example, beer or ale, when bottled, contains in it a quantity of air, the elasticity of which is resisted by the pressure of the condensed air between the cork and the surface of the liquid. On removing the cork, the liquid and the air which it contains are relieved from this intense pressure. The liquid itself, not being elastic, is not affected by this; but the elastic force of the condensed air, which has been fixed in it, having no adequate resistance, immediately escapes, and rises in bubbles to the surface, and produces the frothy appearance consequent upon opening the bottle. On a similar principle we may account for the following appearance. If a man fall into the water, and is drowned, the carcass in a few days rises and floats on the surface. The privation of life, and the stagnation of the fluids, are soon followed by a putrid fermentation, which decomposes the body. This fermentation disengages a great quantity of air, which is disseminated among the internal vessels, and as this air cannot escape, the body swells by its expansion, until it becomes specifically lighter than the water, and rises to its surface. But, as the putrefaction goes on, the parts give way, the air escapes, and the body, being thus rendered specifically heavier than the water, sinks to rise no more. It is likewise by the elastic property of air that fishes are enabled to rise and sink in the water. They are furnished with an air-bladder, which they have the power of contracting or dilating at pleasure. When the fish compresses this bladder, its whole volume becomes less, and it sinks in the water; when the pressure is removed, the air in the bladder instantly expands, and it is enabled to rise to the surface. A variety of instances of a similar kind, illustrative of the elasticity of the air, might be exhibited: but instead of dwelling on these, we shall now proceed to another department of our subject

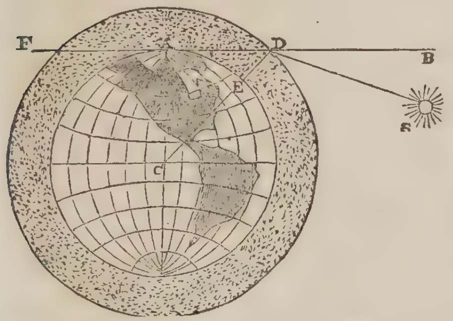
CHAPTER V.

THE HIGHT OF THE ATMOSPHERE; OR, THE ELEVATION TO WHICH IT EXTENDS BEYOND THE SURFACE OF THE EARTH.

The hight of the atmosphere is considered, by many writers and lecturers on this subject, as a point fully determined, and is treated as familiarly as the hight of the Andes, or the Alps, or of Mount Etna, or Mount Blanc. But the hight of the atmosphere has never yet been fully ascertained, and it is probable will never be accurately determined. If, indeed, the air were of an equal density, from the surface of the earth to the top of the atmosphere, its hight might be easily determined; for it is found by experiment, that the weight of a column of air extending to the top of the atmosphere is equal to the weight of a column of water of the same base and 32 feet high. Supposing water to be 840 times heavier than air—multiply 840 by 32 feet, and the product will be 26,880 feet, or 5 miles and 160 yards for the hight of the atmosphere, were its density at every elevation exactly the same as at the surface of the earth. But we know that the density of the air decreases and is more rarefied and expanded the higher we go; and, from other considerations we know that it extends far beyond the limit now stated; so that this calculation can afford us no accurate idea of the hight to which the atmosphere extends.

Another method, therefore, of determining this point was devised by philosophers, which approaches nearer to the truth. It is found by observation, that the sun is about eighteen degrees below the horizon before twilight comes to an end in the evening. Now, twilight is caused by the rays of the sun being refracted and reflected from the higher parts of the atmosphere to the earth; otherwise, we should be involved in total darkness at the moment the sun descended below the horizon. From this circumstance, the hight of the highest part of the atmosphere which is capable of refracting the rays of light may be determined.

Fig. 5.



Let F A B (fig. 5) represent the horizon of an observer at A; S D, a ray of light falling upon the atmosphere at D, and making an angle, S D B, of 18° with the horizon; the angle S D A will then be 162°. From the center C, draw C D, and it will be perpendicular to the reflecting particles at D, and will likewise bisect the angle S D A. In the right-angled triangle C D A, the angle C D A is equal to 81°; or, if we allow for refraction, 81° 30′, A C, the radius, or half-diameter of the earth, is nearly equal to 4000 miles. Then by the rules of trigonometry,

As the sine of the angle C D A	81° 30	9.995203
Is to the side A C	4000	3.602060
So is radius, sine of 90°		10.000000
To the side C D, 4044½ miles		3.606857

From C D, equal to the semidiameter of the earth and atmosphere, subtract C A, or the semidiameter of the earth, and the remainder, E D, equal to 44½ miles, will be the hight of the atmosphere. In this operation, the logarithms of the second and third terms of the proportion are added, and the logarithm of the first term subtracted from the sum.

Thus 3.602060
10.000000

13.602060
9.995203

3.606857

The same result is produced by the following proportion:—

As Radius	10.000000
Is to A C 4000	3.602060
So is the secant of A C D=8½°	10.004800
To C D=4044½	3.606860

It appears, then, that in ordinary cases, the air, at the hight of forty-four miles and a half, is capable of reflecting to us the rays of light. But, as a sensible illumination has been perceived when the sun is much farther below the horizon than what has been now stated, there is some reason to conclude, that the air is sufficiently dense for reflecting a sensible degree of light at the hight of nearly two hundred miles.

Various considerations, founded on meteoric phenomena, serve to prove that the atmosphere extends to a much higher elevation than forty-four or fifty miles. In the year 1719, a remarkable luminous meteor, or fire-ball, was seen, whose altitude was computed to be seventy-three miles above the surface of the earth. On the 18th of August, 1783, a brilliant fire-ball passed over Britain and the adjacent countries; and, from various circumstances which were particularly marked by different observers, it was calculated that its elevation above the earth could not be less than ninety or a hundred miles. In passing over certain parts of England a loud report was heard and a hissing noise. The meteor of 1719 is said to have been attended with an explosion, which was heard over the whole island of Great Britain, occasioning a violent concussion of the atmosphere, and seeming to shake even the earth itself. Now, in these, and multitudes of similar phenomena, we have instances of fire and flame being supported, and sounds conveyed to the earth from a hight of ninety or a hundred miles; and, consequently, even in these elevated regions, notwithstanding the great rarefaction of the air, it must still have the power of supporting flame and propagating sound. Even although the fire-balls alluded to be supposed to consist of electrical matter—which is the general opinion—yet the difficulty is not thereby removed; for, it is found, by some late experiments, that the electrical fire cannot penetrate a perfect vacuum. And, therefore, there is reason to conclude, that we are still ignorant of the precise extent of the atmosphere, and of the nature of the fluids which occupy its superior regions. That the meteors now referred to, however elevated, were not beyond the limits of the atmosphere, appears from this consideration, that the atmosphere revolves with the earth in its course round the sun, at the rate of 68,000 miles an hour. Now, as the meteor of 1783 moved from north to south, if it had been beyond the limits of the atmosphere, it would have been left, in the course of a minute, more than a thousand miles to the westward, by the earth flying out before it, both in its annual and diurnal course.

In short, it appears not altogether improbable to suppose, that the visible universe is filled with some fine elastic fluid or air, but of such rarity as to be no sensible hindrance to the celestial orbs in their rapid motions through the regions of space; and that this fluid accumulates itself around every planetary body, in proportion to the quantity of matter it contains—the larger bodies attracting more of it and the smaller bodies less; and thus forming an atmosphere around each, corresponding to its nature and destination. And, if this be the case, the atmosphere of the earth can have no definite boundary, but may be said to mingle with the atmospheres of all the other planets which belong to our system. There is a certain portion of atmospheric air, however, which must always be considered as attached to the earth, and which revolves with it in its diurnal rotation, and is carried along with it in its course round the sun. If the atmosphere did not revolve along with the earth, we should constantly experience an easterly wind, blowing with an immense velocity of more than a thousand miles an hour, which would produce a most tremendous hurricane, which would level with the ground houses, trees, forests, and every prominent object on the surface of the earth. But the particular region where the motion of the atmosphere terminates, it is impossible for us to ascertain.

CHAPTER VI.

THE COMPOSITION OF THE ATMOSPHERE.

For a long series of ages, air was considered by philosophers as one of the four elements of which all things are composed, the other three being fire, earth, and water. But the discoveries of modern chemistry have fully demonstrated that all these are compound bodies—that even the air itself, fine and invisible as it is, is not a simple substance but compounded of different ingredients. This is one of the most curious and interesting discoveries of modern times; and little more than seventy years have elapsed since it was first surmised that the atmosphere is not a simple and homogeneous, but a compound fluid. The experiments which led to this discovery were first made by Dr. Priestley, on the 1st of August, 1774, on which day he obtained what was then termed dephlogisticated air, now known by the name of oxygen gas, and which forms one of the constituent principles of atmospheric air. It was also discovered in the year 1775, by M. Scheele, a Swedish chemist, without any previous knowledge of what Dr. Priestley had done, and he gave it the name of empyreal air, from its powerful influence in supporting flame. But, instead of entering into the history of such discoveries, and of the processes by which they were made, a few of the properties possessed by the different ingredients of which our atmosphere is composed may be simply stated.

The air of the atmosphere, then, is found to consist chiefly of two very opposite principles or fluids, termed oxygen gas, and nitrogen gas, along with a very small proportion of fixed air or carbonic acid gas. If any portion of the atmosphere, such as the air in our apartments, be supposed to to be divided into a hundred equal parts, twenty-one of these parts will be oxygen gas, about seventy-eight nitrogen, and a hundredth part, or according to some chemists, a thousandth part will be fixed air, or carbonic acid gas. In the first place, a few remarks shall be offered on the nature and properties of oxygen gas.

This gas, like common air, is colorless, invisible, and elastic, and capable of indefinite compression and expansion. Its peculiar and distinguishing properties are:—1st. It is essential to combustion, and is the only principle with which we are acquainted by which flame can be supported. When acting by itself, it produces the most rapid conflagration of all combustible substances. If a lighted taper be let down in a jar of oxygen-gas, it burns with such splendor that the eye can scarcely bear the glare of light, and, at the same time, produces a much greater heat than when burning in common air. If a piece of iron wire, a watch-spring, or a steel file, armed with a piece of wood, or phosphorus in an inflammable state, be put into this gas, the steel will take fire, throwing out sparks, and producing the most brilliant appearance, almost dazzling the eye with their splendor. In the next place, it is essential to the support of animal life; for it has been proved by many experiments, that no animal can exist for a single moment in any kind of air which does not contain a certain portion of oxygen; so that man, and all the other ranks of animated beings, may be said to depend upon this substance, not only for their comforts, but for their very existence.

Again, the basis of oxygen gives the acid character to all mineral and vegetable salts, from which property its name is derived; for the term oxygen literally signifies, the generator of acids. In short, oxygen is the vehicle of heat to the animal system—it imparts the red color to the blood in its passage through the lungs—it constitutes the basis both of the atmosphere which surrounds the earth, and of the water which forms its rivers, seas, and oceans; for water is found to be nothing else than a combination of two kinds of air, oxygen and hydrogen gas. It pervades the substance of all the vegetable tribes, and enables them to perform their functions. In combination with the different metals, it serves the most important purposes in the useful arts; and, on the whole, may be considered as the most extensively useful, and the most powerful and energetic agent in the system of nature.

Oxygen gas may be procured from a variety of substances, particularly from niter, manganese, and the red oxyde of mercury, and also from vegetables immersed in water and exposed to the solar rays. It is heavier than common air, nearly in the proportion of eleven to ten; one hundred and sixteen cubic inches of oxygen are found to weigh about thirty-nine grains, while the same quantity of common air weighs only thirty-five and a half grains.

One of the most extraordinary effects of oxygen appears when it is combined with nitrogen in a certain proportion, so as to form what is commonly called nitrous oxyde. This gas consists of sixty-three parts nitrogen and thirty-seven parts oxygen. When it is put into a bladder, and inhaled into the lungs, by means of a pipe, and shutting the nostrils, it produces an extraordinary elevation of the animal spirits—involuntary muscular motion—a propensity to leaping and dancing—involuntary bursts of laughter—a rapid flow of vivid and agreeable ideas, and a thousand delightful emotions, without being succeeded by any subsequent feelings of languor or debility. When Mr. Southey, the poet, inhaled this gas, he declared that it produced in him sensations perfectly new and delightful. His first sensations were a kind of dizziness, so as to produce a fear of falling. This was succeeded by a laugh, which was involuntary but highly pleasurable, accompanied with a peculiar thrilling in the extremities perfectly new, and with the most delightful sensations. For many hours after this experiment, he imagined that his taste and smell were more acute, and is certain that he felt unusually strong and cheerful.

In Professor Silliman's *American Journal of Science*, we have the following account of the effects of this air on one of the professor's students, at Yale College, New Haven. "The person on whom the experiment was made, was a man of mature age and of a grave character. For nearly two years previous to his taking the gas, his health was so very delicate, and his mind so gloomy and distressed, that he was obliged almost entirely to discontinue his studies. In this state of debility, he inhaled about three quarts of the nitrous oxyde. The consequences were, an astonishing invigoration of the whole system, and the most exquisite perception of delight. These were manifested by an uncommon disposition for mirth and pleasantry, and by extraordinary muscular power. The effects of the gas were felt without diminution for at least thirty hours; and in a greater or less degree for more than a week. But the most remarkable effect was upon the organs of taste. Before taking the gas, he felt no peculiar choice in the articles of food; but, immediately after that event, he manifested a taste for such things only as were sweet, and for several days, ate nothing but sweet cake. His singular taste was, indeed, carried to such excess, that he used sugar and molasses, not only upon his bread and butter and lighter food, but even upon his fresh meat and vegetables; and this he continues to do (says the narrator) at the present time, although eight days have elapsed since he inhaled the gas. His health and spirits since that time have been uniformly good, and he attributes the restoration of strength and mental energy to the influence of the nitrous oxyde. He is quite regular in his mind, and now experiences no uncommon exhilaration, but is habitually cheerful, whereas, before, he was habitually grave, and even, to a degree, gloomy and melancholy."

The writer has inhaled this gas, and can attest its pleasing and exhilarating effects. It produced a disposition to laughter, which no consideration could resist, and a wish to flee from the apartment in which the experiment was performed, that laughter might be indulged without restraint. It produced, likewise, an agility and a tendency to skip and jump; and, during its effect, a flow of pleasing ideas passed through the mind, and the lapse of a few seconds seemed to be magnified into as many hours. He has witnessed its effects both on the male and on the female sex. He has seen a little grave man, possessed of a meek and well-cultivated mind, capering through the room with all the airs of a king, brandishing his staff, and jumping until his head nearly touched the ceiling of the room, about eight feet high. When, afterward, asked why he brandished his stick, as if he had been going to fight, he replied, that he imagined there was a beautiful and extensive scene before him, which he wished to approach; but was prevented by the company around him, and, therefore, was obliged to clear his way, like a policeman when keeping off a crowd. The writer has, also, seen a female rapt into perfect ecstasy in consequence of the feelings she experienced, expressing her emotions in the most poetic exclamations, and tossing her shawl, her head-dress, and her slippers, from her as unworthy of attention, and altogether regardless of the looks and opinions of surrounding spectators. But, in order that this gas may produce its full effect, it requires some attention and dexterity in breathing it. The nostrils must be stopped, and no atmospheric air, if possible should be allowed to mix with the nitrous oxyde. For want of attending to such precautions, some persons who attempt to breathe it never felt its peculiar effects.

It has been ascertained from various experiments, particularly from those made by the late Sir Humphrey Davy, that the nitrous oxyde produces a somewhat similar effect upon insects, and other animals, which are found to jump and caper about in a frolicsome manner, as if highly delighted, when immersed in this gas.

These, and other effects, arising from the breathing of this very singular fluid, show us with what ease the Almighty could produce in us either the most delightful or the most painful sensations, merely by a slight modification or change of the principles of which the atmosphere is composed. Certain combinations of oxygen and nitrogen gas would produce a fluid, which would inflict the most excruciating pain, and destroy the corporeal system in a few minutes. Sulphuric acid, or aquafortis, a most deadly fluid, when taken into the mouth or stomach, is composed of seventy-five parts oxygen and twenty-five parts nitrogen, which is only a different proportion of the same ingredients which constitute the air we breathe. Were, therefore, our atmosphere composed of such a proportion of these two gases, it is easy to foresee the fatal consequences which would result from breathing such a fluid. On the other hand, we may learn how an intelligent mind connected with a corporeal frame, somewhat analogous to ours, may be preserved in a state of uniform cheerfulness, and even of exquisite delight, by breathing an atmosphere somewhat similar to that of nitrous oxyde. In other worlds, where the inhabitants have retained their original integrity, this may be the case. The other planets of our system or of other systems, although encompassed with atmospheres, may have them of very different qualities from ours, as to their transparency, their refractive and reflective powers, and the influence they produce on the mental and corporeal constitution of their inhabitants. Our atmosphere exhibits evident marks of Divine wisdom and benevolence; but it is adapted to man considered as in a state of depravity and imperfection, and appointed to a short mortal existence, and is not fitted to preserve him in an immortal existence in the present state, as was probably the case when this world was first arranged, and when man proceeded from the hands of his Creator as a holy being.

The next component part of the atmosphere is nitrogen gas, or what is sometimes termed azote. It is chiefly distinguished by its negative qualities. In the first place, no combustible body will burn in it; for, if a burning candle be immersed in a jar filled with nitrogen, it will be extinguished as instantaneously as if plunged in water. If a lighted taper be put into a close vessel full of common air, it will burn until all the oxygen be consumed, after which, as nothing but nitrogen remains, it will instantly go out. In the next place, it is incapable of supporting animal life; for, if any living being be obliged to respire it, it drops down dead almost instantaneously; and, from this circumstance it derived the name of azote, which signifies life-depriver. It is this gas which passes from the lungs at every expiration; and, were we to breathe it again, without any mixture of other air, we should be instantly suffocated. But, being lighter than atmospheric air, it rises above our heads, and enters into new combinations. It is owing to the presence of this gas, rising from several hundreds or thousands of lungs, that candles burn so dimly in the higher parts of crowded churches and assemblies. It is, therefore, a striking consideration, that nearly four-fifths of the air we breathe consists of this noxious and destructive fluid. But, though it is destructive to animal life, it forms an important element in the system of nature: it enters extensively into combination with other substances; and its existence in such a large quantity is a chief distinction between the constitution of animal and vegetable matter. It likewise exists in the products of several vegetables, and appears to be favorable to plants and flowers, which vegetate freely when surrounded with nitrogen. This gas is permanently elastic, transparent, colorless, and inodorous. Its specific gravity is 0.9748, that of common air being 1.0000; and one hundred cubic inches of it weigh about thirty grains. It slightly tinges delicate blue colors with green.

The other ingredient mentioned as forming a small portion of the atmosphere, is carbonic acid gas, or what was formerly called fixed air. This gas constitutes about a hundredth or, according to some chemists, about a thousandth part of the atmosphere. It is found in a state of combination with limestone, chalk, marble, manganese, and other substances, from which it may be extracted by the application of heat, or of the mineral acids, and in considerable abundance in mines, caves, the bottom of wells, in wine-cellars, brewers' vats, and in the neighborhood of lime-kilns. It is invisible and elastic, and is the heaviest of all the gases, being considerably heavier than common air; and, therefore, may be poured from one vessel to another, like water. Its specific gravity is 1.5123, that of common air being reckoned 1.0000, so that its gravity is more than one and a half that of atmospheric air. One hundred cubic inches of oxygen weigh nearly thirty-four grains, while one hundred cubic inches of carbonic acid weigh more than forty-six and a half grains. It is this gas which has deprived of life many individuals who have descended into deep wells which had been long shut up from the air, and which produces so many ravages in coal-mines, under the name of the choke-damp; for it is almost instantaneously fatal to all animals that breathe it. Wherever it is found, it always occupies the lowest place, on account of its superior weight; and, therefore, in those caves where it abounds, a person may walk erect without danger; but, were he to lie down, he would be instantly suffocated. The Grotto del Cani, or the Dog's Grotto, in Italy, is well known. It is an artificial cave, in which there is a constant natural exhalation of carbonic-acid gas. The following feat is shown to strangers:—A man carries in a dog, and places him on the floor; the dog, if left long enough, dies; but the man is not affected; for the carbonic-acid gas, by its weight, occupies the lowest stratum of about eighteen inches depth, and the stratum above that hight is pure air. But that it is poisonous to man, is evinced by the fate of persons who incautiously expose themselves to the vapors of charcoal burning in ill-ventilated apartments, or who venture into large vessels, in which fermentation had been conducted, as in breweries and distilleries. Many persons, from ignorance of the prevalence of this gas in the vicinity of lime-works, have lain down to repose, and in a short time have slept the sleep of death. As this gas is destructive to animal life, so it extinguishes flame. This can be strikingly shown by letting down a burning taper to the bottom of a glass jar, filling a bottle with carbonic-acid gas, and pouring it as if it were water into the jar; the flame is immediately extinguished. It is this gas which gives briskness and an agreeable pungency to fermented liquors, as porter and ale, and which appears on their surface in the form of a white froth. All kinds of spring and well-water contain carbonic-acid, which they absorb from the atmosphere, and to which they are partly indebted for their agreeable flavor. Boiled water has an insipid taste from the absence of carbonic-acid.

The base of carbonic acid gas is distinguished by the name carbon, which is nearly allied to charcoal. It exists largely in animal substances, and is extensively distributed in the mineral kingdom. The only body in which carbon has been found to exist in a state of absolute purity, is the diamond—a precious stone which has always been esteemed as the most valuable of the gems; a superiority which it owes to its hardness, luster, and high refractive power. It uniformly occurs crystallized, and presents a great variety of forms. Its specific gravity is 3.5, water being 1. Its hardness is extreme, so that it can be worn down only by rubbing one diamond against another, and is polished only by the finer diamond powder The diamond, by being intensely heated with a burning-glass in oxygen gas, burns with a bright red light, and converts the oxygen into pure carbonic-acid gas, as charcoal does. Carbonic-acid gas is, therefore, to be considered as a solution of diamond in oxygen gas, even when it is prepared by the combustion of mere charcoal. It may not be altogether useless to remark, that in all places such as wine-cellars, vaults, and deep wells, where the presence of carbonic-acid gas is suspected, it is proper to use the precaution of trying whether a candle or taper will burn in such places before we venture into them. If it be a deep well that requires to be cleaned, a burning candle should be let down with a cord, and if it go out before reaching the bottom of the well, no person ought to venture down before the noxious air is removed.

Such, then, are the three constituent principles of the atmosphere in which we live and breathe. We ought not, however, to conceive that the principles which form our atmosphere, and the proportion in which they are combined, constitute the only fluid which is fitted for supporting animal life and vigor. It is a fluid which seems to be adapted only to mortal men, and calculated to support the vital functions only to the period of eighty or one hundred years. It is not at all improbable, that it is owing to the large proportion of nitrogen which enters into the composition of the atmosphere that renders it unfit for supporting human life beyond a certain short and limited period; and that, were a much larger quantity of oxygen combined with other gases, in a certain proportion, and some slight changes effected in the other elements of nature, the lives of men and other animals might be protracted to several hundreds or thousands of years, and their spirits preserved, at the same time, in uninterrupted cheerfulness and vigor. Nor is it altogether improbable that, in the course of those improvements which are now commencing throughout the world, the air of our atmosphere may be greatly ameliorated, and rendered more salubrious and invigorating to animated beings, when the stagnant marshes which abound in every part of the globe shall be completely drained; when those immense forests which now cover a great part of Asia, of New Holland, and of the continent of America, shall be cut down, and the soil laid open to the influence of the solar rays—when the reefs which are now rising from the ocean, by the agency of minute creatures, shall be formed into continents and islands—when the barren deserts of Africa shall be transformed, by human science and industry, into fruitful fields—when the soil throughout every region of the globe shall be universally cultivated—when those immense thickets and jungles where the lion and the tiger now roam undisturbed, shall be changed into cornfields, gardens, and orchards, and become the seats of civilization and of peace—in short, when the whole earth shall form one wide scene of rural and architectural beauty—we have every reason to believe that then the different climates of the earth will be greatly meliorated; that the fury of those storms which now carry destruction in their train will be greatly abated—and that the very atmosphere round us will be so modified, purified, and improved, as to render it capable of prolonging the life of man for perhaps two or three hundred years. Such effects correspond to what is predicted respecting the state of the world during the millennium, when the instruments of warfare shall be beaten into plowshares and pruning-hooks; when peace shall reign triumphant over the world, and when every man shall sit under his vine and fig-tree without fear of annoyance. At which period it is predicted, that the life of man shall be extended beyond its present boundaries. For thus saith Jehovah, "As the days of a tree* are the days of my people"—"they shall build houses and inhabit them; and they shall plant vineyards and eat the fruit of them; .... and mine elect shall long enjoy the work of their hands." "Then shall the earth yield her increase; and God, even our own God, shall bless us."

All the operations and ameliorations now alluded to are perfectly practicable, were the moral state of man improved. Could we undermine the principle of avarice and selfishness in the human heart; could we promote a spirit of harmony and general benevolence among human beings; and were the whole body of mankind to exert their powers in unison, in the cause of universal improvement—this earth, which, in many places, appears like a world in ruins, might, ere long, be transformed into one wide terrestrial paradise But principles and dispositions directly opposite to these have, for the most part, hitherto prevailed. The present state of the moral world, and the infernal passions which have raged among mankind for ages past, have rendered it expedient, in the moral government of the Almighty, that the life of man should not extend much beyond "threescore years and ten," in order that wickedness may be kept within certain bounds. And, therefore, no extraordinary or extensive improvements in science and art, or in the general cultivation of the earth, can be expected until the moral powers of man be cultivated and improved along with the intellectual; until the religion of Jesus be universally recognized in all its bearings; until its holy principles and practical precepts pervade every heart; and until a spirit of love, kindly affection, and benevolence distinguish the general mass of society in every land.

But, to return from this digression, it may be further remarked, that it is highly probable that the component parts of the atmosphere, in the ages before the flood, were very different from what they now are, and that it was owing to the peculiar constitution of the air which then existed, that the lives of the antediluvians were prolonged to nearly a thousand years. At the period of that awful catastrophe, when the fountains of the great deep were broken up, and the windows of heaven were opened, and the solid strata of the earth disrupted, it is probable that the atmosphere, too, underwent an important change by the dissolution of some of its elementary parts, so that it had a tendency to cut short the lives of mankind in all succeeding ages; and, until the ruins which were produced by that physical convulsion be in some measure repaired, the same cause will produce the same effects.

In short, an atmosphere is not peculiar to the globe on which we dwell. We know, from observation, that the planets Mars, Venus, and Jupiter, are furnished with atmospheres; and it is probable that every planetary world has a similar appendage. But their nature may be as different from ours as are the nature of their inhabitants and the constitution of the globes on which they reside. While our atmosphere is fitted only to prolong the lives of mortal men for a limited number of years, the atmospheres of some of the other planets may be so impregnated with the vital principle as to support immortal bodies in undecaying vigor, and to cause such an elevation of spirits as will produce uninterrupted ecstasy and delight. And all this may be effected by the same elementary principles of which our atmosphere is composed, but differently modified and compounded by the hand of the Almighty. The experiments with nitrous oxyde, formerly mentioned, show us what striking effects may be produced by different combinations of the gaseous fluids; and, therefore, it is not improbable that the atmospheres of all the worlds in the universe are only different modifications of these substances, suited to the constitutions of their inhabitants, and the spheres they occupy in creation. In the operations of the Almighty throughout the system of nature, we perceive a striking simplicity in the means, producing an infinite variety of astonishing results. From a few simple substances—caloric, light, water, air, and carbon—are produced all the diversity of forms and colors which appear among the sixty thousand species of plants which adorn the vegetable kingdom, and almost all the diversified phenomena of sublunary nature. And it is not unlikely that different combinations of these, and a few other substances, produce all that variety which appears throughout the boundless universe; and may give birth to all the changes and revolutions through which the different systems of creation may pass during every period of infinite duration. For He who arranged the system of universal nature "is wonderful in counsel, and excellent in working"—"his wisdom is unsearchable," his power irresistible, and the ways of his providence "past finding out."

---

* Certain species of trees are said to continue in vigor during a period of five hundred years, as the oak and several other trees.

CHAPTER VII.

THE BENEFICIAL EFFECTS OF THE ATMOSPHERE IN THE SYSTEM OF NATURE.

This subject presents an immense field of contemplation, which it would require several volumes fully to illustrate: and, therefore, a few general statements and illustrations can only be given.

1. In the first place, air is essentially requisite to the germination and growth of plants; and, therefore, to the influence of atmospheric air all the beauties of the vegetable creation are to be chiefly ascribed. By experiment, it is found that the access of atmospheric air is no less necessary for plants than it is for the continuation of animal life. Like animals, they are found to die when confined within a vacuum, or deprived of the vital air. The influence of the atmosphere is equally essential at every period of their existence, from the germination of their seeds to the full development of all their organs in the perfect plant. Their leaves, acting in some measure like the lungs of animals, absorb oxygen gas during the night, and carbonic-acid gas during the day; and this alternate process is found to be essential to their growth and nourishment. Even the green color of plants, which is produced chiefly by the influence of light, is proved not to be perfected without the co-operation of oxygen gas. It is found that pure air, or oxygen gas, may be procured by putting the leaves of plants into water, and exposing them to the sun. In purifying contaminated air, Dr. Priestly discovered that vegetables answered this purpose most effectually. Having rendered a quantity of air very noxious, by mice breathing and dying in it, he divided it into two receivers, inverted in water, introducing a sprig of mint into one of them, and keeping the other receiver, with the contaminated air in it, alone. He found, in about eight or nine days after, that the air of the receiver into which he had introduced the sprig of mint had become respirable; for a mouse lived very well in this, but died immediately upon being introduced into the other receiver, containing the contaminated air alone. It is likewise proved by experiment, that the simple component principles which are essential to the formation of vegetable matter are but three in number, namely, carbon, oxygen, and hydrogen; and these form the bases of carbonic-acid gas, oxygen gas, and hydrogen gas. From the various proportions in which these ingredients are combined, results almost all the variety of vegetable matters which fall under our notice.

To the atmospheric influence, therefore, we are indebted for all the productions of our fields and gardens, and for all that diversity of prospect and coloring which the vegetable tribes spread over the landscape of the world. It is true, indeed, that water is also necessary for the production of plants. But what is water? It is nothing else than a composition of two kinds of air, oxygen and hydrogen, combined in certain proportions. Now, it is found that plants have the power of decomposing water into these two principles, throwing off a part of the one, and absorbing a part of the other. The elasticity of the air has likewise an important influence on the air-vessels of vegetables; for the contained air, alternately expanding and contracting, according to the increase or diminution of the heat, alternately presses the vessels, and eases them again, thus keeping up a perpetual motion of their juices. It has likewise been ascertained, from recent experiments, that the pressure of the atmosphere has a powerful influence on vegetation, which suggests to us one of those causes which prevent trees from flourishing on the elevated sides of lofty mountains.

2. The pressure of the atmosphere has an influence in preserving water in the state in which we find it. Nothing is of more importance to the comfort of man and other creatures, and to almost all the processes of the arts, than water—without which our globe would be transformed into an immense desert. But, if there were no atmosphere, all the waters on the face of the earth would boil, and be evaporated with a very slight degree of heat. The ocean would be drained to its lowest caverns, the rivers would cease to flow, the springs would be dried up, and the whole surface of the land exhausted of that moisture so essential to the existence of the animal and vegetable world. Indeed, it is not improbable, that all the substances on the earth, solid as well as fluid, would be dissipated into vapor. That such effects would actually take place, appears from a variety of experiments. If we fill a long-necked bottle with boiling water, and cork it close, so as to exclude the air, and place it in a basin of cold water, the water will sink in the neck of the bottle as it cools. This shrinking of the water will produce a vacuum in the upper part of the bottle, and the water within it will be seen to recommence boiling with great violence, which can arise from nothing but the cork taking off the pressure of the atmosphere from the water. In like manner, if we place water that has been cooled several de

grees below boiling, under the receiver of an air-pump, it will begin to boil as soon as the air is exhausted. It requires a heat of 212° of Fahrenheit's thermometer to make water boil under the common pressure of the atmosphere; but in the exhausted receiver of an air-pump, it boils when heated to only about 67°. The phenomenon exhibited by what is called the pulse-glass, is also owing to the same cause. This glass, having two bulbs, is partly filled with spirits of wine, the air is extracted, and the glass hermetically sealed; and when the hand is applied to one of the bulbs, it causes a heat which produces an ebullition in the spirits of wine. It is likewise owing to this pressure that porter, ale, and other fermented liquors are preserved in bottles; without which they would either rush with violence out of their mouths, or burst them to pieces. It is owing to the same power that boiling water is preserved in our pots and kettles, when used in cooking, without the influence of which it would soon dilate itself, rush over the vessels, and be dissipated into vapor.

3. It is to the atmosphere we are indebted for the action of fire and flame. Fire is essentially necessary to human existence, even in the warmest climates of the globe. By its means the inhabitant of the desert frightens from his dwelling the beasts of prey, and drives away the insects which thirst for his blood. By its means also, man, in every country, prepares his food, dissolves the metals, vitrifies rocks, hardens clay, softens iron, tempers steel, and gives to all the productions of the earth the form and combinations which his comfort and necessities require. But, without the vital air, no flame can be extricated, nor fire made to burn. This is proved by putting a burning taper within the receiver of an air-pump, and when the air is extracted it is instantly extinguished. The act of combustion effects an analysis of the air; it separates its component parts: the oxygen of the atmosphere combines with the combustible body; caloric, in the form of sensible heat, is thrown off in every direction; and therefore, where no oxygen exists, it is imposssible to make even the most combustible body produce heat or flame.

4. It is on the influence of the atmosphere that respiration of all animals depends. The process of respiration is carried on by means of the lungs. These are distinguished into right and left. The right, or larger lung, is divided into three lobes; the left or smaller, into two. The internal fabric of the lungs is composed of an infinite number of small membranous cells, full of air, communicating with one another, the number of which Dr. Keil and other anatomists have computed to be at least 1,744,000,000, that is, one thousand seven hundred and forty-four millions. The air from without rushes into these vesicles, and is again expelled 1200 times every hour: and during the same time we consume about 48,000 cubic inches of air, or, at the rate of seventy-seven wine hogsheads in a day. The chief uses of respiration are—1, to bring the blood in contact with the air; 2. to effect certain changes in the mass of the blood; and 3, to produce animal heat. Accordingly, the lungs are so constructed as to allow the largest possible quantity of deteriorated blood to enjoy the fullest intercourse with the largest possible quantity of vital air. It has been calculated by Dr. Hales, that each air-cell is the one-hundredth part of an inch in diameter, and that the amount of surface furnished by them, collectively, is equal to twenty thousand square inches. Others have estimated the surface to be more than 1500 square feet; and Dr. Monro states, that it is thirty times the surface of the human body. From numerous experiments, it has been found that the blood perpetually receives oxygen gas from the atmosphere by the agency of the lungs, and that its red color is derived from this source. The blood is purple when it arrives at the lungs from the heart; but, having there thrown off hydrogen and carbon, it imbibes the vital air of the atmosphere, which changes its dark color to a brilliant red, rendering it the spur to the action of the heart and arteries, and the source of motion and of animal heat. The blood is thus indebted every moment to the invigorating influence of the atmosphere, without which the heart would cease to beat, the circulating fluids would stagnate, and the body become a cold, putrid mass, without sensibility or motion.

The following are some of the results of experiments in relation to this subject, lately performed by Dr. S. Smith, "1. The volume of air ordinarily present in the lungs is twelve English pints. 2. The volume of air received by the lungs, at an ordinary inspiration, is one pint. 3. The volume of air expelled from the lungs, at an ordinary expiration, is a little less than one pint. 4. Of the volume of air received by the lungs at one inspiration, only one-fourth part is decomposed at one action of the heart, and this is so decomposed, in the five-sixth parts of one second of time. 5. The blood circulates through the system, and returns to the heart in one hundred and sixty seconds of time, which is exactly the time in which the whole volume of air in the lungs is decomposed. These circuits are performed every eight minutes; five hundred and forty circuits are performed every twenty-four hours. 6. The quantity of blood that flows to the lungs, to be acted upon by the air at one action of the heart, is two ounces, and this is acted upon in less than one second of time. 7. The quantity of blood in the whole body of the human adult is twenty-four pounds avoirdupois, or twenty pints. 8. In twenty-four hours, twenty-four hogsheads of blood are presented to the lungs, to receive the influence of the vital air. 9. In the mutual action which takes place between the quantities of air and blood which come in contact in twenty-four hours, the air loses three hundred and twenty-eight ounces of oxygen, and the blood, ten ounces of carbon."

Such are the wonderful processes in reference to respiration as dependent on the atmosphere. When we reflect that a stratum of blood, several hundred feet in surface, is exposed to a stratum of air still more extensive, and all compressed within the compass of a few inches, we cannot but be filled with admiration at the Divine wisdom displayed in this and many other functions of the human system, which so far surpass all the contrivances of genius, science, and art. In every part of the workmanship of the Almighty, even the most minute, we perceive the impress of infinite goodness and intelligence, demonstrating that He who formed the human frame and the surrounding elements is "wonderful in counsel, and excellent in working." Not only are terrestrial animals and the fowls of heaven dependent for existence on the atmosphere, but even the fishes of the sea cannot subsist for any length of time without its invigorating influence. Every fish is furnished with an air-bladder, by which it is enabled to rise in the water, or sink into it at pleasure. The lungs of fishes are their gills; these consist of filaments, arranged somewhat like the feathers of a quill; they are found to be covered with minute processes, crowded close together, and on which are observed, by the microscope, millions of capillary blood-vessels spread, like a net-work, over the whole surface. It is through the thin coats of these vessels that the air acts upon the blood they contain. When a fish is taken out of the water, the reason it cannot breathe is, that these filaments collapse, and adhere together in a mass, and the air cannot separate them. If the air be extracted from the water in which fishes swim, or if they have no free communication with the air, they are soon deprived of existence.

5. The atmosphere is the medium in which the process of evaporation is carried on, and in which clouds, rain, and dew are produced. By the heat of the sun and other causes, an immense portion of matter is daily carried up into the atmosphere in the form of vapor, in which state it occupies a space 1400 times greater than in its ordinary liquid state. It has been found, by experiment, that an acre of ground, in the course of twelve hours of a summer's day, dispersed into the air by evaporation, 16,000 gallons of water. Every hour there are exhaled in this way, from the surface of the ocean, many millions of gallons, and every year about 40,000 cubical miles of water. This vast body of water, sometimes in an invisible form, and sometimes in the shape of clouds, is carried by the winds over the different regions of sea and land. A part of this water is condensed into thick clouds, and falls down in rains on the continents and islands, to fertilize the soil; a part descends on the seas and oceans; and another part supplies the sources of the rivers, by which it is again returned to the ocean, whence it was chiefly derived. This continued circulation of vapor through the atmospherical regions, is one of the most important processes in the system of nature connected with our globe. By means of it, the Creator displays his wisdom and unbounded benevolence, in conveying fertility to the different climates of the earth, and thus supplying nourishment and comfort to man and to all the inferior orders of animated existence. But it is evident that, without the ministration of the atmosphere, these beneficent operations could not be carried on, and the earth would be left to parch under the rays of the sun, until it were transformed into a bleak and barren desert. It is owing to this process of evaporation that our clothes and linens are dried, after having been washed, and that our roads are rendered clean for walking upon, after having been drenched with heavy showers of rain, or covered with deep snows; without the operation of which, a thousand discomforts and inconveniences would be felt in all the scenes of domestic life, and the operations of art; and this world would cease to be an abode of happiness and enjoyment.

6. The density of the atmosphere gives buoyancy to the clouds, and enables the feathered songsters to transport themselves with ease from one part of the earth to another. If the air near the earth were much rarer than it is, the clouds would sink to the surface of the earth, involve the world in a dismal gloom, and intercept our views of the beauties of the terrestrial landscape, and of the glories of the midnight sky. The birds would be unable to perch on the tops of lofty trees, or to wing their flight from shore to shore. As a proof of this, Mr. Robertson, who ascended in a balloon from St. Petersburgh, in 1804, informs us that he took along with him some live pigeons, and, at different hights, gave liberty to these birds, who seemed very unwilling to accept of it. The poor animals were so terrified with their situation, that they clung to the boat of the balloon until they were forced from it, when it appeared their fears were not groundless; for their wings were nearly useless, from the rarity of the air, and they fell toward the earth with great rapidity. The second struggled with eagerness to regain the balloon, but in vain; and the third, thrown out at the greatest elevation, fell toward the earth like a stone, so that he supposed it did not reach the earth alive. This was evidently owing to the extreme rarity of the air in those upper regions to which the balloon ascended.

7. The atmosphere is the region in which winds are produced, which perform many important offices in the economy of our globe. Winds are nothing else than portions of air in motion; and although they sometimes excite our fears by the violence of their rage, and scatter destruction by sea and land; yet their agency, on the whole, is highly beneficial, and even essentially necessary to mankind. They purify the air by keeping it in perpetual motion; they disperse the noxious vapors that are continually rising from stagnant marshes and common sewers; they sweep the chambers of the atmosphere; they ventilate the streets of populous cities, and prevent the accumulation of those noxious effluvia which would produce pestilence and death; they scatter the seeds of various plants over every region; they fan the air under the scorching heats of summer, and diffuse refreshment over a fainting world; they make our millstones revolve as nimbly as the wheels of a chariot, and they serve as wings to our floating edifices, to impel them across the ocean, and to bring them back laden with the treasures of distant lands.

Were the agitation to cease which the wind produces, all nature would be thrown into the utmost confusion. Navigation to distant shores, as hitherto most generally conducted, would be at a stand, and ships would be arrested in the midst of the ocean. The vapors exhaled by the heat of the sun would remain forever fixed over those particular spots whence they arose, instead of being dispersed, as they now are, over every region. One part of the world, by the interposition of stationary clouds, would be forever deprived of the direct influence of the solar rays, and of the light of the stars; while, in another part, the soil would be parched, and the grass burned up, for want of a vail of clouds to modify the heat of the sun. One region would be scorched for want of moisture, and another drenched with excessive rains. The putrid exhalations of dunghills, marshes, and populous cities, would remain perpetually suspended around the places whence they arose, and produce diseases and pestilence, which would sweep the inhabitants of the earth in rapid succession to the grave. But in the existing economy of nature, all such disastrous effects are prevented by the agency of the winds, which distribute the clouds in due proportion over every land, and serve as ventilators to all the regions of the atmosphere.

8. Air is the vehicle of smells, by the transportation of which we become acquainted with the good or bad qualities of the food which is set before us, and are warned against sitting in places that are damp and dangerous, or entering houses that are unwholesome or infectious. By means of the air, the odoriferous effluvia of plants and flowers are diffused over the fields, and conveyed to the nostrils, to increase our delightful sensations, when wandering among the scenes of nature.

9. Air is likewise the medium of sounds. In consequence of its elasticity and undulating

motion, it conveys to us knowledge and enjoyment of different kinds, which cannot be conveyed to the organs of sight, of taste, or of smell. A few strokes on a large bell will, in the course of a few seconds, by the undulation of the atmosphere, reach the ears of a hundred thousand men, and convey intimations either of joy or terror. The sounds produced by the undulations of the air may be considered as so many couriers running backward and forward, and in every direction, to warn us of danger, or to inspire us with joy, and to communicate various delightful sensations. When we walk along the road, musing, and unapprehensive of danger, a mail-coach may be whirling on in its rapid career, and just at our heels, ready to roll over us; but the air, like a watchful friend, dispatches a courier from a considerable distance to warn us that danger is approaching, and to remove to the path of safety. While we walk along the streets of London, and other cities, we are continually in danger of cabs, coaches, drays, and other vehicles, rolling upon us; and were it not that the air, by its undulations, gives us timely notice of their approach, the accidents from this cause which occasionally occur, would be much more numerous than they now are. To this property of the air, we owe all the advantages we derive from hearing sermons and lectures, and all the pleasures we enjoy from friendly and instructive conversation. By means of the tongue and the lips we form articulate sounds, which, by the previous consent of mankind, become the signs of certain ideas; these sounds are conveyed to the ears of our friends, and inform them of the thoughts and ideas that were previously passing through our minds, and their understandings and hearts become impressed with the same sentiments. Without the ministration of the atmosphere in such cases, all would be sullen and unmeaning listlessness and silence, as in the intercourse of the deaf and dumb. So that the air may be considered as the cement of society—the medium of communication between one mind and another, and the interpreter of the thoughts and purposes of mankind.

To the same cause, we are indebted for all the pleasures and harmonies of music. Music is one of the purest and most refined of our sensitive pleasures. It possesses the power of charming our ears, soothing our passions, and affecting our hearts; it dissipates the gloom of melancholy, animates the vital spirits, and gives sublimity to our thoughts and sentiments. When a lady tunes her melodious voice, or touches with her fingers the keys of the piano-forte, or the strings of the lyre, the air distributes every musical variation and every note, with the utmost precision. It conveys its message with the greatest impartiality to the ear of every listener. Though many instruments may be employed, and a thousand persons be present, and placed in every direction, it distributes the harmony alike to every ear. It keeps the most exact time—it conveys the slightest inflections of the voice, and the smallest variation of a tone. It runs through the whole compass of music, swells the sounds, and makes them even thunder in our ears. The next moment, it makes them flutter and melt into dying strains. After this, it swells the notes again, and sinks them in their turns. Thus it expresses, in the most lovely manner, every passion and emotion of the soul, and charms every heart with its persuasive sounds.

That all the effects now stated are owing to the ministration of the atmosphere, is proved by one decisive experiment. Place a small bell under the receiver of an air-pump; let it be rung, and the sound will be heard at a considerable distance. Exhaust the air from the receiver, and the sound can scarcely be heard by the nicest ear. Even in places where the air is not excluded, but only highly rarefied, as in the higher regions of the atmosphere, sounds are scarcely heard. Fredlichius, a gentleman of Hungary, informs us, that when he was on one of the loftiest tops of the Carpathian mountains, he fired a pistol, which at first made no greater noise than if he had only broken a stick or a staff; but after a little time there was a murmuring for awhile which filled the valleys and woods below. Descending to the lower valleys and the rugged rocks, he fired again, which made a dreadful sound, as if great guns had been discharged, and as if the whole mountain had begun to tumble about his ears. The sound lasted for half a quarter of an hour, until it had reached the most secret caverns, where the sound was enlarged and reflected back in every direction. These facts show that the elasticity of the air, which is always greatest where the air is densest, is essential to the propagation of sound.

10. The atmosphere is the cause of that splendor and universal light around us, which lays open to our view the landscape of the world. Were this atmosphere destroyed, we might see the sun without enjoying the light and brilliancy of day. That luminary would, indeed, strike our eyes with a vivid brightness when we turned round to behold his flaming orb; but it would appear only as a blazing fire during night in a spacious plain, where all is gloom and darkness around.—It would suddenly burst on our view in the eastern horizon, in the morning, and would not change its aspect in the least, during its course through the heavens, until it suddenly disappeared in the western sky. The objects immediately around us would be partially visible; but the rays of the sun which fell on distant objects would be forever lost in the expanse of the heavens; and when we turned our back to the sun, nothing would present itself, but an abyss of darkness, and the whole horizon involved in a dismal gloom. The number of objects in the heavens would, indeed, be augmented, for the stars would shine through a canopy as black as ebony, even when the sun was above the horizon; but all the gay coloring of the terrestrial landscape, which now delights the eye and the imagination, would be forever vailed from the inhabitants of the world. In such a state of things, it would be always night; and the difference between such a night and that which we now enjoy, would be, that the celestial orbs, instead of being grounded on a beautiful azure sky, would appear on a black canopy, like so many white points on a dismal mourning carpet.

But the Almighty, whose arrangements have all a respect to the happiness of his creatures, has enveloped our globe with an atmosphere, and has endowed it with a capacity of reflecting and refracting the rays of light in all directions. This atmosphere, too, is charged with innumerable myriads of watery particles, exhaled by evaporation from every region of the sea and land. In the serenest days of summer, when no clouds nor vapors are to be seen, these rarefied particles of water, which are imperceptible to the keenest eye, fill the whole sphere of the atmosphere around us, both above and below the region of the clouds. It is among these rarefied waters in the higher regions of the air that the rays of light reflected from the surface of the land meet, and are again reflected in every direction to the earth;

and hence is produced that beautiful azure color which distinguishes the aspect of the heavens. This azure is sometimes lighter, according to the quantity of the rays which enter the atmosphere, and sometimes darker, when the absence of the twilight hightens the blue of the celestial concave, by means of that black and void space which lies beyond the limits of the atmosphere. In corroboration of these remarks, it may be noticed, that the higher we ascend above the surface of the earth, the darker does the sky appear. And hence all travelers affirm, that, on the tops of lofty mountains, it sometimes appears as black as ebony, which causes the Milky Way to appear like a pure flame shot across the heavens, and the stars to shine with a greater brightness, and to appear far more numerous than in the plains below.

11. The atmosphere is the cause of the morning and evening twilight. We all know that the day is gradually ushered in after the darkness of the night. More than an hour before the rising of the sun, in this part of the world, a streak of light appears in the eastern horizon. This light increases in brilliancy every moment—the landscape of the earth, which had been previously covered with a mantle of blackness, appears gradually to emerge from an abyss of darkness, like the light at the first creation—the circle of the horizon becomes inflamed with a bright vermilion—the mountain tops are tinged with purple; and at length appears the most beautiful and sublime object in nature, the sun rising in his might and glory. And, when this luminary has described the circuit of the heavens, and passed the verge of the western horizon, darkness does not come on instantaneously, but by slow and imperceptible degrees, so as to warn us to prepare for its approach. The season of twilight, particularly that of a summer evening, is perhaps one of the most agreeable and interesting periods of the day. How many delightful walks and excursions—how many cheerful and solemn musings—how many endearing intercourses of love and friendship does it recall to our recollection, when we strolled along the solitary walks, or reclined in the bower of friendship, until the rising moon and the twinkling stars called us to our nightly repose!

Now, all such pleasures and advantages, derived from the twilight, are owing to the agency of the atmosphere. When the sun approaches in the morning within eighteen degrees of the horizon, his rays strike obliquely on the higher parts of the atmosphere, and, instead of passing directly forward, they are refracted, or bent a little downward, and thus descend by inflection to the earth. In this way we reap the benefit of those rays which would otherwise have been totally lost, and enjoy the light of day for a considerable time before the sun reaches the horizon. It is owing to the same cause that the sun is visible several minutes before he is actually above the horizon in the morning, and after his setting in the evening. This increases the length of every day, about 6½ minutes at an average, which amounts to 3½ equinoctial days in a year, and nearly a whole year's sunshine in the course of a century. And, if we reckon an hour and a half of twilight in the morning and as much in the evening, at an average, through the different seasons, we have more than ninety equinoctial days of twilight throughout the year. This is a circumstance of the utmost importance to those who inhabit the polar regions; in consequence of which, the inhabitants of Nova Zembla and of Greenland enjoy the direct light of the sun for thirty-two days while he is under the horizon, beside the long twilight which precedes his rising, and continues after his descent below the horizon. But what would be the consequences if we had no twilight? Not only should we be deprived of the advantages now stated, but subjected to many inconveniences and dangers. Should the day break in upon us all at once in meridian brightness, immediately after the dark shades of night, our eyes would be dazzled, and in danger of being blinded by its excessive splendor. Should the night rush on in the same precipitate manner, and hurry us in a moment from the splendors of the day to the horrors of midnight, it would strike the living world with amazement. The traveler would be arrested in the midst of his journey, and bewildered with terror; and if the sky were then covered with clouds, the darkness would be so thick and black, that not the least glimmering ray would strike across the universal gloom nor a single object be perceived, even within the distance of a foot. Man would then appear as if he were placed without an object near him in the midst of infinite space—

> ———" Dark as was chaos, ere the infant sun
> Was rolled together, or had tried his beams
> Athwart the gloom profound."

These arrangements, then, by which light is reflected over the face of nature, and twilight is produced, evidently show the wisdom and intelligence of the Almighty Creator, and his benevolent regards to his sensitive and intelligent offspring. A few small bubbles of air and water appear very insignificant to the eye of man. But in the hand of the Almighty they work wonders of love and beneficence. He has distributed them over our heads in every direction with so much caution and skill, in order that the light of his sun and his stars might not be rendered useless to the world. With these invisible particles of water and air, he enriches and embellishes whatever he pleases; and in his hands they become an inexhaustible source of glory and happiness. From these insignificant atoms, he fetches the brightness of the aurora, and draws forth those twilights which lengthen our days, and prepare our eyes for receiving the brightness of the meridian sun. From these he produces the splendor of day, which the sun itself could never procure us. He makes them contribute to the preservation of that heat which nourishes the vegetable kingdom, and which is essential to the comfort of "everything that lives." Of them he has formed that magnificent arch which surrounds us on all sides, which enchants the eye of every beholder, and forms the canopy of our terrestrial habitation; for it is the light reflected from the air, and the innumerable particles of vapor it contains, which produces that beautiful azure which adorns the vault of heaven. This azure canopy the Creator might have painted with a darker hue, or even made it entirely black. But black is a sad and dismal color, which would have thrown a melancholy gloom over the face of nature. A deep red would have been almost as disagreeable and hurtful to the sight; a white color, by its excessive glare, would have been oppressive to every eye, and would have prevented the light of the planets and stars from being distinguished. A yellow would not have been quite so unsuitable; but this color was reserved for the aurora which adorns the sky before the rising of the sun. Beside, a whole arch of a yellow color would not have presented a sufficient contrast to the light of the celestial luminaries. The green, which is a pleasing color to the eye, would have formed a better ground for the light of the stars; but it is with this lovely color that the Almighty has adorned the surface of our earthly abode, and has spread it as a carpet under our feet; and it was necessary that there should be a contrast between the color of the earth and of the sky, in order to complete the beauty and the magnificence of the scene of nature. The blue is, on the whole, a mild and pleasant color, without gloom or sadness in it; and while it forms a contrast to the verdure of the fields, it has the additional merit of forming a proper ground on which luminous bodies may be seen, and thus hightens the luster and beauty of the stars.

In such admirable arrangements we cannot fail to perceive the marks of intelligence and skill, in causing the assemblage of invisible atoms to produce so many sublime and beneficent effects; and we must be void of gratitude, if we do not recognize the hand of Divine goodness in adorning our habitation with so many beautiful contrasts, and rendering every scene of nature subservient to our convenience and delight.

12. The transparency of the atmosphere is not the least of its advantages. It is not, indeed, perfectly transparent, otherwise it would not reflect the blue color of the sky, nor would the distant mountains appear bedimmed and tinged with purple. But it has such a degree of transparency, that every object on the terrestrial landscape, within a reasonable distance, can be distinctly perceived. Even objects at the distance of a hundred and fifty miles, are visible through the air; and the telescope, though it magnifies the aërial particles, can make objects, at the distance of twenty miles, appear as if they were placed at the distance of three hundred yards. Were the air tinged with the least degree of yellow, red, or green, it would give the same color to every other object, just as a stained glass makes every object seen through it appear of the same color as itself. Were its particles much larger, and more opaque than they now are, so as to become perceptible to the eye, we should never obtain a distinct view of any other object. We should then see the air and the exhalations rising from the surface of the earth continually before us, like the particles of dust in a darkened chamber, when the rays of the sun are admitted through a small hole.

But the Almighty, by rendering the air invisible, has enabled us, in the first place, to take an extensive and delightful view of his wonderful operations in heaven and earth, and of all the objects which immediately surround us—and, in the next place, has concealed from our eyes those objects which would have excited disagreeable sensations and even disgust. If the air, like all other bodies, were an object of sight, the exhalations from the earth and waters would be much more easily discovered. The smoke of our chimneys still remaining visible as it ascended, would disfigure the rich landscape of the world and obscure the canopy of heaven. We should perceive all those gross humors which an incessant perspiration drives out of the bodies of all animals, and all the filthy exhalations that rise from kitchens, dunghills, stagnant marshes, streets, and common sewers. We should be apt to imagine our situation both unsafe and contagious, unless we fled into deserts and mountains, to avoid those incessant annoyances which would be the unavoidable result of such a visibility of the air and its exhalations. At the same time, lest these vapors should prove injurious to us through their invisibility, the good providence of God has forewarned us of such danger, by imparting to us the sense of smell, and has also appointed the winds to disperse such nuisances, to carry them aloft, and to serve as the ventilator of the atmosphere; for by the sense of smell, we are enabled to perceive when we are within the range of pestilential effluvia; and the winds seldom permit the air to remain in a stagnant state, provided our habitations are so arranged as to be within the sphere of their influence.

If we wish to feel grateful to the Supreme Disposer of the universe for the blessings of that world in which he has placed us, it is requisite that we should frequently fix our attention on such circumstances as those now stated. We pass from one day to another, and frequently from one period of human life to another, without reflecting on those admirable contrivances which appear in every surrounding object, by which our comforts are secured, and the universe rendered a spectacle of beauty and grandeur. Because we have never yet contemplated a world in confusion and ruins, we are apt to imagine that the arrangements around us could not be otherwise than they presently are. But, were that Being who created the atmosphere to make only a very slight alteration in its constitution—were he just to alter two apparently insignificant circumstances—were he to deprive it of its refractive and reflective powers—and were he to render it visible by tinging it with any color, all other things remaining as they now are—immediately the scene of nature would be divested of all its beauty and magnificence—and this earth which now cheers so many millions of animated beings with its comforts and embellishments, would be transformed into a scene of misery, an abode of darkness and desolation.

13. Were the atmosphere capable of being frozen, or congealed into a solid body, the most disastrous consequences would immediately ensue. All other fluids with which we are acquainted are subject to congelation. Even spirits of wine, which long resist the influence of the cold, and are, therefore, used in our thermometers, have been converted into a solid mass, by the cold of northern regions; and quicksilver, which is naturlly a fluid substance, has been converted by cold into a compact body, capable of being hammered like a piece of lead. Nay, even some of the gases, or aërial fluids, show a disposition to congeal by a reduction of temperature. The oxygenized muriatic acid gas becomes concrete, and forms into crystals, at a temperature of near to that at which water freezes. All the gaseous substances, when they have lost their elasticity, by forming certain combinations, are disposed to assume the solid state if the temperature allow it. Ammoniacal gas, and carbonic acid gas become solid, as soon as they enter into combination; and hydrogen gas, the most subtile of the ponderable elastic fluids, forms, along with oxygen, that very water which is afterward congealed into ice. What is the reason, then, that the atmospheric air which we every moment breathe, is not subject to congelation? We know no other reason than the will of the Creator. Were we thoroughly acquainted with every particular respecting the nature of the gases of which it is composed, and the mode of their combination, we might, perhaps, discover the physical cause of this singular property; but still we should ultimately have to refer it to the Divine purpose and will that such a cause existed. We know that the vapors which are suspended in the higher regions of the atmosphere, are frequently congealed into hailstones of considerable size, and were

any large portions of the air around us to be congealed in a similar manner, it is easy to foresee what disastrous effects would quickly be produced; and were the whole atmosphere to be frozen into a solid body, destruction would inevitably seize upon all the tribes of the living world, and the beautiful face of nature we now behold, would be transformed into a chaos.

Such is the intimate connection that subsists between every part of the system of nature, and such is the exquisite mechanism with which all its parts are constructed and arranged, that if a single wheel or pinion of this vast machine were either wanting or deranged, the whole system would soon be dissolved and fall into ruins. But that Almighty Being who sits on the throne of the universe, presides over all its subordinate movements, preserves every element in its respective station, and directs the apparently jarring principles of nature to accomplish his wise and benevolent designs.

In fine, we may just farther remark, that man has acquired a certain degree of sovereignty over the atmosphere, by which he renders it subservient to his comforts, and to the execution of his designs He causes it to sigh in the pipe, to complain in the flute, to thunder in the trumpet and the gong, and to utter a thousand melodious strains in the piano-forte and the organ. He causes it to announce tidings of joy or sorrow. He forces it to grind his corn, to blow his furnace, to winnow his grain, to raise water from the deepest pits, and to extinguish the flames when his buildings are on fire. He compels it to act as a prime mover in an endless variety of machinery, and by its agency, in combination with other powers, ten thousands of wheels and pinions are daily set in motion—power looms are weaving fabrics of various descriptions—spinning-jennies are set in action, steam vessels impelled along rivers, and across oceans—and railway trains carried forward in every direction with the most rapid motions. He yokes it to his ships, and compels it to expand the sails, and to waft him across the billows of the ocean to the remotest shores. And, in short, it is on the wings of the atmosphere that he raises himself, with his balloons, above the mountain-tops, looks down from on high on the dusky earth, and ranges at large through the region of the clouds.

Thus, a few of the beneficial effects produced by the atmosphere in the system of nature have been briefly stated. Its influence is essential to the germination and growth of plants, to the preservation of water in a state of fluidity, to the existence of fire and flame, to the respiration of all kinds of animals, to the process of evaporation, and the production of rain and dew; to support the clouds and to give buoyancy to the feathered tribes. It is the region of winds—the vehicle of smells—the medium of sounds, and the source of all the pleasures we derive from the harmonies of music; it is the cause of that universal light and splendor which are diffused around us, and of the advantages we derive from the morning and evening twilight; and all these advantages are more fully secured by the transparency of its particles, and by its being rendered incapable of being congealed into a solid body.

What, then, would be the consequences were the earth to be divested of its atmosphere? Were the hand of Omnipotence to detach this body of air from our globe, and could we suppose living beings at the same time to exist, the landscape of the earth would be disrobed of all its vegetable beauties, and not a plant nor flower would be seen over the whole face of nature; the springs and rivers would cease to flow, even the waters of the mighty deep would be dried up, and its lowest caverns be exposed to view, like frightful and hideous deserts. No fire nor heat would cheer the abodes of man, either by day or by night, no rains nor dews would refresh the fields, no gentle zephyrs would blow, nor aromatic perfumes be wafted from blooming flowers. The birds would no longer wing their flight on high, nor would their warblings be heard among the groves. No sound whatever would be heard throughout the whole expanse of nature, universal silence would reign undisturbed over the world, and the delights of music be forever unknown. The morning would no longer be ushered in by the dawn, nor the day protracted by the evening twilight. All would be gloom and obscurity by day except in that quarter of the heavens where the sun appeared, and no artificial light nor flame could be procured to cheer the darkness of the night. The whole surface of the globe would present one wide prospect of barrenness and desolation, without a single object of beauty to relieve the horrors of the scene; and this earth, which now presents to the beholder so many objects of sublimity and beauty, would appear as if it had sunk into the primitive chaos whence it arose. But, as we are certain that, according to the present economy of the animal system, no living creatures could exist in such a state of things, it would be an inevitable consequence of the annihilation of the atmosphere, that all the myriads of living beings which now people the waters and the earth, would sink into remediless destruction, and the great globe we inhabit be transformed into one immense sepulcher, without enjoyment, motion, or life.

If, therefore, the Creator had not a regard to the happiness of his sensitive and intelligent offspring—or, if he wished to transform this globe into an abode of darkness and a scene of misery, he has only to support the functions of animal life on a new principle, and then to sweep from the earth the atmosphere with which it is now environed, and the dismal catastrophe is at once accomplished. Such a consideration shows us the propriety and the emphasis of the language of Inspiration, "In Him we live, and move, and have our being"—"In his hand is the soul of every living thing, and the breath of all mankind." But since we are assured that "the Lord is good to all: and his tender mercies are over all his works," and as we find no arrangement in the system of the universe whose ultimate object is to produce pain or misery to any sensitive being; we have no fear that such a catastrophe will ever be permitted to take place. At the same time, we know not what the great ends of his moral government may incline the Deity to perform. We know that, at one period, the system of nature connected with this globe was disarranged on account of the wickedness of its inhabitants, and a deluge of waters overwhelmed all the abodes of men. This catastrophe changed the aspect of the earth and atmosphere, and produced convulsions which shook the foundations of the earth, and disrupted its solid strata; the vestiges of which are still visible in every land, and form some of the subjects of scientific investigation. And, therefore, were the inhabitants of the world ever again to rise to the same pitch of wickedness as they did before the flood, we know not but the Almighty, instead of covering the earth with an abyss of water, might detach from it the surrounding atmosphere, and leave its inhabitants to the effect of such an awful catastrophe

We learn from Revelation, that a period is approaching, "when the elements shall melt with fervent heat, the earth also, and the works that are therein shall be burned up." In the hand of Him who sits on the throne of the universe, the atmosphere is fitted to become the means of producing this tremendous event. The atmosphere, as formerly stated, consists chiefly of two fluids, or gases, of very opposite qualities; one of these, namely oxygen gas, is the principle of combustion, and forms about one-fifth part of atmospheric air; the other, namely nitrogen, instantly extinguishes every species of fire or flame. Were the nitrogen, then, which forms four-fifths of the atmosphere, to be swept away, and the oxygen left to exert its native energies, all the combustible substances on the face of the earth would instantly take fire, nay, the hardest stones, the most solid rocks, and even water itself, would blaze under its force with such energy as to carry destruction throughout the expanse of nature. Such are the elementary principles in the hand and under the superintendence of the Almighty, which are ready at his command to bring into effect all the events, changes, and revolutions, in relation to our world, which are predicted in the word of Divine Revelation.

CHAPTER VIII.

THE WISDOM AND BENEVOLENCE OF THE CREATOR, AS DISPLAYED IN THE CONSTITUTION OF THE ATMOSPHERE.

As this topic has been partially alluded to in the preceding chapter, only two or three additional illustrations may now be given.

1. The wisdom and goodness of God are manifest in the proportion which subsists between the different gases of which the atmosphere is composed. Were the oxygen less in quantity than it now is—were it, for example, in the proportion of fifteen to eighty-five, in a hundred parts of nitrogen, instead of twenty-one to seventy-nine, fire would lose its strength, candles would not diffuse a sufficient light, plants would wither, and animals could not breathe without the utmost difficulty and pain. On the other hand, were the nitrogen diminished and the oxygen greatly increased, the least spark would set combustible bodies in a flame, and, in a few moments, they would be entirely consumed. Candles would be wasted in a few minutes after they were lighted, and would serve no other purpose than to dazzle our eyes with a transient blaze. Were a few houses in a large city set on fire such would be the rapidity with which the flames would spread on every side, that in a few hours, or even minutes, the whole city would be wrapt in one wide and unquenchable blaze, and no human art could arrest the progress of the destructive conflagration. In such atmospheric air, iron would be calcined, instead of acquiring from the fire that softness necessary for forming it into various instruments; it would accelerate to a dangerous degree the circulation of the fluids in animal bodies, and produce a degree of heat through the influence of which they would rapidly waste and decay. We know by experience that nitric oxyde, which consists of forty-four parts of nitrogen and fifty-six of oxygen, produces instant suffocation in all animals that attempt to breathe it. We also know that the nitric acid, one of the most corrosive substances, is composed of seventy five parts oxygen and twenty-five parts nitrogen, which are only different proportions of the substances in atmospheric air; so that were the atmosphere composed of the same proportion of ingredients, our breathing it might produce the same effect as if we were to swallow a pint of aquafortis, or nitrous acid, which we all know would produce our immediate destruction. Can we, then, be at a loss to perceive, in the adjustment of the gases which compose our atmosphere, the wisdom and benevolence of the Deity; and, at the same time, the infinite comprehension of the Divine Mind, in foreseeing all the effects that would be produced by the different combinations of these gases, and in selecting that particular combination for the atmosphere which is precisely adapted to the existence and the comfort of living beings?

2. The Divine wisdom and goodness are no less conspicuous in determining the relative specific gravity of these gases. The oxygen gas is found to be a little heavier than common air, and the nitrogen a little lighter, which enables it to rise to the higher regions of the atmosphere. In respiration (or breathing) there are four stages or periods:—1. Inspiration, or drawing in the air.—2. A pause when the lungs are filled.—3. Expiration, or breathing out the air from the lungs;—and 4. A pause when the lungs are emptied. In breathing, the air which is evolved from the lungs at every expiration, consists chiefly of nitrogen (and a small portion of carbonic-acid gas), which is entirely unfit to be breathed again, and therefore, by its levity, rises above our heads before the next inspiration. The pause which takes place between every inspiration is evidently intended to allow time for the nitrogen gas which is thrown out of the lungs to rise in the air, in order that a fresh portion of the atmosphere may be taken in, and that the same air may not be breathed again. During that remarkable interval, there is time left for the noxious fluids to separate, the nitrogen to ascend while the carbonic-acid gas preponderates, leaving a space between for a fresh current of pure atmospheric air to rush into the lungs. But what would be the consequence if nitrogen gas, instead of being a little lighter, had been a slight degree heavier than common air, or of the same specific gravity? Then we should not only have been obliged to breathe a portion of it again at every inspiration, but the vast quantity of it thrown off by the respiration of men and other animals would have perpetually occupied the lower regions of the atmosphere; and especially in our chambers it would have accumulated to such a degree as to have produced diseases, pestilence and death, in rapid succession. But, being a little lighter than the surrounding atmosphere, it flies upward, and we never breathe it again until it has entered into new and salutary combinations. Such is the benevolent skill which the

great Author of nature has displayed for the preservation and comfort of the human family and of every species of animated existence.

3. The wisdom of the Creator is displayed in the process for supplying the waste of oxygen, and promoting the renovation of the atmosphere. The quantity of carbonic-acid which is daily formed, by combustion and the respiration of animals, is so great, that it must have rapidly increased to a most dangerous extent, had not the Almighty provided means for its being as rapidly decomposed. It is well known that whenever atmospheric air becomes charged with one-tenth of this gas, it is unfit for promoting combustion, and is fatal to most animals that breathe it. Hydrogen too, and carbureted hydrogen gas, are perpetually evolved at the surface of the earth from various sources, particularly from marshes, dunghills, and stagnant pools; and these are likewise prejudicial, and even destructive, to the animal creation. On the other hand, oxygen gas, which is the support of fire and animal life, is continually wasted by the various processes of combustion, as in the case of furnaces, burning candles, and domestic fires, and by the breathing of all animals. How, then, has the Allwise Creator contrived to supply this waste, and to protect the inhabitants of the world from the baneful effects of the other gases with which the atmosphere is contaminated? The process appears to be this:—Vegetables are so constituted that carbon and hydrogen are the necessary food of plants, and are conducive to the support of vegetable life. Their vegetating organs seize the carbonic-acid gas that comes within their reach, and while they appropriate the carbon to themselves, the oxygen is thrown off to renovate the atmosphere, by its union with the nitrogen ejected by animal respiration. The leaves of trees, shrubs, and other vegetables, give out, during the day, a large portion of oxygen gas, which unites with the surrounding air, keeps up the equilibrium of the gases, and preserves the salubrity of the atmosphere; for it is found by experience that the air in every region, in the most crowded cities, as well as in the open fields, contains the same quantity of oxygen gas. Thus it appears, that what is noxious to man is rendered beneficial to the vegetable tribes, and the oxygen, of which they do not stand in need, is separated by them, in its utmost purity, for the use of man. The wisdom, the simplicity, and the beneficence of this arrangement, cannot fail to produce conviction in every reflecting mind, that the laws of nature are not to be referred to blind chance, but to unerring intelligence combined with boundless beneficence. In every breath we draw, we may perceive, if we reflect on the above stated arrangements, that we are every moment indebted to an all-wise and almighty Being, in whom we live and move, for the continuance of our existence and for every comfort we possess, and therefore praise, adoration, and thanksgivings, are due to him from all the ranks of his intelligent offspring.

The department of the subject already treated, may now be concluded with a reflection or two, founded on the statements previously made.

1. From the invisibility of the atmosphere, and its numerous and important effects in the system of nature, we may learn the folly of denying the reality of a future and invisible state of existence, because the objects connected with that state are not perceptible by our corporeal senses. Who could have imagined, previously to modern discoveries, that all the functions of the vegetable kingdom, and all the comforts enjoyed by animated beings, are dependent upon the operation of a few invisible fluids, and that all the beauties of this lower creation are owing to the composition and decomposition, in a thousand different ways, of those gaseous substances whose operations are imperceptible to the keenest eye? And yet, the researches of modern chemistry have proved this fact to a demonstration, and shown us that every breath we draw, every pleasing sensation we feel, every portion of food we eat, every particle of heat that warms our apartments, every ray of artificial light that illuminates our streets and habitations, and every musical sound that enchants our ears, are owing to the unremitting motion and energy of invisible substances. And shall we, then, assert that the invisible principle of mind is not in existence or in action beyond the limits of this diurnal sphere, because its operation in that state lies beyond the range of our senses? We behold multitudes of rational beings daily departing from the living world; their organical frames crumbling into the dust, and the intellectual principle which animated them disappearing from mortal view. But we have no more reason to doubt that it is existing and operating in another sphere, than we have to doubt of the incessant energy of the invisible gases in giving life and beauty to sublunary nature. The disembodied spirits of men, whether existing in a pure ethereal form, or invested with fine material vehicles, may be employed in active services, and in sublime contemplations and investigations, of which we can at present form no adequate conception. We may, on the same grounds, form a conception of spirits suffering pains, anxieties, sorrows, and miseries, of different kinds, from a retrospective view of their former feelings, affections, and conduct, even when separated from those material organs with which they were formerly connected.

With regard to the great objects of religion, many of them lie beyond the range of our corporeal vision, as some of the agents employed in certain chemical processes elude our senses. Faith is described to be "the confident expectation of things hoped for, and the conviction of things which are not seen."* It substantiates and realizes those objects which are invisible to the eye of sense, or which lie far beyond its present range of view. Hence we are told that, in the present world, we should "walk by faith, not by sight." The objects connected with a future world are real, although they are placed at such a distance as not to be cognizable by our present visual organs. They are not all merely of a spiritual nature, they are also connected with material objects; but, between our sensitive organs and such objects, immeasurable regions of space intervene. The glorified body of the Redeemer of mankind is a material substance and an object of sense, and it inhabits a region somewhere within the bounds of the material creation, but its distance from the sphere in which we now reside removes it from our view; and we want that vigor and energy of our corporeal organs which the martyr Stephen seems to have enjoyed, when the heavens were opened, and "he saw the glory of God, and Jesus standing on the right hand of God."

In certain pools of water, animalcules are found, whose bodies, when magnified a hundred thousand times their natural size, are visible only as so many moving points. A considerable portion of the watery element on our globe is filled with such invisible inhabitants, which have never been perceived by the millionth part of mankind. In this and similar instances, we have an invisible world of animated beings existing around us, but no one calls in question their existence because they can only be observed by powerful microscopes, and are not perceptible by the majority of mankind. In short, the Divine Being pervades every part of space with his essence, and is intimately present with every one of his creatures, yet remains forever invisible to mortal eyes. But, on this ground, no one but an atheist ever calls in question his existence. In like manner, the invisibility of the objects connected with a future world ought to form no ground of doubt respecting the certainty and reality of their existence.

---

* Doddridge's Translation of Heb. xi. 1.

2. We may learn what ought to be our great object in the study of the sciences, and in the investigation of the phenomena of nature.

Some persons are disposed to consider science and natural history merely as genteel studies; others apply their minds to such subjects with the view of bearing a part in the conferences of men of learning. Some, again, prosecute such pursuits for the purpose of making collections of scarce and valuable curiosities, and of displaying a degree of knowledge and taste superior to those of their neighbors; and the greater part of mankind consider such studies as only an amusement, or a relaxation of mind from the fatigues of their daily avocations. But the study of nature and of science is highly dishonored by such groveling and contracted views. The prospect of the universe was exposed to our view for more noble and exalted purposes—to make us wiser and better men, to expand our views of the perfections of our Creator, and to inspire us with a grateful sense of all the blessings we daily receive from his bountiful hand.

There are two great objects which we ought always to keep in view in our investigations of the laws of nature and of the principles which operate in the material world. In the first place, to deduce from our observation of physical facts, those principles by which the powers of man may be extended—the useful arts improved and carried to perfection—and the comforts and enjoyments of mankind promoted and increased. In the next place, and chiefly, that our conceptions of the Creator's power, wisdom, benevolence, and superintending providence, may be enlarged, and that we may be more disposed to pay him that tribute of adoration and gratitude which is due to his name. Every study which sets the supreme Being on one side and nature on the other, is nothing more than an idle amusement—it is lost labor, and productive of little else than ignorance and error, pride and arrogance. To employ our thoughts on a thousand particulars in nature without directing them to the great Creator of all things—to profess to admire the displays of his wisdom, omnipotence, and goodness, while we violate his laws, and persist in a course of avarice or of dissipation—to be conscious of the blessings we every moment receive, and, at the same time, to be utterly unmindful of the hand from whence they flow—is a most glaring inconsistency, a shameful abuse of our understanding, and an act of the most flagrant ingratitude. All our knowledge is of no further importance to us than as it has an influence on our affections and conduct, and leads us to entertain impressive and reverential ideas of that almighty Being, "in whose hands our breath is, and whose are all our ways."

Let us, then, for the air we breathe, and the numerous benefits we derive from the surrounding atmosphere, display our gratitude, and consecrate all our powers and faculties to the service of Him who "made the earth by his power," and "hath established the world by his wisdom;"—who "causeth the vapors to ascend from the ends of the earth;" who "maketh lightnings with rain, and bringeth the wind out of his treasures," and whose "tender mercies are over all his works." To Him who hath created and redeemed us, all our powers and energies ought to be devoted from henceforth and forever, for he is worthy to receive all praise, honor, and dominion from men, from angels, and from the inhabitants of all the worlds dispersed throughout the regions of the universe

PART II.

ATMOSPHERIC PHENOMENA.

This is a subject which would admit of illustration sufficient to occupy a distinct volume; but the present limits will admit of only a very condensed and superficial view of the diversified objects connected with the phenomena of the atmosphere.

The atmospherical phenomena may be arranged under the following heads:—

I. Aqueous meteors; as evaporation, rain, snow hail, clouds, etc.
II. Winds, sea and land breezes, monsoons, hurricanes, etc.
III. Luminous and fiery meteors, as fire-balls, falling-stars, thunder and lightning, luminous arches, fata morgana, aërial specters, etc.

CHAPTER I.

AQUEOUS METEORS

1. Evaporation.—This is a process by which water and other substances are converted into elastic fluids by the influence of heat or caloric. Vapors being lighter than air, are raised into the upper regions of the atmosphere, and afterward, by a partial condensation, form those clouds which we see floating around us. They are elastic, invisible substances, like common air, but lighter; being to common air, according to Saussure's experiments, as ten to fourteen. If we expose water to heat, bubbles at first adhere to the sides of the vessel, which by degrees ascend to the surface and burst. These bubbles rise the more rapidly in proportion to the heat. Water is evaporated by the heat of the sun merely, and even without it in the open air; and the vapor rising into the air is condensed into clouds. An immense quantity of vapor is, in this way, raised from the different regions of the earth. In order to estimate the quantity thus raised, Dr. Watson, bishop of Landaff, made the following experiments:—Having provided a large drinking-glass, the area of the mouth of which was twenty square inches, he placed it with its mouth downward on a grass-plat which was mown close. The sun shone bright and hot, and there had been no rain for upward of a month. When the glass had stood on the grass-plat one quarter of an hour, and had collected a quantity of condensed vapor, he wiped its inside with a piece of muslin, the weight of which he had previously ascertained, and, as soon as the glass was wiped dry, the muslin was weighed. The medium increase of weight from various experiments, between twelve and three o'clock, was six grains in one quarter of an hour, from twenty square inches of earth. At this rate of evaporation, computing seven thousand grains troy to one pint of water, and eight pints to a gallon, it may be shown that one thousand six hundred gallons of water would be raised from one acre of ground in twenty-four hours. It is evident that the quantity will be still greater when the ground has been drenched with rain. To prove this, the same philosopher made two other experiments, one of them the day after the ground had been wetted by a thunder-shower; and to ascertain the circumstances more exactly, he took the heat of the earth by a thermometer laid on the grass, which in the first experiment was ninety-six degrees, when the evaporation was at the rate of 1973 gallons from an acre in twelve hours. The other experiment was made when there had been no rain for a week, and when the heat of the earth was 110 degrees; this experiment gave after the rate of 2800 gallons from an acre in twelve hours; the earth was hotter than the air, being exposed to the reflection of the sun's rays from a brick wall.

Hence it appears that evaporation must form a very important process in the economy of nature. The following are some facts in relation to this process. A much greater quantity of vapor rises during hot weather than during cold, as appears from the preceding experiments. Even where the temperature is the same, it varies according to circumstances. It is least of all in calm weather, greater when a breeze blows, and greatest with a strong wind. In our climate, the evaporation is about four times as great between the vernal and autumnal equinox as in the rest of the year. The degree of cold produced by evaporation is much greater when the air is warmer than the evaporating surface, than when the latter is the warmer of the two. From these and other facts, it is plain that tracts of land which are covered with trees are much colder than those where there is a less surface of vegetable matter, such grounds being found to emit one-third more vapor than the same space covered with water. Hence the important change of climate which a country undergoes by being cleared and cultivated America is not the same country at present, either with respect to temperature or salubrity, as it was several centuries ago, when it was covered with woods.

By this perspiration of the globe, it has been estimated that thirty-six inches of water per annum are raised from the surface of all the seas and rivers, and at least thirty inches from all the regions of the land. Hence it follows, that by this constant process of evaporation, 100,000 cubic miles of water are, every year, raised into the atmosphere; the greater part of which, at a certain hight, parts with its heat, and is condensed into clouds. Were this prodigious mass of water all to subsist in the atmosphere at once, it would increase about a twelfth part, and raise the barometer nearly three inches. But this never happens; no day passing without rain in some parts of the earth, so that part of the evaporated water is again constantly precipitated. The clouds formed by evaporation are carried by the winds over the land, broken, and precipitated by the action of mountains and trees, and thus rendered the means of watering the soil, and producing fertility throughout every region of the globe. It is owing solely to this process that our clothes, when washed and spread out to the open air, are soon dried. Were there no such process as evaporation in the system of nature, our linens and other clothes, when drenched in water, might remain for centuries without being dried—a circumstance which is seldom thought of by thoughtless men, but which demands our thanksgiving and gratitude. Hence we are called upon by the sacred writers to praise "the name of the Lord," who "causeth the vapors to ascend from the ends of the earth." Psalm cxxxv. 5.

2. *Clouds.*—The aqueous vapors, condensed by cold, or rising in the atmosphere to a region of air lighter than themselves, form strata of visible vapors, which we call clouds. These masses assume a great variety of shapes and configurations, which sometimes enliven the face of the sky, and at other times cause a gloom and shadow of darkness to overspread the landscape. The distance of the clouds above the surface of the earth varies at different times, and according to the nature of the cloud. Thin and light clouds frequently rise to the hight of four or five miles, as they are sometimes seen above the tops of the highest mountains. Their average hight may be reckoned about two and a half miles; but some dense clouds frequently descend so low as to touch mountains, hills, steeples, and even high trees, particularly during thunder-storms. The size of some of these clouds has been estimated to cover a space of fifteen or twenty square miles, and their thickness above a thousand feet. Their motions are generally directed by the winds, excepting when thunder is about to happen; in which case, they seem to move very slowly, and sometimes remain absolutely stationary, which is probably owing to their being impelled by two opposite currents of air.

Clouds have been arranged by modern naturalists into several classes, according to their different configurations, and the regions of the atmosphere where they are generally found. They have been distinguished by Howard into seven modifications, the peculiarities of which are supposed to be caused by the agency of electricity. There are three primary modifications—the cirrus, the cumulus, and the stratus; two which may be considered as intermediate in their nature—the cirro-cumulus, and the cirro-stratus; one which appears to be a compound—the cumulo-stratus; and, lastly, the cumulo-cirro-stratus, or nimbus, a state which immediately precedes the resolution of clouds into rain. These clouds are generally assigned to three atmospherical regions, the upper, the middle, and the lower one; to which a fourth, the lowest, may be added. In the upper region, the atmosphere is in such a state that it can receive and sustain only light and thin vapors, and to this district belongs the cirrus.

The cirrus has the least density of all the forms of cloud, but the greatest hight and variety of shape and direction. It is the first indication of serene and settled weather, and first shows itself in a few fibers spreading through the atmosphere. It sometimes looks like a fine whitish thread penciled on a clear blue sky. These fibers, by degrees, increase in length, and new fibers attach themselves to the sides. The duration of the cirrus is uncertain: in some kinds of weather, its figure is so rapidly and continually changed, that, after turning the eye from it for a few minutes, it will frequently be found almost completely changed. In other cases, it is sometimes visible for many hours and even days together, without much changing its appearance. From its usually curling appearance, this species of cloud is called the mare's-tail cloud.

The cumulus is a cloud of a dense structure, formed in the lower region of the atmosphere, and moving along in the current of wind which is next to the earth. Its first appearance is generally a small irregular spot, which increases in size, preserves a flat horizontal base, and assumes more or less of a conical figure. Such clouds are sometimes pretty well-defined hemispherical masses; at other times, they rise into mountains, ranged in one plane, their silvery summits presenting a beautiful appearance. Before rain they increase very rapidly, and descend low in the atmosphere. Great masses of them, during high winds, are seen in the quarter of the heavens toward which the wind blows, and indicate approaching calm and rain.

The stratus has a mean degree of density; it is the lowest of clouds, and its inferior surface frequently rests on the earth or on the water. The time of its appearance is about sunset, and it disappears soon after sunrise. It comprehends all those creeping mists which, in calm evenings, ascend in spreading sheets, like an inundation of water, from the bottom of valleys. Sometimes it remains quiet, and accumulates in layers, until the atmosphere is capable of sustaining its weight, when it assumes the position of the dark nimbus, and falls in a shower of rain.

The other species of clouds may be briefly stated, which are compound modifications. The cirro-cumulus consists of a collection of small white clouds, of a roundish form, which give to the sky the appearance called dappled, and are, in summer, considered as a prognostic of settled weather; or, at least, of an increase of temperature. They form a very beautiful sky, and are more frequent in summer than in winter. The cirro-stratus is generally in the form of long horizontal streaks, which are ever shifting their figure and position. It precedes wind and rain, the near or distant approach of which may sometimes be estimated from its greater or less abundance. It is frequently seen in the intervals of storms. The form and relative position, when seen in the distance, frequently give the idea of shoals of fish. It is that modification which most frequently exhibits the phenomena of the solar and lunar halo. The cumulo-stratus is a large, lofty, dense cloud, which may be compared to a mushroom, with a very thick, short stem. It rises through the interstices of the superior clouds; and the whole, seen as it passes off in the distant horizon, presents to the fancy mountains covered with snow intersected with dark ridges, rocks, towers, and other objects. Before thunder-storms, it frequently appears reddish. The nimbus is the cloud of rain. Before rain takes place, the clouds are uniformly found to undergo a change, attended with appearances sufficiently remarkable to indicate this as a distinct modification of clouds. It consists of a horizontal sheet, above which the cirrus spreads, while the cumulus enters it laterally, and from beneath.

Clouds are frequently highly charged with electricity. These not only produce violent storms of thunder and lightning, but are sometimes the cause of the destruction of life and the most dreadful devastations. In the year 1772, a bright cloud was observed, at midnight, to cover a mountain in the island of Java, which emitted flames of fire so luminous, that the night became as clear as day. It destroyed everything for twenty miles around: buildings were demolished, plantations buried in the earth; fifteen thousand cattle, a vast number of horses and other animals, and above two thousand human beings, were destroyed by the agency of this tremendous cloud. On the 29th of October, 1757, in the island of Malta, a little after midnight, a great black cloud appeared, which changed its color as it approached the city, until it became like a flame of fire, mixed with black smoke, and a dreadful noise was heard on its approach. It tore an English ship to pieces, and carried the masts, sails, and cordage, to a great distance. Small boats, in its course, were broken to pieces and sunk. In passing through the city, it laid in ruins everything in its way; houses were leveled with the ground, the roofs of churches were demolished; not one steeple was left in its passage, and the bells, together with the spires, were carried to a distance. In this awful catastrophe, the number of human beings killed and wounded amounted to nearly two hundred. Thus it appears that, while clouds serve occasionally as so many screens to abate the heat of the sun in warm countries, and form depositories of rains, which water and fertilize the earth, they are also sometimes used in the hands of the Almighty as instruments for the infliction of his judgments upon the nations; for the clouds are his chariots, the thunder his voice, and he "walketh upon the wings of the wind."

3. *Rain.*—We have already stated that the waters of the earth, by evaporation, yield a certain quantity of moisture to the air, which, being condensed, assumes the form of clouds, floating at different distances above us in the atmosphere. Whatever suddenly disturbs the heat or density of the air, or the electricity of the clouds, occasions the particles of vapor to rush together, and form drops of water too heavy to continue suspended in the atmosphere; they fall in the shape of rain, and increase in size as they fall, by combining with the floating vapors as they pass through them. We have but an obscure conception, however, of the chemical nature of vapor, and of the chemical processes which are going on in the production of vapor, and its subsequent resolution into rain. Dr. Thomson has this general remark on the subject, after quoting the opinions of Dr. Watson, Dr. Hales, and others, that "the formation of the clouds and rain cannot be accounted for by a single principle with which we are acquainted. It is neither owing to the saturation of the atmosphere, nor the diminution of heat, nor the mixture of airs of different temperatures; for clouds are often formed without any wind at all, either above or below them: and even if this mixture constantly took place, the precipitation, instead of accounting for rain, would be almost imperceptible" Instead, therefore, of detailing conflicting opinions on this subject, we shall state only a few general facts in relation to rain.

It is worthy of our notice, that drops of rain are always found larger in the lower regions of the atmosphere. In going down a high mountain in the time of rain, the drops gradually increase, until, reaching the bottom, they increase from a drizzling shower to a heavy rain. To ascertain the generality of this fact, Dr. Heberden, in the year 1776, made the following experiment. He placed a rain-gauge on the square part of the roof of Westminster Abbey, another on the top of a neighboring house, considerably lower than the first, and another on the ground, in an adjoining garden. The rain collected in each was as follows:—top of Westminster Abbey, twelve inches; top of the house, eighteen inches; and on the ground, twenty-two inches; so that more rain was collected in the lower than in the upper rain-gauge. The proportions of rain vary in different months of the year. In summer, we have not so many rainy days as in winter; but the showers are then heavier, the streams of rain closer together, and the quantity which falls is greater than during any other season. Dr. Dalton states that the first six months of the year may be regarded as dry, and the last six as wet months. From certain long-continued observations, it has been inferred that, in spring, it rains oftener in the evening than in the morning; but that toward the end of the summer, oftener in the morning than in the evening; and that storms at this time are apt to occur a little after sunrise. In the progression of the seasons, rain falls at all times during the twenty-four hours, but it has been ascertained that much less falls by day than by night.*

The annual quantity of rain is greatest in tropical countries, and diminishes as we approach the pole, owing to the greater evaporative qualities of the atmosphere in warm than in cold countries. Within the tropic, rain is not of the drizzling character of rain in the temperate zone, but generally falls in such torrents as in other zones would be called waterspouts, and they produce greater floods in a single day than in Europe in six days. Winter is distinguished from summer chiefly by the quantity of rain, which, for six months, is often constant for many days together, and lasts a certain number of hours per day. The rivers, in consequence, overflow, and in many countries produce inundations, which intercept all communications between neighboring towns and villages. The mean quantity of rain which falls annually in England is thirty-two inches. In the western parts of Scotland, the depth is from thirty to thirty-five inches; in the eastern parts, from twenty-four to twenty-eight inches. At Edinburgh, it is twenty-four inches and a half; and in London, twenty-two and one-fifth. There is more rain in the western part of Britain than in the eastern, because these parts receive the first clouds as they are brought from the Atlantic by the westerly winds. In the West Indies, one hundred and twenty inches fall annually; and, in the East Indies, from eighty to one hundred inches. At Bombay, eighty-two inches, and at Calcutta, eighty-one inches fall annually.

When mountain-ranges, and other distant objects, appear nearer to us than usual—when sounds are heard more clearly from a distance—when the odor of plants is more than usually powerful, rain may be soon expected. Ducks, geese, and other water-fowls, before the approach of rain, may be seen to throw water, with their bills, over their heads. Cattle may likewise be seen stretching out their necks, and snuffing in the air with distended nostrils. Dogs, closely confined in a room, become drowsy and stupid before rain; the same is observed in cats, though in a less degree; horses neigh frequently; cattle low; the fallow-deer become restless; and swallows fly in a low course. Delicate persons are often affected, before rain, with headaches, pains in old sores which have healed, irritability of temper, the aching of corns, and excessive nervousness. Several flowers and plants are prognosticators of rain. When the flower of the chickweed closes, showery weather or continued rain may be expected. The trefoil, the convolvulus, and other plants, contract their leaves before the approach of rain. When the moon is of a pure silvery color, good weather is indicated; but when it has a brownish tint, rain may be expected. When stars are surrounded with colored halos, the approach of rain is indicated.

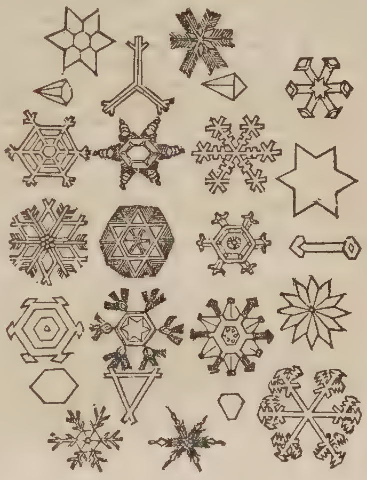
---

* It is said, that on the 29th of October, 1827, there fell, at Joyeus, in France, twenty-nine inches of rain in twenty-two hours; and, in eleven days, thirty-six inches; which is double that at Paris during the year.

In the present constitution of our globe, rain—though sometimes attended with a few inconveniences—is essential for promoting the enjoyments both of man and beast. It moistens and softens the earth, and prepares it for being cultivated, and for affording nourishment to the vegetable tribes, which both adorn the landscape of the world, and afford nourishment to the human race and to every species of animated existence. By falling on high mountains, it carries down with it many particles of loose earth, which serve to fertilize the surrounding valleys, and purifies the air from noxious exhalations, which tend, in their return to the earth, to meliorate the soil. It moderates the heat of the air, and forms one of the sources whence fountains and rivers are supplied. Without the influence of rain, trees, shrubs, and flowers would soon wither, sicken, and die, and every land be then turned into a barren wilderness. But when the clouds, at seasonable periods, pour down their watery treasures, all sublunary nature is invigorated and refreshed, and the vegetable productions of the soil are made verdant and flourishing, and adorn the surface of the earth with their gay attire and diversity of colors. In the language of the Psalmist, "The little hills rejoice on every side. The pastures are clothed with flocks; the valleys also are covered over with corn; they shout for joy, they also sing." He who at first formed the earth for man, "watereth the ridges thereof abundantly," maketh it "soft with showers," blesseth "the springing thereof," and crowneth the year with his goodness. It is represented by the inspired writers as the peculiar prerogative of Jehovah to send rain upon the earth: "Are there any among the vanities of the Gentiles that can cause rain? or can the heavens give showers? Art not thou He, O Lord our God?—for thou hast made all these things." The effects produced by the want of rain are emphatically described by these writers: "Thy heaven that is over thee is as brass, and the earth that is under thee as iron." "The field is wasted, the land mourneth; for the corn is wasted. * * Be ye ashamed, O ye husbandmen; howl, O ye vine-dressers, for the wheat and for the barley; because the harvest of the field is perished. The vine is dried up, and the fig-tree languisheth; the pomegranate-tree, the palm-tree also, and the apple-tree, even all the trees of the field, are withered. * * * How do the beasts groan! The herds of cattle are perplexed, because they have no pasture; yea, the flocks of sheep are made desolate; * * * for the rivers of waters are dried up, and the fire hath devoured the pastures of the wilderness." Joel i. 10–12, 18, 20.

4. *Snow.*—Snow consists of such vapors as are frozen while the particles are small. It differs from hail and hoar-frost, in being crystallized, which they are not. When a flake of snow is examined by a magnifying-glass, the whole of it will appear to be composed of fine shining spicula, diverging like rays from a center. As the flakes fall down through the atmosphere, they are continually joined by more of these radiated spicula, and thus increase in bulk, like the drops of rain or hailstones. Many of the flakes of snow are of a regular figure, for the most part stars of six points, and are as perfect and transparent ice as any we see on a pond or river. Their forms present an almost endless variety, are often very regular and beautiful, and reflect, with exceeding splendor, the rays of the sun. When they are very large, they are said to indicate the approach of thunder. The different forms which the flakes of snow exhibit, when viewed through microscopes, are represented in figure 6. These crystals of snow are from one-third to one thirty-fifth of an inch in diameter, in their natural size. Experiments have been made, which prove that snow is twenty-four times lighter than water, and that it fills up ten or twelve times more space at the moment of falling, than the water produced from it, when melted. It is worthy of remark, that previous to the fall of snow, and during its continuance, the temperature continues at about 32 degrees. The lightness of snow, although it is firm ice, is owing to the excess of its surface in comparison to the matter contained under it. Its whiteness is owing to the small particles into which it is divided; for ice, when pounded, will become equally white.

Fig. 6.



Snow is frequently formed in the lower regions of the atmosphere. A very cold stream of air admitted into a room in which the contained air is much warmer, and loaded with watery particles, will occasion its formation. In the huts of those who inhabit the arctic regions, snow is frequently formed in this manner. Dr. Robertson states that, in a crowded assembly-room in St. Petersburg, a stream of cold air was accidentally admitted into the room by a gentleman breaking a pane of glass, on which the vapor in the air was immediately congealed, and fell in the form of snow-flakes. In Siberia, Nova Zembla, and other northern regions, the same phenomenon frequently happens. Snow occurs in all regions of the globe at a certain hight above the level of the sea, but it falls more abundantly on plains as we proceed from the equator to the poles. In the arctic regions, snow falls nine days out of ten in the months of April, May, and June, and often to a depth of two or three inches in an hour. Among the mountains of Germany, Italy, and Switzerland, snow is sometimes accumulated to such an extent as to produce the most terrific and destructive effects, as in the case of the rolling avalanche. An avalanche is a mountain-mass of ice, or frozen snow, which is sometimes loosened from its base, and descends from the mountains with a force so terrible, that it crushes the traveler beneath its power, and buries hamlets and villages in a common grave. In the year 1749, the whole village of Rucras, in the canton of Grisons, in Switzerland, was covered, and at the same time, removed from its site, by an avalanche of this description. But this change, which happened in the night-time, was effected without the least noise; so that the inhabitants were not aware of it; and, on awakening in the morning, could not imagine why day-light did not dawn. A hundred persons were dug out of the snow, sixty of whom were still alive, the interstices between the snow containing sufficient air to support life. Not many years ago, an instance occurred of a family buried under one of these avalanches, and who continued in that situation for above a fortnight, remaining all that time in utter darkness, and incrusted in a body of snow several hundred feet in thickness. A massy beam supported the roof against this enormous pressure; and a milch ass, that happened to be thus incarcerated with the people, furnished sufficient nourishment for the support of life, until they were, at length, restored to the light of day.

The great Dispenser of universal bounty has so ordered it, that snow is eminently subservient, as well as all his other works, to his benevolent designs. As the winter cold is much more hurtful to vegetables than to animals, the plants would perish, if their roots were not preserved by some covering. God has, therefore, ordained that the rain, which in summer cools and revives the plants, should, in winter, fall in the form of a soft wool to cover the vegetables, and to guard them from the inclemency of frosts and winds. It prevents the internal heat of the earth from escaping, and forms a safe covering to the tender herb, until the winter cold has abated under the influence of the genial spring.

5. *Hail.*—Hail, which is a more compact mass of frozen water than snow, is formed by the congelation of vapor in the higher regions of the atmosphere. The drops of hail assume various figures, being sometimes round, at other times pyramidal, angular, thin, and flat, and sometimes stellated with six radii, like the small crystals of snow. When hail-stones are broken open, or cut across, they are sometimes found within to be of a spongy structure; sometimes the interior presents a very beautiful radiated appearance, and not unfrequently exhibits regular and very remarkable concentric plates. They are often of considerable dimensions. They vary in size from that of a small seed, to that of a boy's marble; and, in some instances, they have been found as large as the eggs of a goose; the small generally falling in the more northerly climates, and on the tops of mountains, and the larger in France, Spain, Italy, and other countries, toward the south of Europe. Hailstones have fallen in Scotland, which have been proved to weigh five ounces. In North America, they have sometimes been picked up weighing fifteen ounces; and on October 5th, 1831, one fell at Constantinople which weighed more than a pound! The average velocity with which they fall, has been estimated at seventy feet per second, or at the rate of fifty miles an hour; and consequently, their great momentum, arising from this velocity, frequently renders them very destructive, particularly in hot climates. They beat down the crops, strip trees of their leaves, fruits, and branches, and sometimes kill even large beasts and men. A few years ago, a tremendous storm happened in Gloucestershire, accompanied with a most remarkable hail-shower. The masses of ice which fell in places where the storm most fiercely raged, bore no resemblance to the usual state of hailstones in magnitude or *formation*, most of them being of a very irregular shape, broad, flat, and ragged, and many of them measuring nine inches in circumference. They appeared like fragments of a vast plate of ice, broken into small masses, by its descent toward the earth.

The phenomena attending the formation and fall of hail are but imperfectly understood, though it is certain they are connected with electricity, and hence, the frequent occurrence of hail-showers during violent storms of thunder and lightning. They occur principally in the temperate regions of the globe, less frequently between the tropics, and are almost unknown in the frigid zones. They are, also, more frequent in summer than in winter. In the south of France, and the adjacent countries, much damage has been produced by the ravages of hail-storms. To avert such ravages, hail-rods have lately been erected on the same principle as lightning rods. They consist of lofty poles tipped with metallic wires communicating with the earth. By thus subtracting the superabundant electricity of the clouds, it is supposed that the formation of hail might be prevented. It has been estimated by the "Linnean Society of Paris," from numerous experiments made in different districts, that "if these hail-rods were established through the whole of France, it would occasion an annual saving to the revenue of *fifty millions* of francs." It is also stated that, in many districts which were formerly year after year devastated by hail, the instrument has been adopted with complete success, while, in neighboring districts, not protected by hail-rods, the crops have been damaged as usual.

6. *Dew.*—Dew is vapor condensed into visible drops. It begins to be deposited about sunset, and is most abundant in valleys and plains near rivers and other collections of water, and abounds on those parts of the surface which are clothed with vegetation. In England, the dew is observed, like the drops of drizzling rain, upon the leaves of grass and other vegetables, upon wood, glass, porcelain, etc., or upon the earth, which is thereby rendered sensibly moist. It falls more copiously in spring and summer than at any other times of the year. In countries situated near the equator, the dews are generally observed in the morning throughout the year; and in some places in the east, where rain seldom falls, they are so copious, as, in a great measure, to supply its deficiency During the heat of the day, a great quantity of vapor is thrown into the atmosphere from the surface of the earth and waters. When the evening returns, if the vapor has not been carried off by currents, it will happen that more remains diffused in the general atmosphere than the temperature of the night will permit to subsist. A decomposition of the aqueous atmosphere then commences, and is continued until the general

temperature and aqueous pressure arrive at an equilibrium, or until the returning sun puts an end to the process.

Hoar-frost, which appears like a powdery crystallization on trees and herbage, is only frozen dew. The conversion of dew into hoar-frost is another wise arrangement of Nature, by which plants are protected from the severity of a freezing cold atmosphere. *Fogs* are clouds which float on the surface of the earth; and clouds are fogs in the higher regions of the atmosphere. From many elevated places they may be seen moving in the valleys, and from the valleys they may frequently be seen creeping along the sides of the mountains.

CHAPTER II.

WINDS

1. Winds *in general.*—Wind is the motion of a body of air flowing from one place to another. The earth, being surrounded by a fine invisible fluid, extending several miles above its surface, is acted upon by heat and cold arising from different causes. This appears to be the general cause of the phenomena of winds; and, according to the force or velocity with which the masses of air move, we use the terms, a breeze, a gale, a storm, a tornado, a whirlwind, a hurricane, etc. When a fire is made in the open air, the rarefied part of that fluid will ascend in a current, and the cooler and denser air will rush in on all sides, in consequence of which a wind is generated, and blows constantly toward the fire. The wind thus produced will be too inconsiderable to be perceived at any great distance, but the rarefaction which arises from natural causes may be such as to agitate our atmosphere sufficiently to produce those torrents of air which have always a powerful effect in nature, and which sometimes overwhelm and destroy the fairest and most superb productions of human art. Among the causes which produce this rarefaction of the atmosphere, and generate wind, the heat of the sun is not the least powerful. When the solar rays, by their reflection from the earth's surface, have heated or rarefied a portion of the surrounding air, the air so rarefied ascends into the higher regions of the atmosphere, and the colder air, by which it was surrounded, moves forward in a sensible current to fill the vacuity. Likewise, when a condensation of vapor in the atmosphere suddenly takes place, giving rise to clouds which speedily dissolve in rain, the temperature of the surrounding air is sensibly altered, and the colder rushing in upon the warmer, gives rise to a sudden gust of wind. In regard to the particular causes which produce the various winds which prevail in different regions of the globe, different opinions have been entertained by philosophers. And, therefore, instead of examining theories and doubtful opinions on this subject, the writer will confine himself to the statement of a few facts respecting the different species of winds as they are found to operate in different countries.

2. *General or permanent winds.*—Winds are commonly divided into three classes, namely, general, periodical, and variable winds. General winds are those which are permanent, and blow always in the same direction, and have received the name of trade-winds. These winds prevail chiefly within the tropics, and a few degrees beyond. On the north of the equator their direction is from the north-east, varying at times a point or two of the compass each way. On the south of the equator, they proceed from the south-east. These winds constantly range in one direction, but never extend farther than 30° from the equinoctial, either north or south. In the Atlantic and Pacific oceans, under the equator, the wind is almost always easterly; more to the northward, it generally blows between the north and east; and, more to the southward of the equator, it blows between the south and east. The origin of these winds appears to be as follows:—the powerful heat of the torrid zone rarefies the air of that region; in consequence of this rarefaction, the air rises, and, to supply its place, a colder body of air from each of the temperate zones, moves toward the equator. But these north and south winds pass from regions where the rotatory motion of the earth's surface is less, to those where it is greater. Unable at once to acquire this new velocity, they are left behind; and, instead of being north and south winds, as they would be if the earth's surface did not turn round, they become north-east and south-east winds.

3. *Periodical winds, or monsoons.*—Those winds, which blow in a certain direction for a time, and, at certain stated seasons, change, and blow for an equal space of time from the opposite point of the compass, are called *monsoons.* During the months of April, May, June, July, August, and September, the wind blows from the southward or south-eastward over the whole length of the Indian ocean, namely, between the parallels of 28° north, and 28° south latitude, and between the eastern coast of Africa, and the meridian that passes through the western part of Japan; but, in the other months, October, November, December, January, February, and March, the winds in all the parts of the Indian ocean shift round, and blow directly contrary to the course they held in the former six months. These winds suffer partial changes in particular places, owing to the form and position of the lands, and other circumstances. When they shift, or when the south-west monsoon is about to commence, it is ushered in by vast masses of clouds from the Indian ocean, accompanied with violent blasts of wind, which are succeeded by floods of rain, during which, the lightnings flash without intermission, and the thunders roll with loud and deafening peals; and, when it ceases, the rain pours down in large volumes. This terrific commotion of the elements lasts for many days.

4. *Land and sea-breezes.*—These are another kind of periodical winds which are common on the coasts and islands situated between the tropics. During the day, the wind blows for a certain number of hours from the sea to the land; but, when evening arrives, it changes its direction, and blows as many hours from the land to the sea. The cause of these alternations appears to be as follows:—water, being a better conductor of heat

than earth, is always of a more even temperature. During the day, therefore, the land becomes considerably heated, the air rarefied, and, consequently, in the afternoon, a breeze sets in from the sea, which is less heated at that time than the land. On the other hand, during the night, the earth loses its surplus heat, while the sea continues more even in its temperature. Toward morning, therefore, a breeze regularly proceeds from the land toward the ocean, where the air is warmer, and, consequently, more rarefied than on the shore.

5. *Variable winds.*—In most countries to the north and south of the tropics, the winds are very irregular and uncertain, and vary in their direction at certain seasons of the year. In Germany, the east wind is most frequent at Gottingen, Munich, Weissemburg, Dusseldorf, Erford, and Buda; the south-east, at Prague and Wirtzburg; the north-east, at Ratisbone; and the west, at Manheim and Berlin. Along the whole south-west of France, the wind blows most frequently from the north, north-west, and north-east; on the west coast, from the west, north-west, and south; and, on the north coast, from the south-west. In Great Britain, the north-east and south-west winds more frequently prevail, along with occasional north-west and south-east winds. From ten years' registers kept by the Royal Society, it appears that, in London, the winds blow in the following order: from the south-west, 112 days; north-east 58; north-west, 50; west, 53; south-east, 32; east, 26; south, 18; north, 16. From the same register, it appears that the south-west wind blows at an average more frequently than any other wind during every month of the year; that the north-east blows most constantly during January, March, April, May, and June, and that the north-west wind blows oftener from November to March, and more seldom during September and October, than any other months. In Scotland, the south-west is by far the most frequent wind over all the country, especially on the west coast. At Edinburgh, the westerly winds have been found to blow 230 days, and the easterly 135. At Saltcoats, in Ayrshire, the south-west wind blows three-fourths of the year, and along the whole coast of Moray, on the north-east side of Scotland, it blows for two-thirds of the year. East winds are common over all Britain, during April and May, but their influence is felt most severely on the eastern coast.

In our northern region, winds seldom excite much alarm, nor are they often attended with the disastrous results which are frequent in the tropical regions. It has, however, sometimes happened, even in England, that winds have produced the most appalling and destructive effects. In the great storm which happened on the 27th of December, 1703, the extraordinary power of the wind created a noise hoarse and dreadful, like thunder, which appalled every heart. Horror and confusion seized upon all, whether on land or at sea. One hundred and twenty-three persons were killed by the falling of dwellings, among whom were the bishop of Bath and his lady, by the fall of the episcopal palace. Eight thousand perished in the Severn and the Thames, and in ships blown away, and never heard of afterward. Land, houses, churches, corn, trees, rivers—all were damaged by its fury. Small buildings were swept away as chaff before the whirlwind; above 800 dwelling-houses were laid in ruins: 2000 stacks of chimneys were blown down in London; 15,000 sheep were destroyed on the banks of the Severn, and 20,000 in the county of Kent; 300 ships, 500 wherries, 300 ship-boats, and 100 lighters and barges, were entirely lost. The Eddystone Lighthouse was precipitated in the surrounding ocean, along with its ingenious architect and those that were with him. The damage done in the city of London alone, by this storm, was computed at above two millions of pounds sterling! Such are some of the dreadful effects of that invisible fluid which surrounds us, when put in rapid motion by the force of currents. Light as its particles seem to be, no human wisdom or power can, in such cases, avert its force, or withstand its dreadful and destructive agency, in allusion to which the Almighty is represented as riding "on the wings of the wind," and directing "the whirlwind and the storm."

6. *Noxious and poisonous winds.*—These winds prevail most generally in southern climes. Of these, the harmattan is a very singular wind, which blows periodically from the interior parts of Africa toward the Atlantic ocean. The season in which it prevails is, during the months of December, January, and February. It comes on at any hour of the day, and continues five or six days; and there are generally three or four returns of it every season. This wind is distinguished by a fog or haze, and extreme dryness; no dew falls during its continuance, vegetables wither, and the grass becomes dry like hay. The dryness is so extreme that the covers of books, though closely shut up in a trunk, are bent as if exposed to the fire. Household furniture is damaged, panels of wainscots split, and veneered work flies to pieces. The human body, likewise, feels the parching effects of the harmattan: the eyes, nostrils, lips, and palate, are rendered dry and uneasy; the lips and nose are inflamed, and there is a troublesome sensation of pricking heat on the skin. If the harmattan continue, the scarf-skin peels off, first from the hands and feet, and afterward from the rest of the body.

The sirocco is a wind which resembles, in some of its effects, the harmattan. It sometimes blows for several days together, and its medium heat is calculated at 112°; it is fatal to vegetation, and destructive to mankind, especially to those who are not natives of the country; it depresses the spirits in an unusual degree; it suspends the powers of digestion in such a manner, that those who venture to eat a heavy supper generally die during the night. The sick frequently sink under the pressure of their diseases, so that it is customary, in the morning after this wind has continued a whole night, to inquire who is dead. During the continuance of this wind, all nature appears to languish, vegetation withers and dies, the beasts of the field droop; the animal spirits are too much exhausted to admit of the least bodily exertion, and the spring and elasticity of the air appear to be lost. In the city of Palermo, in Sicily, where it frequently prevails, the inhabitants shut their doors and windows to exclude the air; where there are no window-shutters, wet blankets are hung on the inside of the windows, and the servants are kept constantly employed in sprinkling the apartments with water, and the streets and avenues of the city appear at such times to be nearly deserted. This wind is frequently felt in Greece, Italy, the Levant, and other parts of southern Europe; it is occasioned by currents of heated air from the deserts of Zahara in Africa; but happily it is not of long continuance. In Sicily, it seldom lasts longer than thirty-six or forty hours.

The samiel, or mortifying wind, is, perhaps beyond all others, dreadful in its effects. It generally blows on the southern coasts of Arabia, and the deserts near the city of Bagdad; and is supposed to have been the pestilence of the ancients, frequently killing all those who are involved in its passage. What its malignity consists in, none can tell, as no one has ever survived its effects to give information. It has been said that it frequently assumes a visible form, and darts in a kind of bluish vapor along the surface of the country. The natives of Persia and Arabia talk of its effects with terror; they describe it as under the conduct of a minister of vengeance, who governs its terrors, and raises or depresses it as he thinks proper. The camels, either by instinct or experience, have notice of its approach, and are so well aware of it, that they are said to make an unusual noise, and cover their noses in the sand. It blows over the desert in the months of July and August, and rushes with violence to the very gates of Bagdad, but never injures any person in the city. To escape its effects, travelers throw themselves as close as possible to the ground, and wait until it has passed by, which is commonly a few minutes. As soon as they who have life dare to rise up, they examine how it fares with their companions by pulling at their arms or legs; for, if they are destroyed by the wind, their limbs are absolutely mortified, and will come asunder. An extraordinary blasting wind is felt occasionally at Falkland's Islands, but it seldom continues above twenty-four hours. It cuts the herbage down as if fires had been made under it, so that the leaves are parched up and crumbled into dust. Fowls are seized with cramp, so as never to recover; and men are oppressed with a stopped perspiration, heaviness at the breast, and sore throats.

The simoon is a hot wind which prevails in Egypt, Arabia, Syria, and the adjacent countries. When it begins to blow in Arabia, the atmosphere assumes an alarming aspect. The sky becomes dark and heavy, the sun loses his splendor, and becomes of a violet color, and the air is thick from the subtile dust with which it is loaded. At first, the wind is light and rapid, and not remarkably hot; its temperature, however, soon increases, until it ranges at upward of 128°. When it occurs, all animated bodies discover it by the change it produces in them. The lungs are contracted and become painful, respiration is short and difficult, the skin parched and dry, and the body consumed by an internal heat. The streets are deserted, and the dead silence of night reigns everywhere. The inhabitants of towns and villages shut themselves up in their houses, and those of the desert in their tents, or in wells dug in the earth, where they wait the termination of this destructive heat. The only refuge travelers have from it is, to fall down with their faces close to the ground, and to continue as long as possible without drawing in their breath. Mr. Bruce thus describes it, in his journey through the desert:—"At eleven o'clock, while we contemplated the top of Chiggre, where we were to solace ourselves with water, Idris, our guide, cried out with a loud voice, 'Fall upon your faces, for here is the simoon.' I saw from the south-east a haze, in color like the purple part of the rainbow, which did not occupy twenty yards in breadth, about twelve feet from the ground, and it moved very rapidly, for I could scarce turn to fall upon the ground, with my head to the north, when I felt the heat of its current plainly on my face. We all lay flat on the ground as if dead, until Idris told us it was blown over. The meteor or purple haze which I saw was indeed passed, but the light air which still blew was of heat to threaten suffocation. For my part, I found distinctly in my breast that I had imbibed a part of it, nor was I free from an asthmatic affection until I was in Italy two years afterward."

Hurricanes are violent tempests of wind, accompanied with thunders and lightnings, rain, or hail. These fearful concussions of the atmosphere happen most frequently in the range of the West India Islands, and about the Cape of Good Hope. The forerunner of these hurricanes, when first seen, is only like a small black spot on the verge of the horizon, called by sailors the bull's eye. All this time a perfect calm reigns over sea and land, while at length, coming to the place where its fury is to fall, it invests the whole horizon with darkness. During its approach, a hollow murmur is heard in the cavities of the mountains, and animals, sensible of its approach, run over the fields to seek for shelter. Nothing can be more terrible than its violence when it begins. The sun, which, but a moment before, blazed in meridian splendor, is totally shut out, and a midnight darkness prevails, except that the air is incessantly illuminated with gleams of lightning, so vivid that one can see to read, and the rain pours down in torrents. All the elements seem to arm themselves for the destruction of human labors, and even of the scenes of nature herself. The velocity of the wind is such, that corn, vines, sugar-canes, forests, houses, boats, ships, are swept away, or buried in the deep.

A tornado is a sudden and violent gust of wind from all points of the compass. It partakes somewhat of the nature of a hurricane, but is still more violent in its effects. The winds seem to blow from every quarter, and settle upon one destined place, with such fury that nothing can resist their vehemence. When they have met in their central spot, the whirlwind begins with circular rapidity. The sphere every moment widens, as it continues to turn, and catches every object that lies within its attraction. The mariner, within the reach of its influence at sea, must try all his power and skill to avoid it, which, if he fail of doing, there is the greatest danger of his going to the bottom. Tornadoes most frequently rage along the coasts of Guinea, and other parts of western Africa.

Such are a few brief sketches of the phenomena of noxious and stormy winds. It is evident that they did not exist in the primitive state of our globe; for the operation of such agents of terror and destruction appears altogether inconsistent with the idea that man is at present in a paradisaical state, and possessed of that innocence and moral purity in which he was created. It appears incompatible with the idea of an Almighty Intelligence, possessed of boundless benevolence, that innocent beings should be so frequently subjected to the influence of such dreadful agents, by which they are swept from the living world in a manner so appalling and terrific. Man is, therefore, a creature who has fallen from his primitive state of integrity; and such fearful agents, and many others, as the volcano and the earthquake, are so many proofs and evidences of the depravity and fallen state of the human race; otherwise they would not be permitted to inhabit a world where so many destructive influences are in operation. An important change appears to have taken place in the constitution of the atmosphere at the period of the universal deluge, which probably may have given rise to many of the physical evils connected with this part of our terrestrial system; which may, in after ages, be in a great measure removed, when the earth shall be cultivated throughout its whole extent, and universal peace and brotherhood prevail among all nations. Notwithstanding, however, the occasional operation of these destructive agents to which we allude, the arrangements connected with our globe, in their prominent bearings, and considered as a whole, evidently display the long-suffering, the tender mercy, and the goodness of Jehovah, and should lead us to humble ourselves in his presence, under a sense of our manifold deviations from the path of his commandments.

The velocity of winds varies, from the gentlest breeze or an imperceptible movement, to a hundred miles an hour. Light airs may be considered as moving at the rate of from one to three miles an hour, or from a foot and a half, to four feet and two-fifths, per second; a breeze, from four to six miles an hour; a brisk gale, from ten to sixteen miles an hour; a fresh gale, from twenty to twenty-five miles; a strong gale, from thirty to thirty-five miles; a hard gale, from forty to forty-five miles; a storm or tempest, fifty miles; a great storm, sixty miles; a hurricane, eighty miles; a violent hurricane, tearing up trees, throwing down houses, etc., moves at the rate of one hundred miles an hour.

Notwithstanding the occasional ravages of winds, they produce many beneficial effects in the system of nature. They serve as ventilators for purifying the atmosphere; they dispel fogs and noxious vapors; they agitate the waters of the ocean, and prevent them from stagnation and putrefaction; in the heat of summer they fan us with gales and gentle breezes. By their mechanical force, windmills and other machinery are set in motion, and ships impelled across seas and oceans to the remotest corners of the globe, to promote commerce, learning, religion, and the mutual intercourse of human beings.

CHAPTER III.

LUMINOUS AND FIERY METEORS.

1. *The Aurora Borealis.*—This is one of the most splendid phenomena which appears in the visible sky, especially when its coruscations diffuse themselves over the whole face of the heavens. The appearances of the aurora may be arranged under the following particulars:—1. A horizontal light, like the morning twilight or break of day. This light generally appears in the north or north by west, and sometimes seems as if it broke out from a few darkish clouds. 2. Fine, slender, luminous beams, well-defined, and of a dense light. These frequently continue a half or a whole minute, apparently at rest, but more frequently with a quick lateral motion, that is, from east to west, or the contrary. 3. Flashes pointing upward, or in the same direction with the beams, which they always succeed. These are only momentary, and have no lateral motion, but they are generally repeated many times in a minute. They appear much broader, more diffuse, and of a weaker light than the beams; they grow gradually fainter until they disappear, and sometimes continue for several hours, flashing at intervals. Sometimes they are confined chiefly to the northern region of the heavens, and at other times illuminate the whole sky with their fantastic coruscations. Such are some of the general appearances of the aurora borealis, but they are strikingly varied at different times, and it is difficult accurately to describe the shifting and splendid phenomena they present.

The aurora has been occasionally seen in all ages: it is spoken of by Herodotus, Xenophon, Diodorus Siculus, Homer, Virgil, and Ossian, the Highland bard. Aristotle, in his work on meteors, describes it as "an appearance observed by night in calm weather, resembling flame mingled with smoke, or the distant appearance of burning stubble; the predominant colors being purple, bright red, and blood color." It has been more frequently observed in Great Britain since the year 1716, when, on the 6th of March, it appeared with a splendor which attracted universal attention, and was considered by many as prognostic of wars, famine and pestilence, and a foreign race of princes.

The following is a description of an aurora, as seen by Dr. Dalton:—"Attention was first excited by the remarkably red appearance of the clouds to the south, which afforded sufficient light to read by at eight o'clock in the evening, though there was no moonlight in the north. From half-past nine to ten, P. M., there was a large luminous horizontal arch to the southward, and one or more concentric arches northward. At half-past ten o'clock, streamers appeared very low in the south-east, running to and fro from west to south; they increased in number, and began to approach the zenith apparently with an accelerated velocity, when all of a sudden the whole hemisphere was covered with them, and exhibited such an appearance as surpasses all description. The intensity of the light, the prodigious number and velocity of the beams, the grand intermixture of all the primitive colors in their utmost splendor, variegating the glowing canopy with the most enchanting scenery, afforded an awful, but, at the same time, pleasing and most sublime spectacle. Every one gazed with astonishment, but the uncommon grandeur of the scene lasted only one minute; the variety of colors disappeared, and the beams were converted into the flashing radiations; but even then it surpassed all other appearances of the aurora; in short, the whole hemisphere was covered with it."

The writer had occasion to witness a splendid and somewhat terrific display of this phenomenon, in the vicinity of Dundee, on the 17th November, 1835. A little before nine o'clock, P. M., the coruscations first began to appear, which in a short time diffused all the brightness which appears in a moonlight evening. About ten o'clock, the aurora shone in all its splendor, when coruscations, or streams of light, more than thirty or forty degrees in length, appeared to issue from a central point near the zenith, and to extend themselves in every direction, south, north, east, and west, like the meridians on an artificial globe. The most singular feature displayed by this aurora was that of a number of streams of light of a dark red color, like blood, and resembling expansive sheets of flame, which were seen in all directions mingling their streams with the more brilliant yellow coruscations, and giving to the whole celestial concave an appearance of terrific grandeur, which seemed to impress the mind of every beholder with awe and terror. This display continued during the night until four o'clock next morning, and was visible over the whole island of Great Britain. In London, it produced such an effect, that the policemen, ignorant of its nature, hurried to and fro through all the avenues of that city in search of fires, which they imagined had burst forth from every quarter. On the evening of September 29, 1847, about ten o'clock, a brilliant and rather uncommon aurora made its appearance, near Dundee. The sky was strongly illuminated in the north, and numbers of spiral coruscations shot upward toward the zenith. But its most striking peculiarity was that, on a sudden, and in a portion of the sky which was perfectly clear, an immense stream of light began to blaze with a quivering motion, like a huge serpent, or in a form like the letter s, extending forty or fifty degrees in length, and several degrees in breadth. Such streams of brilliant light, which appeared and vanished with all the rapidity of lightning, were to be seen over most regions of the sky.

This phenomenon appears more frequently, and displays itself in still greater splendor in the polar regions than in our country. It is also said that, in those regions, a hissing sound is heard during its continuance. During the long nights of winter in those countries, particularly in Lapland and Greenland, its radiations, along with the light of the heavenly bodies, are sufficient to guide the inhabitants in their journeys, and to enable them to engage in all the other avocations of life. In the northern parts of Siberia, the aurora begins with single bright pillars rising in the north, which gradually increasing, comprehend a large space in the heavens, rush about from place to place with incredible velocity, and at last cover almost the whole sky up to the zenith, and produce an appearance as if a vast tent were expanded in the heavens glittering with gold, rubies, and sapphires. It has been found likewise, that these brilliant phenomena are visible in the south polar regions as well as in the north. The general appearance of the aurora borealis is pretty well described by Thomson, the poet of the "Seasons."

> "Silent from the north
> A blaze of meteors shoots; ensweeping first
> The lower skies, they all at once converge
> High to the crown of heaven, and all at once
> Relapsing quick, as quickly re-ascend
> And mix and thwart, extinguish and renew
> All ether coursing in a maze of light."

Various opinions have been formed as to the cause which produces the phenomena of the aurora. Most philosophers seem to agree that it is of an electrical nature, as its appearance can be imitated by artificial electricity. Dr. Faraday considers it as highly probable, "that it is a luminous accumulation of electricity flowing from the equator to the poles, for the restoration of electric equilibrium." But whatever may be the physical cause of the aurora, it presents to our view one of the most beautiful, sublime, and at the same time awful and mysterious phenomena which appear in our sky—while its coruscations sometimes cover with inconceivable magnificence, the concave of the whole hemisphere, changing their positions every moment, now resembling vast pyramids, or innumerable columns, now vanishing in a moment, leaving the heavens somber and black, and now returning with increased splendor, shedding a matchless glory over the heavens. Such striking phenomena evidently display the majesty and glory of the Creator and his power to cause the invisible elements of nature to produce the most grand and diversified scenery—and although their mode of operation is not thoroughly discovered, they are, doubtless, intended to subserve beneficial purposes in the system of creation.

2. *Luminous arches.*—These are somewhat striking phenomena, which sometimes precede, or accompany the aurora borealis, but they make their appearance only at very distant intervals. The writer has seen only four or five of these arches within the space of the last thirty years. One of the most brilliant of the arches appeared on the 27th of August, 1846, and was first perceived a few minutes before nine o'clock in the evening. It was a grand and beautiful luminous arch, which stretched from one side of the heavens to the other, forming a most resplendent object in a clear and serene sky. Its highest point was about seventy-five degrees above the southern horizon—a little above the brilliant star Vega Lyræ. Like all the other arches of this kind he has seen, it had a gradual motion downward toward the southern horizon, so that in the course of twenty minutes it was considerably below the star now mentioned. Its direction was from east by north, to west by south, or nearly at right angles with the magnetic meridian—which seems to indicate that it is connected with the operation of the magnetic principle. This is the exact direction of all the luminous arches now referred to, and they are all evidently connected with the appearance of the aurora borealis, and may be considered as a peculiar modification of this phenomenon. Its breadth was greater than that of a common rainbow; there appeared no prismatic colors, but a pure brilliant white, contrasting most beautifully with the deep azure of the sky. An aurora appeared at the same time in the north and north-west, but its coruscations were not very vivid, and continued only for a very short time. The arch began first gradually to disappear at its extremities, near the eastern and western horizon, and, about forty minutes after having been first seen, it was completely dissipated. The hight of such phenomena above the earth has been variously estimated. Euler estimated them at 1000 miles; Boscovich, at about 800; Bergman, at 460; and Dr. Dalton, at 150 miles, which is, perhaps, nearest the truth. Whatever may be the hight of the luminous arches, we have reason to believe that the elevation of the aurora borealis above the earth is the same, as they evidently are produced by the operation of the same cause.

3. *Fire-balls.*—These are a species of luminous or fiery bodies, which are occasionally seen to wing their flight through the upper regions, with a considerable degree of velocity and splendor. In tropical climates, these bodies are more frequently seen than in our more temperate regions. The following are a few brief descriptions of some of the meteors. Mr. Barham relates that, when he was riding in Jamaica, one evening, he beheld a ball of fire apparently about the bigness of a bomb, swiftly falling down with a great blaze. Approaching the place where it fell, he found the ground strangely broken up and plowed, and several holes appeared of the bigness of a man's head, and all the green herbage burried up near the holes; at the same time, a strong smell of sulphur. In the year 1676, a great globe of fire was seen at Bononia, in Italy, about forty minutes after sunset. It passed with a most rapid course, and at the rate of not less than one hundred and sixty miles a minute, and at last stood over the Adriatic sea. It crossed all Italy in its course, and by computation, it was found that it could not have been less than thirty-eight miles

above the surface of the earth. Wherever it approached, the inhabitants below could distinctly hear it, with a hissing noise, resembling that of a firework. It was heard to go off with a violent explosion. Its magnitude, when at Bononia, appeared twice as long as the moon, one way, and about as broad the other. It was estimated to be a mile long and half a mile broad.

One of the most striking and extraordinary meteors of this kind made its appearance on the 18th of August, 1783, about nine o'clock in the evening. It was seen in all parts of Great Britain, from the Shetland isles to the English channel, over all France, and the greatest part of Italy, and is supposed to have described a tract of at least one thousand miles over the surface of the earth. It appears to have burst and re-united several times, and the first bursting which was noticed was somewhere over Lincolnshire, in England. Its appearance produced universal wonder and alarm. When it was observed at Brussels, the moon appeared quite red, and the illumination was so great as totally to obliterate the stars. A report was heard some time after it disappeared, which was loudest in Lincolnshire, and afterward in the eastern parts of Kent. A hissing sound was said also to accompany its progress. At Greenwich, two bright balls, parallel to each other, led the way, and were followed by an expulsion of eight others. The balls were tinted first with a pure bright light, then followed a yellow mixed with azure, red, and green, which, with a coalition of bolder tints, and a reflection from the other balls, gave the most beautiful rotundity and variation of color with which the human eye could be charmed. The hight of this fireball was reckoned at from seventy to ninety miles, its diameter was estimated at nearly two miles, and its velocity at about 1000 miles a minute. The same year, on the 4th of October, at forty-three minutes past six in the evening, another meteor appeared nearly of the same description, but much smaller and of shorter duration. It was first perceived to the northward as a stream of fire, like the common shooting stars, but large; and presently burst out into that intensely bright bluish flame, which is peculiar to such meteors. It was nearly globular, but left behind it a dusky red streak of fire. After moving ten degrees in this state, it became suddenly extinct without any explosion. Its hight was estimated at between forty and fifty miles.

As to the physical causes which produce these extraordinary meteors, we are still in a great measure ignorant. The general opinion among philosophers is, that they owe their origin to the operation of electricity. The velocity with which these meteors wing their flight—the electrical phenomena attending them, the lambent flames and sparks proceeding from them—their connection with the aurora borealis, on whose appearance luminous balls have been seen formed and darting about with great velocity—and their general motions, which are constantly from or toward the north, or north-west — have been viewed as so many arguments corroborative of their electrical origin. Still it is difficult to account for all the phenomena exhibited by these bodies by electricity alone, since some of these bodies appeared to be of a denser and more compact structure than electricity could produce.

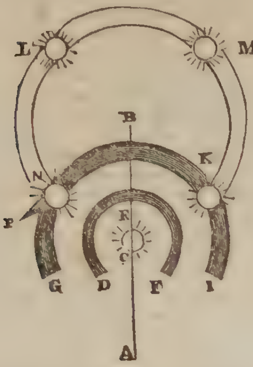
4. *Shooting or falling stars.*—These are meteors which are frequently seen darting through the sky, in the form of stars, and most frequently accompanied with a train of light. The nature of these bodies has not yet been well ascertained, and philosophers have of late been disposed to alter their former opinions respecting them. It appears, from certain late observations made at Breslau by Professor Brandes and his pupils, that the hight of some shooting stars is not less than five hundred miles, and that they move at the rate of eighteen miles in a second. A most extraordinary and wonderful display of the phenomena of shooting stars has of late occurred in different places, particularly in America. On the evening of the 12th and the morning of the 13th November, 1833, a shower of these meteors happened at Boston, New York, and other places, and their number was considered to equal one-half of the flakes which fill the air in an ordinary fall of snow. It was calculated that, in some places, they fell at the rate of 36,000 per hour, and the phenomena lasted more than seven hours. At Boston, the number of shooting-stars which were seen was estimated at two hundred and forty thousand. Similar phenomena, though not in such numbers, have appeared in various other places, and in the subsequent years, from the 12th to the 15th November, and hence they have been denominated the November meteors. M. Arago, the French philosopher, is of opinion, that such extraordinary phenomena cannot well be accounted for, unless it be supposed that, beside the planetary bodies which revolve around the sun, there are myriads of smaller bodies, which only become visible at the moment when they come within our atmosphere and assume a meteoric appearance; and that they move in groups, and also singly. Dr. Olmsted, of New Haven, who particularly investigated the meteoric showers of 1833, deduces the following among other conclusions:—That the distance of the body whence they emanated was about 2238 miles—that they entered the earth's atmosphere with a velocity of four miles per second—that some of the larger meteors must have been bodies of great size, not less than a mile in diameter—and, that they consisted of portions of a nebulous body which revolves around the sun, in one hundred and eighty-two days.

We may learn from such phenomena that, if the universe were not under the superintendence of a wise and benevolent Being, or if the powers of nature were left to act at random, the world in which we live might be subjected to manifold disasters from unknown bodies and unseen causes, from which we have hitherto been protected.

5. *Parhelia, or mock suns.*—A parhelion is a meteor in the form of a very bright light appearing on one side of the sun, and resembling that luminary. They generally seem about the size of the true sun, not quite so bright, though sometimes they are said to rival their parent luminary in splendor. When there is a number of them, they are not equal to each other in brightness, and externally they are tinged with colors like the rainbow. They differ in number and size; but they all agree in breadth, which is that of the apparent diameter of the sun. Appearances of this kind have been observed, both in ancient and in modern times, Gassendi, the Italian astronomer, relates, that in 1635 and 1636, he often saw one mock sun. Two were observed by M. de la Hire, in 1689, and the same number by Cassini, 1693; Mr. Grey, in 1700; Dr. Halley, in 1702; the Rev. Mr. Hamilton, in Dublin, in 1783; but the most remarkable appearances of this kind were seen at Rome by Scheiner; by Muschenbroeck, at Utrecht; and by Hevelius, at Sedan; by the former, four mock suns were observed, and by the latter seven.

The phenomenon of these meteors observed by Scheiner, at Rome, is represented at figure 7, in which A is the place of the observer; B, his zenith; C, the true sun; A B, a plane passing through the observer's eye, the true sun, and the zenith.

Fig. 7.



About the sun, C, there appeared two concentric rings, not complete, but diversified with colors. The lesser of them, D E F, was fuller and more perfect; and though it was open from D to F, yet those ends were perpetually endeavoring to unite, and sometimes they did so. The outer of these rings was much fainter, so as to be scarcely perceptible. It had, however, a variety of colors, but was very inconstant. The third circle was very large, and entirely white, passing through the middle of the sun, and everywhere parallel to the horizon. In the intersection of this circle, and the outward iris, G K I, there broke out two parhelia, N and K. The brightness of the middle of them was something like that of the sun, but toward the edges they were tinged with colors like the rainbow. The parhelion N was a little wavering, and sent out a spiked tail, N P, of a color somewhat fiery. The parhelia at L and M were not so bright as the former, but were rounder and white, like the circle in which they were placed. The parhelion N disappeared before K, and while M grew fainter, K grew brighter, and vanished the last of all. Parhelia have been visible for two, three, and four hours together, and in North America they are said to continue some days, and to be visible from sunrise to sunset.

6. *Thunder and lightning.*—These sublime and terrific phenomena are well known to every individual, and are occasionally displayed in every region of the globe. A thunder storm usually happens in calm weather, though sometimes it has been accompanied with furious winds. A dark cloud is observed to attract other clouds to it, by which it continually increases both in magnitude and apparent density; and when it has thus accumulated to a great size, its lower surface swells in particular parts toward the earth, and light flimsy clouds are sometimes seen flying under it, and continually changing their ragged shape. During the time the cloud is thus forming, the heavens begin to darken apace, the whole mass sinks down, wind arises, and frequently shifts in squalls, flashes of lightning are seen to dart from one part of it to another, and often to illuminate the whole mass and the surrounding landscape. When the cloud has acquired a sufficient expansion, the lightning strikes the earth in two opposite points; its paths lying through the whole body of the cloud. Heavy rains, and sometimes hail showers, accompany these dire phenomena, until, after numerous successive discharges, the cloud rarefies and the storm ceases. The scene of a thunder storm is generally in the middle regions of the atmosphere; and it is not a frequent case that an electrical discharge is made into the earth. The lightning darts from one cloud into another, and when the clouds are high, there is no danger to persons or objects on the surface of the earth. But when the cloud is low, and within the striking distance of the earth, when the flashes appear to strike perpendicularly, and when only a second or two elapse between seeing the flash and hearing the report of the thunder, every object around may be considered as within the limits of danger; for then the lightning strikes into some parts of the earth, and every object in the line of its course is liable to be injured. We may ascertain the distance of a thunder-cloud, by counting the number of seconds or pulsations that intervene between seeing the lightning and hearing the first sound of the thunder, allowing about 1142 feet, or 380 yards for every second. Thus, if two seconds intervene, the distance is 760 yards; if three seconds, 1140 yards, if four and a half seconds, 1710 yards, or nearly a mile, etc. During a thunder storm, the lightning sometimes assumes different forms. Sometimes it appears as balls of fire, moving with great velocity: this is the most dangerous species of lightning, and where they strike, corn-yards are set on fire, and sometimes flocks of sheep, herds of cattle, and human beings are instantly killed. Another form is that of zigzag lightning, which most frequently accompanies thunder storms. It is likewise destructive, but not to the same extent as the ball-lightning. The next species is the sheet-lightning, which appears in the form of a lambent flame, or a sudden illumination, without any determinate form. It is never known to do any injury.

As to the cause of thunder storms, it is now ascertained, beyond dispute, that lightning and electricity are identical. This had been long ago, surmised, after the attention of philosophers had been directed to the subject of electricity. It was observed that lightning, in its course, took the best conductors of electricity, such as bell-wires, and gildings; that it burned, exploded, and destroyed conducting substances, as electricity does; that it struck the most elevated objects, as trees and spires; that the crooked form of zigzag lightning was similar to that of an electric spark; and that it affected the nervous system, and changed the polarity of the mariner's needle, as electricity was found to do. This was, at last, put to the test of experiment by Dr. Franklin, by elevating during a thunder storm, a kite, with a metallic point on the head of it, when he drew an electric spark from the cloud by means of a key, connected with the wet string, which was connected with the kite. Nearly at the same time an experiment, somewhat similar, was performed by M. Dalibard, at Marly de Ville, about fifteen miles from Paris. These experiments were made in 1752, and since that period, lightning, and the electric matter, have been considered as the same; though there are still many phenomena connected with thunder storms of which we are ignorant. The grand practical use to which Dr. Franklin applied his discovery, was to secure buildings from being damaged or destroyed by lightning; which is accomplished by fixing a pointed metallic rod higher than any part of the building, and communicating with the earth. This wire the lightning will seize upon, in preference to any other part of the building, by which it is conducted to the earth without injuring the inhabitants.

Maxims during a thunder-storm.—When in the open fields, avoid trees, but be near them—say at the distance of thirty or forty feet—as high objects are more likely to be struck with lightning than those which are low. When walking in the open air, avoid ponds, rivers, streamlets, and every mass of water; for water, being a conductor of electricity, might determine the lightning to the place we occupy. Do not avoid rain, as it is safer, in a thunder-storm, to be completely drenched than otherwise. When in a house, persons should avoid sitting near the fireplace, as it brings us in connection with the highest part of the building, and which contains such conducting substances, as the grate, the fender, and fire-irons. Bell-wires, mirrors, gildings, lusters, and other metallic substances, should also be avoided. The safest position is in the middle of a large room, at a distance from conducting substances, with our chair placed on a mattress.

In the preceding pages, we have taken a cursory survey of the nature and properties of the atmosphere, and of the phenomena it frequently presents, and have noticed the evidences of Divine wisdom and beneficence as displayed in the arrangements connected with this admirable appendage to our globe. A devout contemplation of this subject is worthy of the serious attention of every rational and Christian mind; for all the works of God are intended to display to intelligent beings certain parts of the character and attributes of the Almighty, and to inspire us with love and gratitude for those merciful and benevolent arrangements by which our lives are preserved, and our happiness and comforts secured. The system of the material world, in all its varieties, may be considered as one of the revelations given by God to man, in order that we may trace, from his external operations, visible to every eye, something of the nature of that Almighty Being who at first brought all things into existence, and who, every moment, superintends all their movements. Hence we are informed, by an inspired writer, that the "invisible things of Him from the creation of the world are clearly seen, being understood by the things that are made, even his eternal power and Godhead."

Had man continued in primeval innocence, in the complete exercise of his moral and intellectual faculties, this would, perhaps, have been the only revelation of which he stood in need. But, in his present fallen state, the investigation and study of the material world are not sufficient to lead him to the knowledge of the true God, and to guide him in the way that leads to immortal happiness. Hence it happened that even the wisest sages of antiquity, who were destitute of any other revelation, completely failed in attaining to just conceptions of the Eternal Divinity, of the worship and homage he required, of the duties they ought to perform, and of their eternal destination. "Professing themselves to be wise, they became fools, and changed the glory of the incorruptible God into an image made like to corruptible man, and to birds, and to four-footed beasts, and creeping things."

The religion of nature is glaringly deficient in directing us to correct views of the attributes of the true God, and particularly of the conceptions we ought to form of his moral character, as a Being possessed of strict and impartial justice and eternal rectitude, and whether he be disposed to the exercise of mercy and love. Hence, some of the ancient philosophers denied his existence, and others embraced the notion of a multiplicity of gods, celestial, aërial, terrestrial, and infernal; and the moral characters and actions attributed to such deities were distinguished for everything that was wicked, base, cruel, and licentious. The light of nature can afford us no certain and indubitable evidence of the immortality of the soul, a future state of eternal rewards and punishments, or of a future and glorious resurrection: for many opposite and discordant opinions prevailed on this subject among those who were destitute of Divine revelation; some of them absolutely denying the existence of such a state as a vulgar error; while others represented it as altogether uncertain, having no solid foundation for its support. The light of nature can convey no proper notion of a creative Power that could produce the universe out of nothing, nor of the time and manner in which the world was created and arranged. Hence, one sect of heathen philosophers held that the world was eternal; and another, that it was formed in its present admirable order by a fortuitous concourse of innumerable atoms. It can afford us no certain information respecting the origin of evil, and the cause of that depravity and misery, which exist among mankind; and, in short, it can point out no method by which those who have offended God may be certainly restored to his favor, and a reconciliation effected between God and man; so that his mercy may be exercised without the violation of his justice, and the pardon of sinners rendered consistent with the honor of his laws and the wisdom and equity of his government. From nature, therefore, there arises no sufficient comfort to sinners to warrant hopes of forgiveness; but, on the contrary, anxious and endless solicitude about the means of appeasing the Deity. Hence the various modes of sacrificing, and the numberless superstitions which overspread the heathen world, but which were unsatisfactory to the wiser part of mankind, even in the times of pagan darkness and ignorance.

While ignorant of the important and interesting truths now adverted to, we can enjoy no solid happiness in the present state, nor any cheering prospects in reference to a future and eternal world. But, on all these subjects, so interesting to every human being, the Christian revelation throws an effulgence of light and evidence, and affords every satisfaction to the anxious mind which it can desire. It has "brought life and immortality to light," and shed a radiance over the mansions of the tomb, and the scenes of a future world; it has unraveled the origin of evil, and the cause of all those miseries and moral abominations which have prevailed in the world; and, above all, it has disclosed the gracious purposes of the God of mercy and love toward our fallen and apostate world, and opened the way by which sinners may be pardoned and restored to the Divine favor, in full consistency with all the perfections of the Divinity, and the honors of his universal government. For thus runs the declaration of the Most High to all the children of men: "God so loved the world that he gave his only begotten Son, that whosoever believeth in him should not perish, but have everlasting life." He sent his Son into our world, as a messenger of peace, "to bear the sin of many," "to bring in everlasting righteousness," to make "intercession for the transgressors," to vindicate the honors of his broken law, to abolish death, and to open the way to the mansions of glory in the heavens, to men of all nations, kindreds, and languages, who receive the record he hath given of his Son, and submit to the method of salvation he hath devised. He hath set forth his Son to the world to be "a propitiation through faith in his blood, to declare his righteousness for the remission of sins, . . .

that he might be just and the justifier of him which believeth in Jesus." It is, therefore, "a faithful saying, and worthy of all acceptation, that Christ Jesus came into the world to save sinners," even the chief. And all who receive the salvation thus proffered, will consecrate themselves to his service, and, by the aid of the Holy Spirit, prosecute a course of obedience, "denying ungodliness and worldly lusts," and living "soberly, righteously, and godly in the present world." Every sin and violation of the Divine law will be carefully avoided; every holy disposition, every heavenly temper, and every Divine virtue and grace will be sedulously cultivated; love to God and man will pervade all the faculties of the soul, and be displayed in the general tenor of the conduct; and, by pursuing such a course of action, the individual will be gradually prepared for the nobler contemplations and exercises of that higher sphere of existence, where there is "fullness of joy," and "where there are pleasures forevermore."

From what we have now stated, we may fairly conclude, that all our contemplations of the works of nature, and all our investigations of the system of the visible creation, ought to be conducted in connection with the views and discoveries unfolded by Divine revelation. The two revelations which God has made to us, when properly studied, will be found not only in perfect harmony, but to throw a mutual light on each other; so that what may appear deficient in one is supplied by the other. While we contemplate the manifestations of Divine power, wisdom, and goodness, in the arrangements and operations of nature, we perceive the same attributes illustrated in the records of revelation; and, in addition to these, we perceive what nature cannot teach us, that God is a Being of perfect and eternal rectitude, of inviolable faithfulness, of boundless benevolence; ready to forgive, and rich in mercy to all who call upon him in truth:—a Being who fills immensity of space with his presence, who possesses the most intimate knowledge of all creatures and events throughout creation, and who superintends all the movements of the material universe. To whatever scene of nature we direct our attention, we find sentiments in Scripture adequate to express every emotion of the soul while engaged in such contemplations. Are we contemplating the immense number and variety of animated beings which people the earth, the waters, and the air, and the ample provision made for their accommodation and subsistence—where can we find language more appropriate to express our feelings than in these words of the Psalmist, "O Lord, how manifold are thy works, in wisdom hast thou made them all: the earth is full of thy riches! So is this great and wide sea, wherein are things creeping innumerable, both small and great beasts. —These wait all upon thee; that thou mayst give them their meat in due season. That thou givest them—they gather; thou openest thy hand—they are filled with good." When we survey the structure of the human frame, and consider the vast number of bones, muscles, veins, arteries, lacteals, and other parts, all curiously combined, performing such a variety of functions, and all contributing to life and enjoyment—can we refrain from adopting the expressive language of the Psalmist? "I will praise thee; for I am fearfully and wonderfully made: marvelous are thy works!—how precious are thy thoughts unto me, O God! how great is the sum of them! If I should count them they are more in number than the sand." When we consider the amazing structure of the heavens—the immense magnitude and number of the mighty orbs contained within the canopy of the sky—that millions upon millions of suns and worlds stretching into the immensity of space far beyond the limits of our vision, or even of our imagination, form only a small portion of the universal empire of the Almighty; and when the mind is overwhelmed and lost, on the view of this stupendous scene—where shall we find language to express our emotions, more emphatic and appropriate, than in such passages as these? "Canst thou by searching find out God? Canst thou find out the Almighty unto perfection? Great is our Lord and of great power: his understanding is infinite;—his greatness is unsearchable.—The heavens declare the glory of God; and the firmament showeth his handiwork. —All nations before him are as nothing; and they are counted to him less than nothing, and vanity—who doeth great things past finding out; yea, and wonders without number.—Great and marvelous are thy works, Lord God Almighty! Who can utter the mighty acts of the Lord? Who can show forth all his praise?"

In short, the man who recognizes the truths of Divine revelation must feel a higher degree of pleasure and satisfaction in contemplating the scenes of creation, than the man who either discards or overlooks the revelations contained in the sacred oracles. To a man who is hastening to the grave, uncertain whether his intellectual powers and consciousness shall exist beyond the limits of the present state—of what avail is it that he has acquired a partial knowledge of some of the departments of the visible world, when all his knowledge shall be lost at the hour of dissolution, and no further prospect remains of his ever again resuming such studies and investigations, and of beholding the mysteries and wonders of the universe more fully unfolded? He may be filled with wonder at many of the astonishing processes going forward in the animal, vegetable, and mineral kingdoms; his mind may be overpowered with admiration and astonishment at the vast extent of the material universe, and at the myriads of worlds it contains, but he can entertain no hopes of seeing such wondrous scenes more fully unraveled and displayed in the light of immortality. But the Christian, who looks forward to the nobler employments of a future world, may with certainty indulge in the hope that in the light of that world, the vail which now intercepts our view of the wonders of creation will be removed, and the glories of the Divinity, as displayed in all his works, more fully unfolded. For the inhabitants of that world are represented as celebrating the perfections of the Most High in such strains as these—"Great and marvelous are thy works, Lord God Almighty!" evidently indicating that the vail is partially removed from the hidden scenes of creation, and their minds expanded to take in large and comprehensive surveys of the wonders of the universe, so as to perceive them to be "great and marvelous." And again, they exclaim, "Thou art worthy, O Lord, to receive glory, and honor, and power; for thou hast created all things, and for thy pleasure they are and were created.'

THE END.
